C. Isoelectric focusing uses a gel with a pH gradient that encourages a variable charge.
D. The gel is unchanged in isoelectric focusing; the protein mixture is treated before loading.

13. Which protein properties allow UV spectroscopy to be used as a method of determining concentration?

A. Proteins have partially planar characteristics in peptide bonds.
B. Globular proteins cause scattering of light.
C. Proteins contain aromatic groups in certain amino acids.
D. All organic macromolecules can be assessed with UV spectroscopy.

14. A protein collected through affinity chromatography displays no activity even though it is found to have a high concentration using the Bradford protein assay. What best explains these findings?

A. The Bradford reagent was prepared incorrectly.
B. The active site is occupied by free ligand.
C. The protein is bound to the column.
D. The protein does not catalyze the reaction of interest.

15. What property of protein-digesting enzymes allows for a sequence to be determined without fully degrading the protein?

A. Selectivity
B. Sensitivity
C. Turnover
D. Inhibition

Explanations to Discrete Practice Questions

1. D

In most electrophoresis experiments, we attempt to separate out one component from the others. Because we are attempting to isolate protein A only, a pH that causes protein A to be negative while proteins B and C are neutral or positive will be best. pH 5.5 accomplishes this goal; proteins B and C will be positively charged. A pH of 4.5, **choice (C)**, would make protein A neutral, and it would thus not migrate across the gel. Any neutral impurities would also remain in the well with protein A, making this pH not the best choice.

2. B

Sodium dodecyl sulfate is a detergent and will digest proteins to form micelles with uniform negative charges. Because the protein is sequestered within the micelle, other factors such as charge of the protein and shape have minimal roles during separation. In essence, the protein micelles can be modeled as being spheres, dependent only on size.

3. D

From the given choices, all of them are involved in cell movement with the exception of **choice (D)**. Centrioles are composed of microtubules, but are involved in mitosis, not cell migration.

4. C

The most prevalent extracellular proteins are keratin, elastin, and collagen. Tubulin and actin are the primary cytoskeletal proteins, while myosin is a motor protein.

5. C

For a ligand present in low quantities to have a strong action, we expect it to initiate a second messenger cascade system. Second messenger systems amplify signals because enzymes can catalyze a reaction more than once while they are active, and often activate other enzymes. Both enzyme-linked receptors and G protein-coupled receptors use second messenger systems, while ion channels do not.

6. D

Ions that are not readily accessible in the cytoplasm or extracellular space are likely to be bound to a binding protein. Classically, calcium and magnesium are protein-bound. Without this background knowledge, the question can still be answered. Sodium, **choice (A)**, and potassium, **choice (B)**, must exist in their free states to participate in action potentials. Chloride, **choice (C)**, is readily excreted by the kidney, which would not be true if it were protein-bound. Calcium must be sequestered in both the bloodstream and intracellularly because calcium is used for muscle contraction, exocytosis (of neurotransmitters and other signals), and many other cellular processes that must be tightly regulated.

7. A

Antibodies are specific to a single antigen. Each B-cell produces a single type of antibody with a constant region that is specific to the host and a variable region that is specific to an antigen.

8. A

The resting membrane potential is displayed by cells that are not actively involved in signal transduction. Ungated or "leak" channels permit limited free flow of ions, while the sodium–potassium pump is also active and corrects for this leakage. Ligand-gated and voltage-gated channels are involved in cell signaling and in the pacemaker potentials

of certain cells, but cause deviation from—not maintenance of—the resting membrane potential.

9. D

All trimeric G proteins have α, β, and γ subunits—**choices (A)**, **(B)**, and **(C)**, respectively. G_s, G_i, and G_q are subtypes of the G_α subunit of the trimeric G protein and differ depending on the G protein-coupled receptor's function.

10. B

The proteins described in the question differ primarily in their molecular weights. Their pI values are very close, so ion-exchange chromatography, **choice (A)**, is not a good choice. The question specifies a large quantity, which is better processed through chromatography than through electrophoresis—**choices (C)** and **(D)**—because the gel can only handle a small volume of protein.

11. C

The overall pI of a protein is determined by the relative number of acidic and basic amino acids. The basic amino acids arginine, lysine, and histidine, and the acidic amino acids aspartic acid and glutamic acid will therefore contribute most significantly. Glycine's side chain is a hydrogen atom, so it will have the least contribution of all the amino acids.

12. C

The gel in isoelectric focusing uses a pH gradient. When a protein is in a region with a pH above its pI, it is negatively charged and moves toward the anode. When it is in a pH region below its pI, it is positively charged and moves toward the cathode. When the pH equals the pI, the migration of the protein is halted.

13. C

UV spectroscopy is best used with conjugated systems of double bonds. While the double bond in the peptide bond does display resonance, this is not adequate for UV absorption. However, aromatic systems are conjugated, and phenylalanine, tyrosine, and tryptophan all contain aromatic ring structures.

14. B

Protein activity and concentration are generally correlated. Because we have a high concentration of protein, we expect a high activity unless the protein has been damaged or inactivated in some way. The protein could have been inactivated by experimental conditions like detergents, heat, or pH; however, these are not answer choices. Rather, we must consider how the experimental procedure works. Protein elutes off of an affinity column by binding free ligand. In this situation, the binding may not have been reversed and thus the free ligand competes for the active site of the enzyme, lowering its activity.

15. A

The selective cleavage of proteins by digestive enzymes allows fragments of different lengths with known amino acid endpoints to be created. By cleaving the protein with several different enzymes, a basic outline of the amino acid sequence can be created.

Concept Summary 124

Introduction

Carbohydrates (or, as they are known colloquially, *carbs*) have experienced a tumultuous few decades in American culinary culture. Remember the food pyramid, which advised that we consume six to eleven servings of carbohydrates—in the form of bread, cereal, rice, and pasta—per day? Nowadays, we're inundated with no-carb or low-carb diets; still, carbohydrates make up most of the food and drink that continues to fill our refrigerators and cupboards. Whether or not this is healthy is debatable, as research on food choices continues. What is certain, however, is that carbohydrates are the most direct source of chemical energy for almost all organisms, ranging from single-celled protozoa to more complex organisms, such as plants and animals—including people.

From a molecular standpoint, carbohydrates used to be defined by the empirical formula $C_n(H_2O)_n$, but this definition is now considered antiquated. This formula only applies to simple monomeric sugars, which are also called monosaccharides. As simple sugars link to form complex sugars, water loss occurs, thus changing the empirical formula to $C_n(H_2O)_m$ for complex sugars.

In this chapter, we'll discuss how the various types of carbohydrates we utilize for metabolism are classified, the structures in which they exist, and the biochemical reactions they undergo.

4.1 Carbohydrate Classification ★★★

Carbohydrates come in many types. They can be classified by the number of sugar moieties that make them up, the number of carbons in each sugar, the functional groups present on the molecule, and the stereochemistry of the sugar.

MCAT Expertise

The MCAT likes to present complex, novel molecules and then test you on the most basic information about them. Therefore, when dealing with carbohydrates on the exam, look for the functional groups we have seen before (aldehydes, ketones, and alcohols) and realize that they retain the same chemical properties that you already know.

NOMENCLATURE

Whenever we discuss carbohydrates (or anything else in biology), it makes sense to start with the most basic structural units, which are **monosaccharides**. The simplest monosaccharides contain three carbon atoms and are called **trioses**. Carbohydrates with four, five, and six carbon atoms are called **tetroses**, **pentoses**, and **hexoses**, respectively. Carbohydrates that contain an aldehyde group as their most oxidized functional group are called **aldoses** and those with a ketone group as their most oxidized functional group are called **ketoses**. Taken together, a six-carbon sugar with an aldehyde group would be called an *aldohexose*, while a five-carbon sugar with a ketone group would be called a *ketopentose*. The basic structure of a monosaccharide is illustrated by the simple sugar ***glyceraldehyde***, which is an aldose as shown in Figure 4.1.

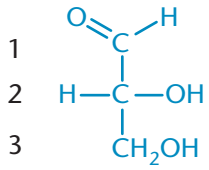

Figure 4.1. Glyceraldehyde
The simplest aldose (an aldotriose).

Glyceraldehyde is a polyhydroxylated aldehyde, or as described above, an aldose (aldehyde sugar). The numbering of carbon atoms in a monosaccharide follows the rules described in Chapter 1 of *MCAT Organic Chemistry Review*. The carbonyl carbon is the most oxidized, and therefore will always have the lowest possible number. In an aldose, the aldehyde carbon will always be carbon number one (C-1). The aldehyde carbon can participate in **glycosidic linkages**; sugars acting as substituents via this linkage are called *glycosyl* residues.

The simplest ketone sugar (ketose) is ***dihydroxyacetone***, shown in Figure 4.2. Again, the carbonyl carbon is the most oxidized; in this case, the lowest number it can be assigned is carbon number two (C-2). This is true, in fact, for most ketoses on the MCAT: the carbonyl carbon is C-2. Ketoses can also participate in glycosidic bonds at this carbon. Notice that on every monosaccharide, every carbon *other* than the carbonyl carbon will carry a hydroxyl group.

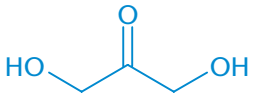

Figure 4.2. Dihydroxyacetone
The simplest ketose (a ketotriose).

Common Names

On the MCAT, a few sugars are tested by referencing their common names, or names that do not necessarily follow the nomenclature rules listed above. You

should be familiar with the names of the important monosaccharides listed in Figure 4.3.

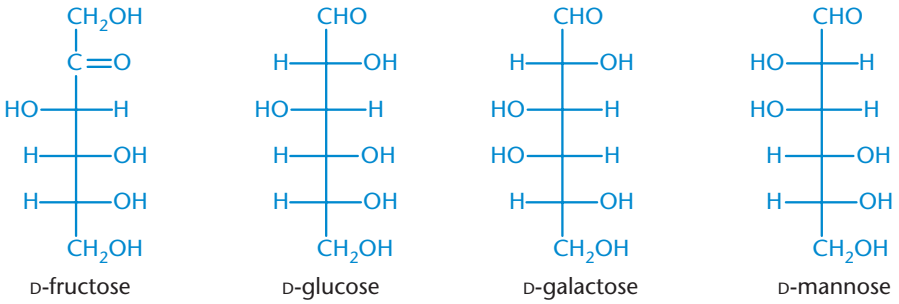

Figure 4.3. Common Names of Frequently Tested Sugars on the MCAT

STEREOCHEMISTRY

Optical isomers, also called **stereoisomers**, are compounds that have the same chemical formula; these molecules differ from one another only in terms of the spatial arrangement of their component atoms. A special type of isomerism exists between stereoisomers that are nonidentical, nonsuperimposable mirror images of each other. These molecules are called **enantiomers**. A chiral carbon atom is one that has four different groups attached to it; any molecule that contains chiral carbons and no internal planes of symmetry has an enantiomer.

Bridge

Isomerism is discussed in detail in Chapter 2 of *MCAT Organic Chemistry Review*. The isomerism seen in carbohydrates is just an extension of that conversation; many sugars are related to each other as enantiomers or diastereomers.

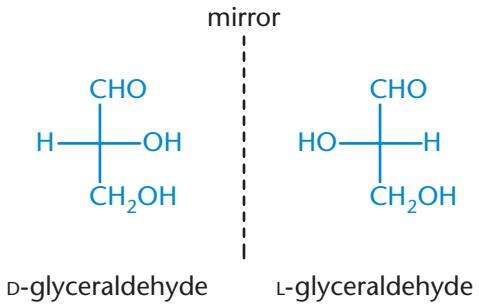

Figure 4.4. Enantiomers of Glyceraldehyde

Figure 4.4 illustrates the two enantiomers of glyceraldehyde: D- and L-glyceraldehyde. The particular three-dimensional arrangement of the groups attached to the chiral carbon determines the compound's **absolute configuration**. While organic chemists use the newer (*R*) and (*S*) system when denoting absolute configuration, biochemists use the older D and L system. Notice in the figure above that D-glyceraldehyde and L-glyceraldehyde are mirror images of one another—this makes them enantiomers because they *must* have opposite absolute configurations. Because there is only one chiral carbon present, these are the only two stereoisomers that exist for glyceraldehyde. As the number of chiral carbons increases, so too does the number of possible

Key Concept

The two systems for naming chiral carbons are not interchangeable! While some D-isomers are equivalent with (*R*), others are (*S*). When dealing with biomolecules like sugars, anticipate using the biochemists' method of nomenclature: D and L.

Key Concept

When trying to figure out how many possible stereoisomers can exist for a multicarbon compound, identify the number of chiral carbons (n) and plug into the formula 2^n. For example, $2^1 = 2$ stereoisomers and $2^2 = 4$ stereoisomers.

Key Concept

D and L are based on the stereochemistry of glyceraldehyde. These are NOT directly related to the (+) and (–) designations denoting optical rotation.

stereoisomers because one compound may have many diastereomers. The number of possible stereoisomers of a compound can be calculated by:

$$\text{Number of stereoisomers with common backbone} = 2^n$$

Equation 4.1

where n is the number of chiral carbons in the molecule.

Early in the twentieth century, scientists used glyceraldehyde to learn about the optical rotation of sugars. The results of this early study led to the **D** and **L** naming convention. D-Glyceraldehyde was later determined to exhibit a positive rotation (designated as D-(+)-glyceraldehyde), and L-glyceraldehyde a negative rotation (designated as L-(–)-glyceraldehyde). Note that the direction of rotation, (+) or (–), must be determined experimentally and cannot be determined from the D or L designation for the sugar.

On the MCAT, all monosaccharides are assigned the D or L configuration based on their relationship to glyceraldehyde. The **Fischer projection** is a simple two-dimensional drawing of stereoisomers. Recall that in a Fischer projection, the horizontal lines are wedges (out of the page), while vertical lines are dashes (into the page), as shown in Figure 4.5.

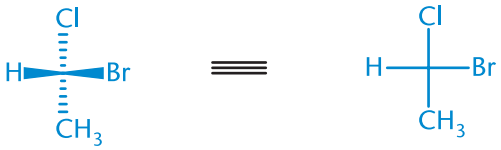

Figure 4.5. Fisher Projection
Horizontal lines are wedges (out of the page); vertical lines are dashes (into the page).

Fischer projections allow scientists to identify different enantiomers. Using this system of structural representation, all D-sugars have the hydroxide of their highest-numbered chiral center on the right, and all L-sugars have that hydroxide on the left. Because D-glucose and L-glucose are enantiomers, this means that *every* chiral center in D-glucose has the opposite configuration of L-glucose, as shown in Figure 4.6.

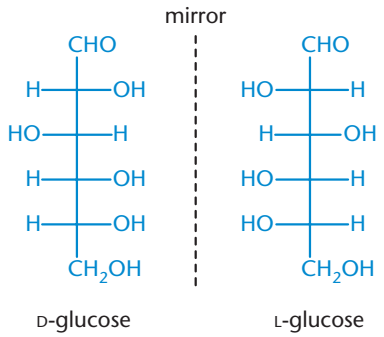

Figure 4.6. Enantiomers of Glucose

Make sure that you are familiar with these three types of stereoisomers:

1. The same sugars, in different optical families, are **enantiomers** (such as D-glucose and L-glucose).
2. Two sugars that are in the same family (both are either ketoses or aldoses, and have the same number of carbons) that are not identical and are not mirror images of each other are **diastereomers**.
3. A special subtype of diastereomers are those that differ in configuration at exactly one chiral center. These are defined as **epimers** (such as D-*ribose* and D-*arabinose*, which only differ at C-2, as shown in Figure 4.7).

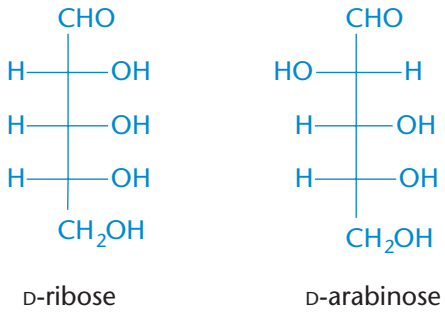

Figure 4.7. D-Ribose and D-Arabinose are C-2 Epimers

A summary of these different types of isomers is provided in Figure 4.8, which shows four different stereoisomers of an aldotetrose, including two optical forms of *erythrose* and two optical forms of *threose*.

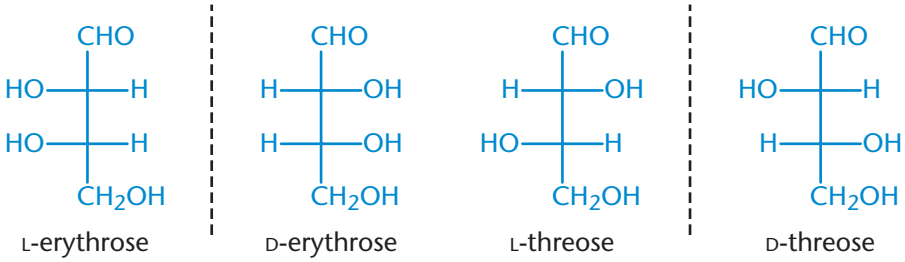

Figure 4.8. Four Stereoisomers of an Aldotetrose

Because D-erythrose and L-erythrose are nonsuperimposable mirror images of one another, they are enantiomers. On the other hand, while D-erythrose and D-threose are *not* mirror images of one another, they are still nonsuperimposable, which makes them diastereomers. Similarly, L-erythrose and D-threose are diastereomers. Because they differ in configuration at only one chiral center, they can also be defined as epimers of one another. Remember, a compound can have only one enantiomer (the left hand to its right hand, or vice-versa), but may have multiple diastereomers, depending on how many (and which) chiral carbons are inverted between the two molecules.

MCAT Concept Check 4.1:
Before you move on, assess your understanding of the material with these questions.

1. Draw all of the possible D-stereoisomers of glucose in Fischer projection form.

2. Which of the diastereomers of glucose from the previous question are considered to be epimers of glucose? Enantiomers?
   - Epimers:

     _____

   - Enantiomers:

     _____

4.2 Cyclic Sugar Molecules ★★

Monosaccharides contain both a hydroxyl group, which can serve as a nucleophile, and a carbonyl group, which is the most common electrophile on the MCAT. Therefore, they can undergo intramolecular reactions to form cyclic **hemiacetals** (from aldoses) and **hemiketals** (from ketoses). Due to ring strain, the only cyclic molecules that are stable in solution are six-membered **pyranose** rings or five-membered **furanose** rings. In fact, such sugars tend to exist predominantly in cyclic form. The hydroxyl group acts as the nucleophile during ring formation, so oxygen becomes a member of the ring structure. Regardless of whether hemiacetal or hemiketal is formed, the carbonyl carbon becomes chiral in this process, and is referred to as the **anomeric carbon**. Figure 4.9 demonstrates how the carbonyl containing C-1 and the hydroxyl group on C-5 of D-glucose undergo intramolecular hemiacetal formation. One of two ring forms can emerge during cyclization of a sugar molecule: α or β. Because these two molecules differ at the anomeric carbon, they are termed **anomers** of one another. In glucose, the **α-anomer** has the –OH group of C-1 *trans* to the $-CH_2OH$ substituent (axial and down), whereas the **β-anomer** has the –OH group of C-1 *cis* to the $-CH_2OH$ substituent (equatorial and up).

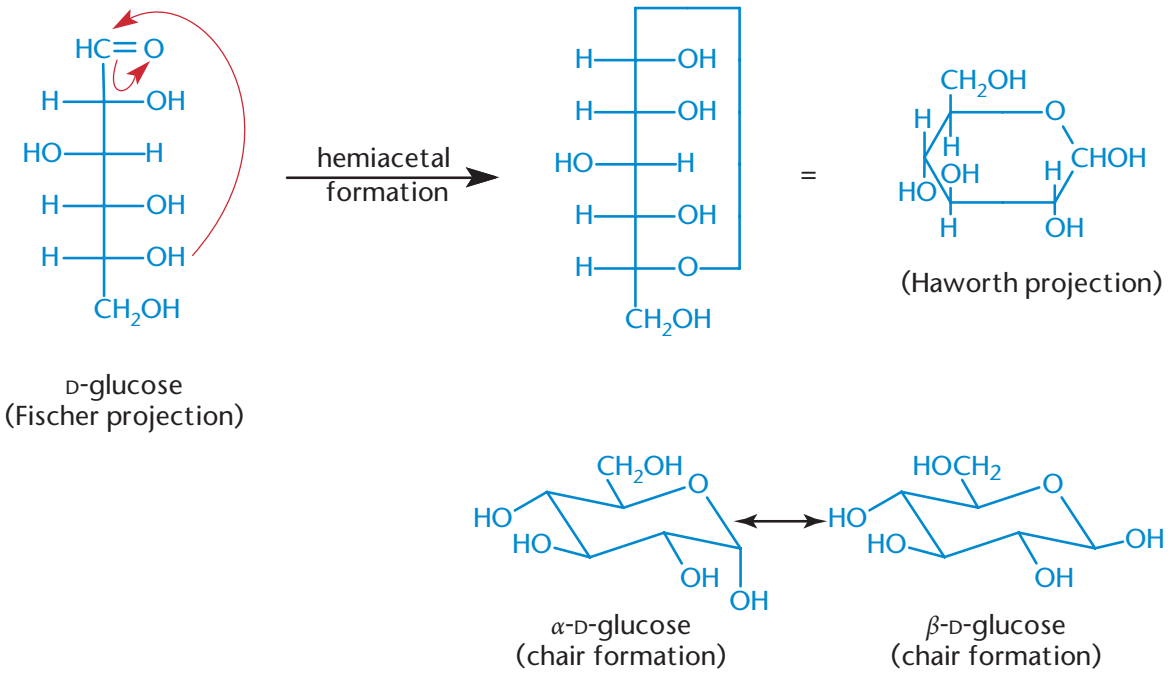

Figure 4.9. Cyclic Sugar Formation via Intramolecular Nucleophilic Addition
Glucose forms a six-membered ring with two anomeric forms: α (left) and β (right).

HEXOSE CONFORMATIONS

Note how Figure 4.9 above has two kinds of projections for glucopyranose: the **Haworth projection** and the **Fischer projection**. The Haworth projection is a useful method for describing the three-dimensional conformations of cyclic structures. Haworth projections depict cyclic sugars as planar five- or six-membered rings with the top and bottom faces of the ring nearly perpendicular to the page. In reality the five-membered rings are very close to planar, but the pyranose rings adopt a chair-like configuration, and the substituents assume axial or equatorial positions to minimize steric hindrance. When we convert the monosaccharide from its straight-chain Fischer projection to the Haworth projection, any group on the right in the Fischer projection will point down.

MUTAROTATION

Exposing hemiacetal rings to water will cause them to spontaneously cycle between the open and closed form. Because the substituents on the single bond between C-1 and C-2 can rotate freely, either the α- or β-anomer can be formed, as demonstrated in Figure 4.10. This spontaneous change of configuration about C-1 is known as **mutarotation**, and occurs more rapidly when the reaction is catalyzed with an acid

or base. Mutarotation results in a mixture that contains both α- and β-anomers at equilibrium concentrations (for glucose: 36% α, 64% β). In solution, the α-anomeric configuration is less favored because the hydroxyl group of the anomeric carbon is axial, adding to the steric strain of the molecule. In its solid state (not in solution), this preference can be mitigated by the anomeric effect, which helps stabilize the α-anomer, although this is outside the scope of the MCAT.

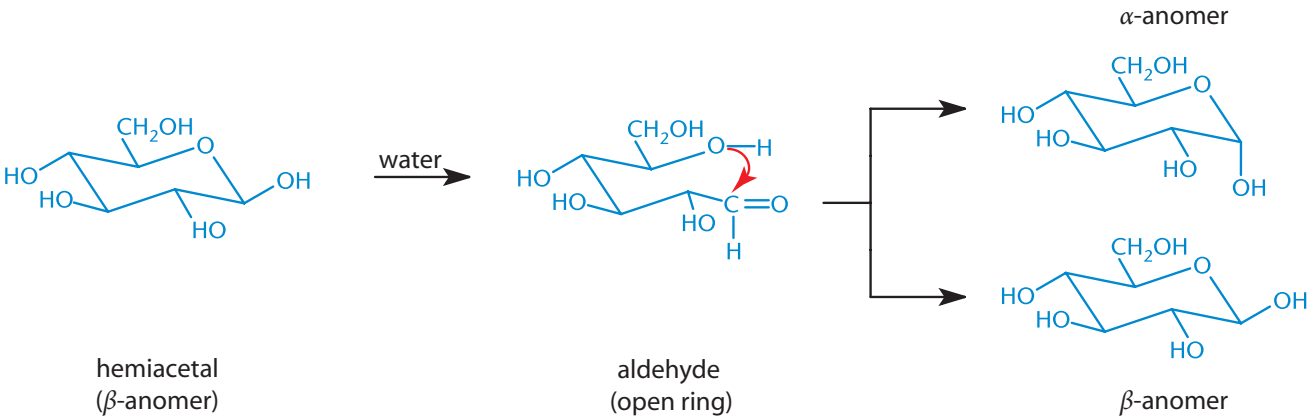

Figure 4.10. Mutarotation
Interconversion between the α- and β-anomers via ring opening and reclosing.

MCAT Concept Check 4.2:
Before you move on, assess your understanding of the material with these questions.

1. Draw the less stable anomer of D-glucose in Haworth projection form.

2. Draw the less stable anomer of D-glucose in chair configuration.

4.3 Monosaccharides ★★

Monosaccharides contain alcohols and either aldehydes or ketones. As such, these functional groups undergo the same reactions that they do when present in other compounds. These include oxidation and reduction, esterification, and nucleophilic attack (creating glycosides).

OXIDATION AND REDUCTION

One of the most important biochemical reactions in the human body is the oxidation of carbohydrates in order to yield energy. As monosaccharides switch between anomeric configurations, the hemiacetal rings spend a short period of time in the open-chain aldehyde form. Just like other aldehydes, they can be oxidized to carboxylic acids; these oxidized aldoses are called **aldonic acids**. Because aldoses can be oxidized, they are considered reducing agents. Therefore, any monosaccharide with a hemiacetal ring is considered a **reducing sugar**. When the aldose in question is in ring form, oxidation yields a **lactone** instead—a cyclic ester with a carbonyl group persisting on the anomeric carbon, as shown in Figure 4.11. Lactones, such as vitamin C, play an essential role in the human body.

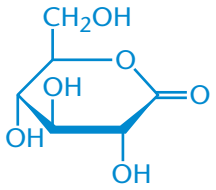

Figure 4.11. Lactone
Contains a cyclic ester.

Two standard reagents are used to detect the presence of reducing sugars: Tollen's reagent and Benedict's reagent. **Tollen's reagent** utilizes $Ag(NH_3)_2^+$ as an oxidizing agent. In a positive Tollen's test, aldehydes reduce Ag^+ to metallic silver. When **Benedict's reagent** is used, the aldehyde group of an aldose is readily oxidized, indicated by a red precipitate of Cu_2O, as demonstrated in Figure 4.12. To test specifically for glucose, one may utilize the enzyme *glucose oxidase*, which does not react with other reducing sugars. A more powerful oxidizing agent, such as dilute nitric acid, will oxidize both the aldehyde and the primary alcohol (on C-6) to carboxylic acids.

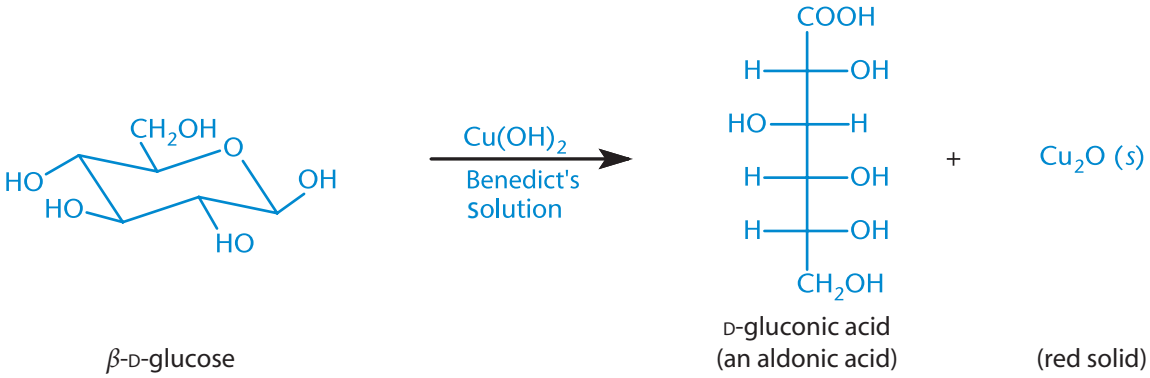

Figure 4.12. Positive Test for an Aldose Using Benedict's Reagent
Aldoses will react, forming copper(I) oxide; ketones may react more slowly.

An interesting phenomenon is that ketose sugars are also reducing sugars and give positive Tollen's and Benedict's tests. Although ketones cannot be oxidized directly to carboxylic acids, they can tautomerize to form aldoses under basic conditions, via *keto–enol* shifts. While in the aldose form, they can react with Tollen's or Benedict's reagents to form the carboxylic acid. **Tautomerization** refers to the rearrangement of bonds in a compound, usually by moving a hydrogen and forming a double bond. In this case, the ketone group picks up a hydrogen while the double bond is moved between two adjacent carbons, resulting in an **enol**: a compound with a double bond and an alcohol group.

Reduced sugars also play an essential role in human biochemistry. When the aldehyde group of an aldose is reduced to an alcohol, the compound is considered an **alditol**. A **deoxy sugar**, on the other hand, contains a hydrogen that replaces a hydroxyl group on the sugar. The most well-known of these sugars is D-2-deoxyribose, the carbohydrate found in DNA.

ESTERIFICATION

Because carbohydrates have hydroxyl groups, they are able to participate in reactions with carboxylic acids and carboxylic acid derivatives to form esters, as shown in Figure 4.13.

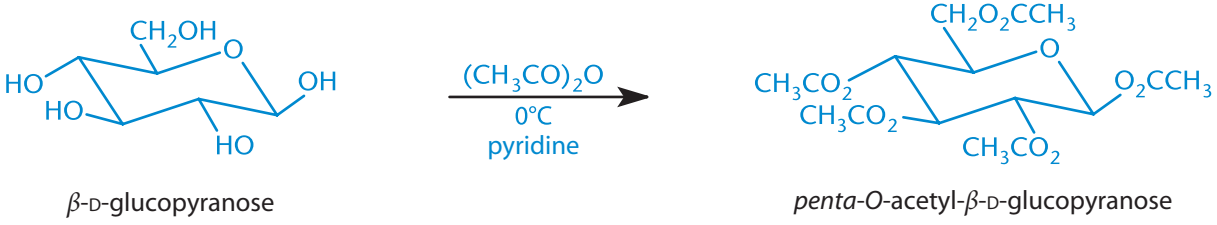

Figure 4.13. Esterification of Glucose
Acetic anhydride used as carboxylic acid derivative.

In the body, esterification is very similar to the phosphorylation of glucose, in which a **phosphate ester** is formed. Phosphorylation of glucose is an extremely important

metabolic reaction of glycolysis in which a phosphate group is transferred from ATP to glucose, thus phosphorylating glucose while forming ADP, as shown in Figure 4.14. *Hexokinase* (or *glucokinase*, in the liver and pancreatic β-islet cells) catalyzes this reaction.

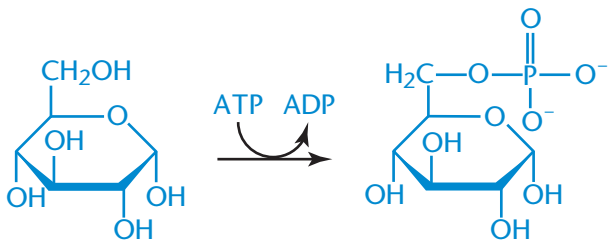

Figure 4.14. Phosphorylation of Glucose

Bridge

The action of hexokinase and glucokinase (as well as all the key glycolytic enzymes) is discussed in Chapter 9 of *MCAT Biochemistry Review*.

GLYCOSIDE FORMATION

Hemiacetals react with alcohols to form **acetals**. The anomeric hydroxyl group is transformed into an alkoxy group, yielding a mixture of α- and β-acetals (with water as a leaving group). The resulting carbon–oxygen (C–O) bonds are called **glycosidic bonds**, and the acetals formed are **glycosides**. An example is the reaction of glucose with ethanol shown in Figure 4.15. Equivalent reactions happen with hemiketals, forming ketals.

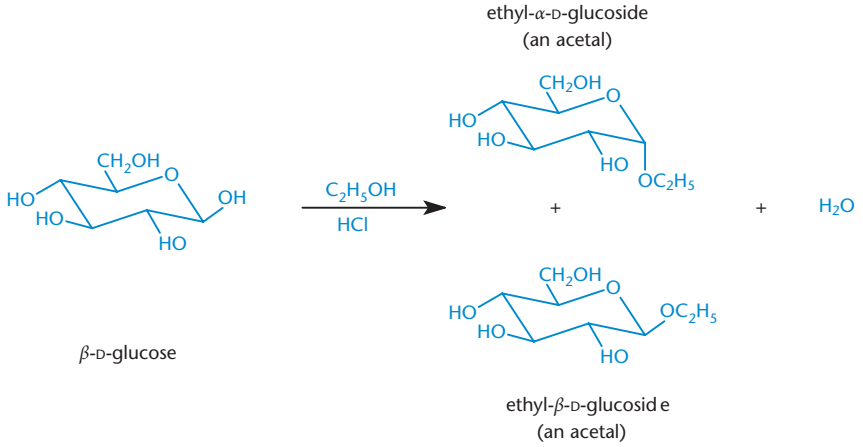

Figure 4.15. Glycosidic Linkage Formation
Hemiacetal (or hemiketal) sugars react with alcohols under acidic conditions to form acetals (or ketals).

Disaccharides and polysaccharides form as a result of glycosidic bonds between monosaccharides. Glycosides derived from furanose rings are referred to as **furanosides** and those derived from pyranose rings are called **pyranosides**. Note that glycoside formation is a dehydration reaction; thus, breaking a glycosidic bond requires hydrolysis.

MCAT Concept Check 4.3:
Before you move on, assess your understanding of the material with these questions.

1. Explain the difference between esterification and glycoside formation.

_____

_____

_____

2. From a metabolic standpoint, does it make sense for carbohydrates to get oxidized or reduced? What is the purpose of this process?

_____

_____

_____

4.4 Complex Carbohydrates ★★★

Complex carbohydrates include all carbohydrates with at least two sugar molecules linked together (disaccharides, oligosaccharides, and polysaccharides).

DISACCHARIDES

As discussed previously, monosaccharides react with alcohols to form acetals. Glycosidic bonds formed between hydroxyl groups of two monosaccharides result in the formation of a **disaccharide**, as shown in Figure 4.16.

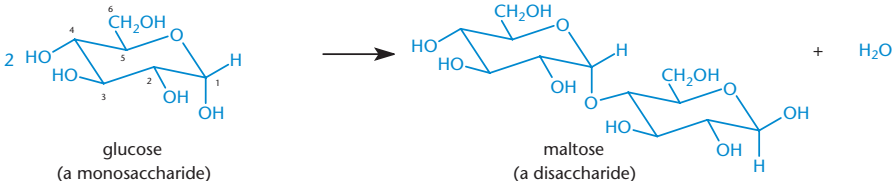

Figure 4.16. Disaccharide Formation
The hydroxyl group on the anomeric carbon reacts with the hydroxyl of another sugar to form an acetal (or ketal) with a 1,2; 1,4; or 1,6 glycosidic linkage.

Formation of an α- or β-glycosidic linkage is nonspecific in that the anomeric carbon of a cyclic sugar can react with any hydroxyl group on any other sugar molecule. The linkages are named for the configuration of the anomeric carbon and the numbers of the hydroxyl-containing carbons involved in the linkage. For example, in an α-1,6 glycosidic bond formation between two D-glucose molecules, the α-anomeric carbon of the first glucose (C-1) attaches to C-6 of the second glucose. Note that the second glucose could be either the α- or β-anomer. In the event that a glycosidic bond is formed between two anomeric carbons, this must be specified in the name. For example, a bond formed between the anomeric carbons of two α-D-glucose molecules would be termed an α,α-1,1 linkage, as demonstrated in Figure 4.17.

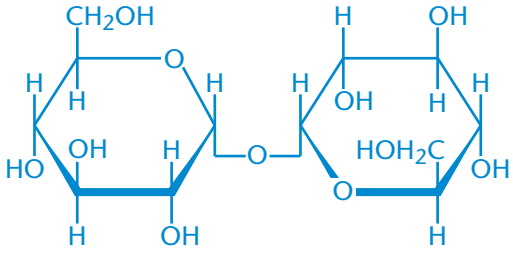

Figure 4.17. Trehalose
Example of a disaccharide with an α,α-1,1 linkage between the α-anomeric carbons of two glucose molecules.

Various combinations of monosaccharides linked by glycosidic bonds result in the formation of different disaccharides. For instance, two glucose molecules linked by an α-1,4 glycosidic bond is called *maltose*, while two glucose molecules joined by a β-1,4 linkage is called *cellobiose*.

Important Disaccharides

When discussing disaccharides in a real-world context, the most important of these sugars are **sucrose**, **lactose**, and **maltose**. These disaccharides are commonly produced in the cell by enzymatic activity. Their molecular structures and linkages are highlighted in Figure 4.18.

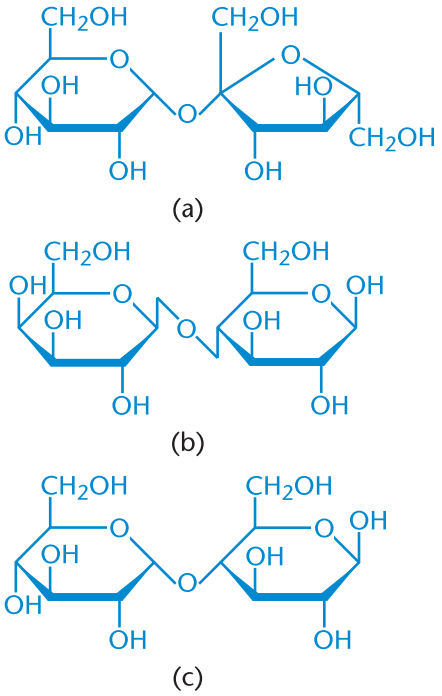

Figure 4.18. Important Disaccharides
(a) Sucrose (glucose-α-1,2-fructose), (b) Lactose (galactose-β-1,4-glucose), (c) Maltose (glucose-α-1,4-glucose).

POLYSACCHARIDES

Polysaccharides are long chains of monosaccharides linked together by glycosidic bonds. While glucose is the most frequently encountered monosaccharide, it is not the only one. A polysaccharide composed entirely of glucose (or any other monosaccharide) is referred to as a **homopolysaccharide**, while a polymer made up of more than one type of monosaccharide is considered a **heteropolysaccharide**. The three most important biological polysaccharides are cellulose, starch, and glycogen. Although these three polysaccharides have different functions, they are all composed of the same monosaccharide, D-glucose. These polysaccharides differ in configuration about the anomeric carbon and the position of glycosidic bonds, resulting in notable biological differences.

Because glycosidic bonding can occur at multiple hydroxyl groups in a monosaccharide, polymer formation can either be linear or branched. Branching happens when an internal monosaccharide in a polymer chain forms at least two glycosidic bonds, allowing for branch formation. We'll take a closer look at how this is a key part of glycogen synthesis and glycogenolysis in Chapter 9 of *MCAT Biochemistry Review*.

Cellulose

Cellulose is the main structural component of plants. A homopolysaccharide, cellulose is a chain of β-D-glucose molecules linked by β-1,4 glycosidic bonds, with hydrogen bonds holding the actual polymer chains together for support. Humans are not able to digest cellulose because we lack the *cellulase* enzyme responsible for hydrolyzing cellulose to glucose monomers. Therefore, cellulose found in fruits and vegetables serves as a great source of fiber in our diet, drawing water into the gut. Cellulase is produced by some bacteria found in the digestive tract of certain animals, such as termites, cows, and goats, which enables them to digest cellulose. A portion of a cellulose chain can be seen in Figure 4.19 below.

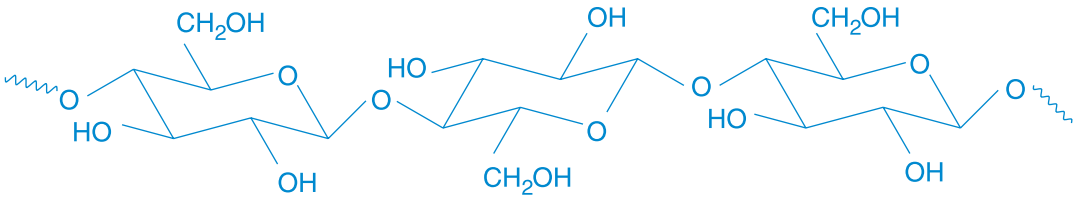

Figure 4.19. Cellulose Structure
Cellulose is a polymer of 1,4-linked β-D-glucose.

Starches

Starches are polysaccharides that are more digestible by humans because they are linked α-D-glucose monomers. Plants predominantly store starch as **amylose**, a linear glucose polymer linked via α-1,4 glycosidic bonds. Another type of starch is **amylopectin**, which starts off with the same type of linkage that amylose exhibits, but also contains branches via α-1,6 glycosidic bonds. Iodine is a well-known reagent that tests for the presence of starch and does so by fitting inside the helix conformation amylose typically makes, forming a starch–iodine complex. The structure of amylose is depicted in Figure 4.20.

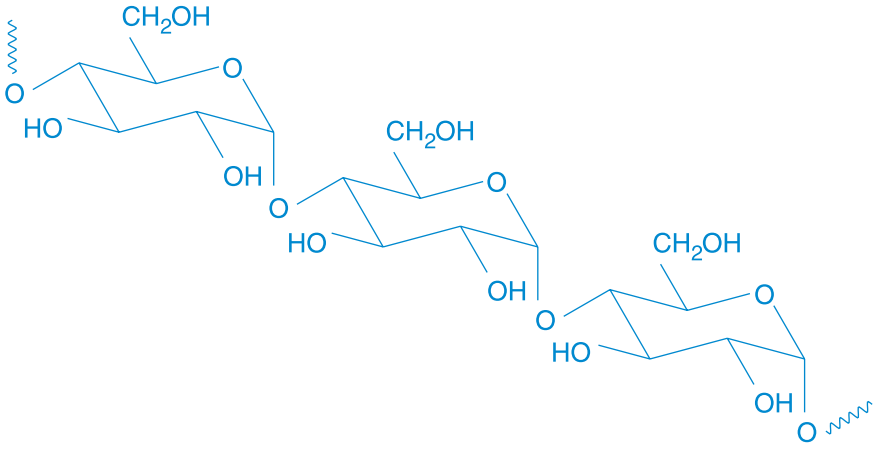

Figure 4.20. Starch Structure
Starches are polymers of 1,4-linked α-D-glucose.

Bridge

The contrast between cellulose and starch digestibility exemplifies the specificity of enzymes. A slight 109.5° rotation of the anomeric carbon to form β-linkages (instead of α-linkages) is enough to make the molecule indigestible by any enzymes in humans—even though they're both D-glucose polymers! Enzyme specificity is discussed in Chapter 2 of *MCAT Biochemistry Review*.

Starches like amylose and amylopectin are broken down by enzymes in the body and are used as a source of energy. **Amylose** is degraded by *α-amylase* and *β-amylase*. **β-Amylase** cleaves amylose at the nonreducing end of the polymer (the end with acetal) to yield maltose, while **α-amylase** cleaves randomly along the chain to yield shorter polysaccharide chains, maltose, and glucose. Because **amylopectin** is highly branched, debranching enzymes help degrade the polysaccharide chain.

Glycogen

Glycogen is a carbohydrate storage unit in animals. It is similar to starch, except that it has more α-1,6 glycosidic bonds (approximately one for every 10 glucose molecules, while amylopectin has approximately one for every 25), which makes it a highly branched compound. This branching optimizes the energy efficiency of glycogen and makes it more soluble in solution, thereby allowing more glucose to be stored in the body. Also, its branching pattern allows enzymes that cleave glucose from glycogen, such as *glycogen phosphorylase*, to work on many sites within the molecule simultaneously. **Glycogen phosphorylase** functions by cleaving glucose from the nonreducing end of a glycogen branch and phosphorylating it, thereby producing glucose 1-phosphate, which plays an important role in metabolism.

Real World

Hers disease, also known as glycogen storage disease (GSD) type VI, is a condition characterized by a deficiency in liver *glycogen phosphorylase*. These patients cannot break down glycogen in their livers, and therefore have hepatomegaly (a swollen liver). They may also have hypoglycemia (low blood sugar) between meals because they cannot use glycogen to maintain blood glucose concentrations.

MCAT Concept Check 4.4:

Before you move on, assess your understanding of the material with these questions.

1. Which of the two forms of starch is more soluble in solution. Why?

_____

_____

_____

2. Regarding glycogen and amylopectin, which of these two polymers should experience a higher rate of enzyme activity from enzymes that cleave side braches? Why?

_____

_____

Conclusion

This chapter examined, in depth, the unique characteristics of carbohydrates. Monosaccharides are the most basic form of carbohydrates, and in terms of human biochemistry, they typically range from three to seven carbon atoms. Classifying these monomers depends on the number of chiral centers present, which tells us the number of potential stereoisomers. Open-chain structures are most easily represented through Fischer projection diagrams; however, sugars tend to exist in ring form in biological systems, so Haworth projections are also used to depict three-dimensional structure. The most important reactions monosaccharides undergo are redox reactions, esterification, and glycoside formation—particularly when glycoside formation results in the formation of disaccharides. Polysaccharides are formed by glycosidic bonding of carbohydrates, and the polymers cellulose, starch, and glycogen are most commonly found in nature. Glycogen is the primary storage form of glucose in humans and other animals, and its unique branching structure allows for rapid access to these glucose stores.

The body has two primary energy-storage molecules: glycogen and triacylglycerols. Each has its own pros and cons—glycogen is more rapidly mobilized, but requires water of hydration, which increases its weight. Triacylglycerols serve as a long-term repository of energy, but take time to utilize. In the next chapter, we turn our attention to triacylglycerols, as well as the lipids used for structure and cell signaling.

CONCEPT SUMMARY

Carbohydrate Classification

- Carbohydrates are organized by their number of carbon atoms and functional groups.
  - Common names are also frequently used when referring to sugars, such as glucose, fructose, and galactose.
  - Three-carbon sugars are trioses, four-carbon sugars are tetroses, and so on.
  - Sugars with aldehydes as their most oxidized group are **aldoses**; sugars with ketones as their most oxidized group are **ketoses**.
- The nomenclature of all sugars is based on the D- and L-forms of glyceraldehyde. Sugars with the highest-numbered chiral carbon with the –OH group on the right (in a Fischer projection) are D-sugars; those with the –OH on the left are L-sugars. D- and L-forms of the same sugar are **enantiomers**.
- **Diastereomers** are nonsuperimposable configurations of molecules with similar connectivity. They differ at at least one–but not all–chiral carbons. These also include epimers and anomers.
  - **Epimers** are a subtype of diastereomers that differ at exactly one chiral carbon.
  - **Anomers** are a subtype of epimers that differ at the anomeric carbon.

Cyclic Sugar Molecules

- Cyclization describes the ring formation of carbohydrates from their straight-chain forms.
- When rings form, the anomeric carbon can take on either an α- or β-conformation.
  - The **anomeric carbon** is the new chiral center formed in ring closure; it was the carbon containing the carbonyl in the straight-chain form.
  - **α-anomers** have the –OH on the anomeric carbon *trans* to the free $-CH_2OH$ group.
  - **β-anomers** have the –OH on the anomeric carbon *cis* to the free $-CH_2OH$ group.
- **Haworth projections** provide a good way to represent three-dimensional structure.
- Cyclic compounds can undergo **mutarotation**, in which they shift from one anomeric form to another with the straight-chain form as an intermediate.

Monosaccharides

- **Monosaccharides** are single carbohydrate units, with glucose as the most commonly observed monomer. They can undergo three main reactions: oxidation–reduction, esterification, and glycoside formation.

- Aldoses can be oxidized to **aldonic acids** and reduced to **alditols**.
- Sugars that can be oxidized are reducing agents (**reducing sugars**) themselves, and can be detected by reacting with **Tollen's** or **Benedict's reagents**.
- Sugars with a –H replacing an –OH group are termed **deoxy sugars**.
- Sugars can react with carboxylic acids and their derivatives, forming esters (**esterification**). **Phosphorylation** is a similar reaction in which a phosphate ester is formed by transferring a phosphate group from ATP onto a sugar.
- **Glycoside formation** is the basis for building complex carbohydrates and requires the anomeric carbon to link to another sugar.

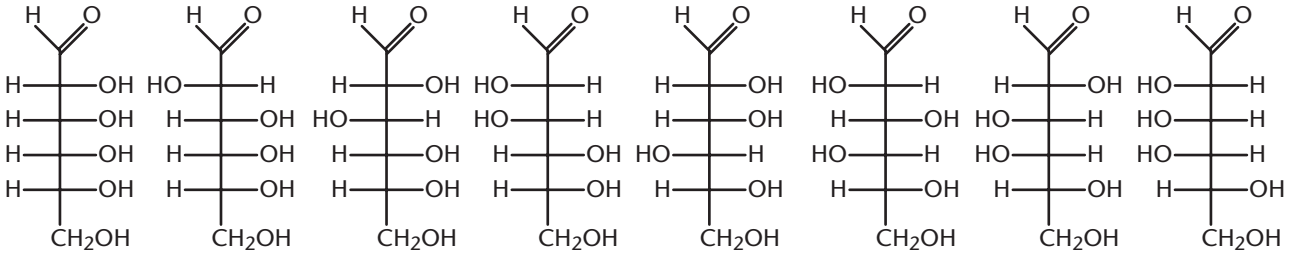
Complex Carbohydrates

- **Disaccharides** form as result of glycosidic bonding between two monosaccharide subunits; polysaccharides form by repeated monosaccharide or polysaccharide glycosidic bonding.
- Common disaccharides include **sucrose** (glucose-α-1,2-fructose), **lactose** (galactose-β-1,4-glucose), and **maltose** (glucose-α-1,4-glucose).
- Polysaccharides play various roles:
  - **Cellulose** is the main structural component for plant cell walls and is a main source of fiber in the human diet.
  - **Starches** (**amylose** and **amylopectin**) function as a main energy storage form for plants.
  - **Glycogen** functions a main energy storage form for animals.

ANSWERS TO CONCEPT CHECKS

4.1

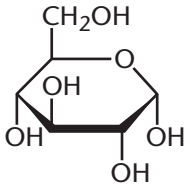
1.



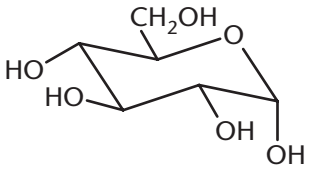
2. D-glucose's epimers are D-mannose (C-2), D-allose (C-3), and D-galactose (C-4). None of the D-stereoisomers is an enantiomer for glucose; L-glucose is the enantiomer of D-glucose.

4.2

1.



2.



4.3

1. Esterification is the reaction by which a hydroxyl group reacts with either a carboxylic acid or a carboxylic acid derivative to form an ester. Glycoside formation refers to the reaction between an alcohol and a hemiacetal (or hemiketal) group on a sugar to yield an alkoxy group.
2. It makes sense for carbohydrates to become oxidized while reducing other groups. This is the case because aerobic metabolism requires reduced forms of electron carriers to facilitate processes such as oxidative phosphorylation. Because carbohydrates are a primary energy source, they are oxidized.

4.4

1. Amylopectin is more soluble in solution than amylose because of its branched structure. The highly branched structure of amylopectin decreases intermolecular bonding between polysaccharide polymers and increases interaction with the surrounding solution.
2. Glycogen has a higher rate of enzymatic branch cleavage because it contains significantly more branching than amylopectin.

EQUATIONS TO REMEMBER

(4.1) **Number of stereoisomers with common backbone** = 2^n

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. When glucose is in a straight-chain formation, it:

A. is an aldoketose.
B. is a pentose.
C. has five chiral carbons.
D. is one of a group of 16 stereoisomers.

2. All of the following are true of epimers EXCEPT:

A. they differ in configuration about only one carbon.
B. they usually have slightly different chemical and physical properties.
C. they are diastereomers (with the exception of glyceraldehyde).
D. they have equal but opposite optical activities.

3. Aldonic acids are compounds that:

A. can be oxidized, and therefore act as reducing agents.
B. can be reduced, and therefore act as reducing agents.
C. have been oxidized, and have acted as reducing agents.
D. have been oxidized, and have acted as oxidizing agents.

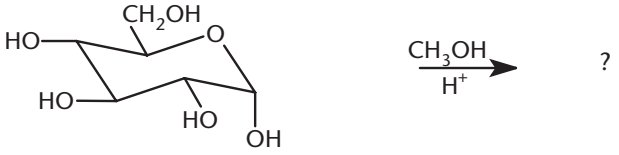
4. The formation of α-D-glucopyranose from β-D-glucopyranose is called:

A. glycosidation.
B. mutarotation.
C. enantiomerization.
D. racemization.

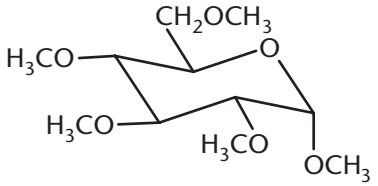
5. Ketose sugars may have the ability to act as reducing sugars. Which process explains this?

A. Ketose sugars undergo tautomerization.
B. The ketone group is oxidized directly.
C. Ketose sugars undergo anomerization.
D. The ketone group is reduced directly.

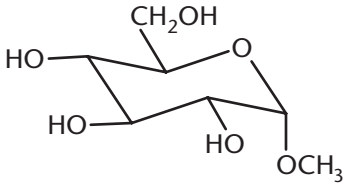
6. What is the product of the following reaction?



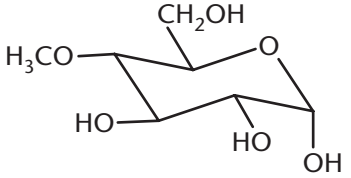
A.



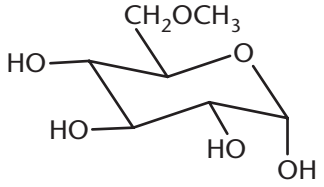
B.



C.



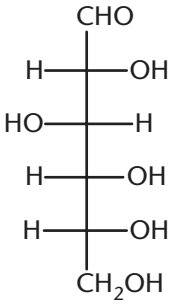
D.



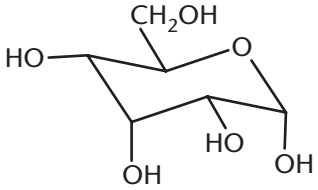
7. Which of the following enzymes cleaves polysaccharide chains and yields maltose exclusively?

A. α-Amylase
B. β-Amylase
C. Debranching enzyme
D. Glycogen phosphorylase

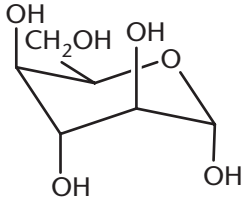
8. When the following straight-chain Fischer projection is converted to a chair or ring conformation, its structure will be:



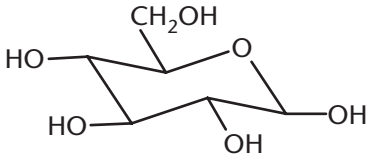
A.



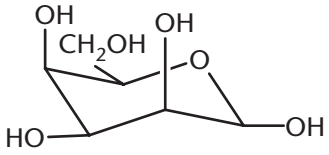
B.



C.



D.



9. Why is the α-anomer of D-glucose less likely to form than the β-anomer?

A. The β-anomer is preferred for metabolism.
B. The β-anomer undergoes less electron repulsion.
C. The α-anomer is the more stable anomer.
D. The α-anomer forms more in L-glucose.

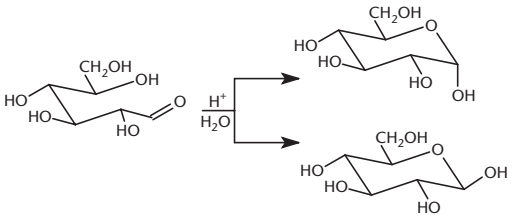
10. Which two polysaccharides share all of their glycosidic linkage types in common?

A. Cellulose and amylopectin
B. Amylose and glycogen
C. Amylose and cellulose
D. Glycogen and amylopectin

11. Which of the following is digestible by humans and is made up of only one type of monosaccharide?

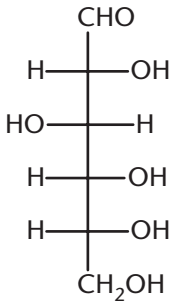
A. Lactose
B. Sucrose
C. Maltose
D. Cellobiose

12. The reaction below is an example of one step in:



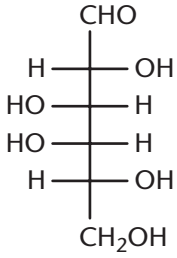
A. aldehyde formation.
B. hemiketal formation.
C. mutarotation.
D. glycosidic bond cleavage.

13. Galactose is the C-4 epimer of glucose, the structure of which is shown below. Which of the following structures is galactose?

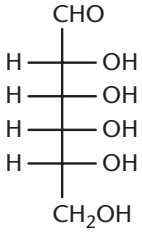


D-glucose

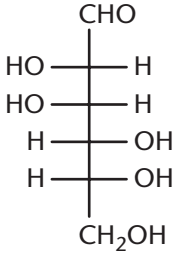
A.



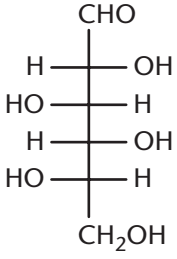
B.



C.



D.



14. Andersen's disease (glycogen storage disease type IV) is a condition characterized by a deficiency in glycogen branching enzyme. Absence of this enzyme would be likely to cause all of the following effects EXCEPT:

A. decreased glycogen solubility in human cells.
B. slower action of glycogen phosphorylase.
C. less storage of glucose in the body.
D. glycogen devoid of α-1,4 linkages.

15. The cyclic forms of monosaccharides are:

I. hemiacetals.
II. hemiketals.
III. acetals.

A. I only
B. III only
C. I and II only
D. I, II, and III

Explanations to Discrete Practice Questions

1. D

Glucose is an aldohexose, meaning that it has one aldehyde group and six carbons. Given this information, **choices (A)** and **(B)** can be eliminated. In aldose sugars, each nonterminal carbon is chiral. Therefore, glucose has four chiral centers, not five, as mentioned in **choice (C)**. The number of stereoisomers possible for a chiral molecule is 2^n, where n is the number of chiral carbons. Because glucose has four chiral centers, there are $2^4 = 16$ possible stereoisomers.

2. D

Epimers are monosaccharide diastereomers that differ in their configuration about only one carbon. As with all diastereomers, epimers have different chemical and physical properties, and their optical activities have no relation to each other. Enantiomers have equal but opposite optical activities. Therefore, **choice (D)** is the only statement that does not apply to epimers.

3. C

Aldonic acids form after the aldehyde group on a reducing sugar reduces another compound, becoming oxidized in the process.

4. B

Mutarotation is the interconversion between anomers of a compound. Enantiomerization and racemization, **choices (C)** and **(D)**, are related: enantiomerization is the formation of a mirror-image or optically inverted form of a compound, whereas racemization is moving a solution toward an equal concentration of both enantiomers. Glycosidation, **choice (A)**, is the addition of a sugar to another compound.

5. A

Ketose sugars undergo tautomerization, a rearrangement of bonds, to undergo *keto–enol* shifts. This forms an aldose, which then allows them to act as reducing sugars. A ketone group alone cannot be oxidized. Anomerization, mentioned in **choice (C)**, refers to ring closure of a monosaccharide, creating an anomeric carbon.

6. B

When glucose reacts with ethanol under acid catalysis, the hemiacetal is converted to an acetal via replacement of the anomeric hydroxyl group with an alkoxy group. The result is a type of acetal known as a glycoside. This corresponds with **choice (B)**. The other choices all show alkoxy groups on the wrong carbon, or too many carbons.

7. B

β-Amylase cleaves amylose at the nonreducing end of the polymer to yield maltose exclusively, while α-amylase, **choice (A)**, cleaves amylose anywhere along the chain to yield short polysaccharides, maltose, and glucose. Debranching enzyme, **choice (C)**, removes oligosaccharides from a branch in glycogen or starches, while glycogen phosphorylase, **choice (D)**, yields glucose 1-phosphate.

8. C

Start by drawing out the Haworth projection. Recall that all the groups on the right in the Fischer projection will go on the bottom of the Haworth projection, and all the groups on the left will go on the top. Next, draw the chair structure, with the oxygen in the back right corner. Label the carbons in the ring 1 through 5, starting from the oxygen and moving clockwise around the ring. Now, draw in the lines for all the axial substituents, alternating above and below the ring.

Remember to start on the anomeric C-1 carbon, where the axial substituent points down. Now start filling in the substituents. The substituent can be in either position on the anomeric carbon, so skip that one for now. The –OH groups on C-2 and C-4 should point downwards while the –OH group on C-3 should point upwards; **choice (C)**, the β-anomer of D-glucose, is the only one that matches.

9. B

The hydroxyl group on the anomeric carbon of the β-anomer is equatorial, thereby creating less nonbonded strain than the α-anomer, which has the hydroxyl group of the anomeric carbon in axial position.

10. D

Glycogen and amylopectin are the only polysaccharide forms that demonstrate branching structure, making them most similar in terms of linkage. Both glycogen and amylopectin use α-1,4 and α-1,6 linkages. Cellulose uses β-1,4 linkages and amylose does not contain α-1,6 linkages.

11. C

While maltose and cellobiose both have the same glucose subunits, only maltose is digestible by humans because the β-glycosidic linkages in cellobiose cannot be cleaved in the human body.

12. C

In solution, the hemiacetal ring of glucose will break open spontaneously and then re-form. When the ring is broken, bond rotation occurs between C-1 and C-2 to produce either the α- or the β-anomer. The reaction given in this question depicts the mutarotation of glucose. **Choice (A)** is incorrect because the reactant is an aldehyde, not the product. **Choice (B)** is incorrect because a hemiketal has an –OH group, an –OR group, and two –R groups. In addition, hemiketals are formed from ketones, and our starting reactant is an aldehyde. Finally, **choice (D)** is incorrect because there is no glycosidic bond in the starting reactant.

13. A

Galactose is a diastereomer of glucose, with the stereochemistry at C-4 (counting from the aldehyde) reversed. Being able to identify C-4 is enough to answer this question, even without looking at the glucose molecule. Because **choices (B)**, **(C)**, and **(D)** have identical stereochemistry at C-4, they are incorrect.

14. D

In Andersen's disease, glycogen is less branched than normal, thereby inducing lower solubility of glycogen. Branches reduce the interactions between adjacent chains of glycogen and encourage interactions with the aqueous environment. The smaller number of branches means that glycogen phosphorylase has fewer terminal glucose monomers on which to act, making enzyme activity slower than normal overall. Finally, without branches, the density of glucose monomers cannot be as high; therefore, the total glucose stored is lower than normal. Glycogen synthase is still functioning normally, so we would expect normal α-1,4 linkages in the glycogen of an individual with Andersen's disease but few (if any) α-1,6 linkages.

15. C

Monosaccharides can exist as hemiacetals or hemiketals, depending on whether they are aldoses or ketoses. When a monosaccharide is in its cyclic form, the anomeric carbon is attached to the oxygen in the ring and a hydroxyl group. Hence, it is only a hemiacetal or hemiketal because an acetal or ketal would require the –OH group to be converted to another –OR group.

Concept Summary 153

Introduction

What do beer, human eyes, and sperm whales have in common? For all of these, lipids play a key role in some of their most interesting characteristics. The taste and smell of hops comes from lipids called *terpenes*. The ability of the human eye to respond to light (and therefore see) relies heavily on *retinal*, a lipid derived from vitamin A. Sperm whales use an enormous reservoir of *spermaceti* to dive to a depth of up to three kilometers to hunt giant squid. Spermaceti is a lipid with a density that changes dramatically with temperature—effectively allowing sperm whales to adjust their density with depth so that they can stay submerged without having to constantly fight buoyancy.

Lipids, as a class, are characterized by insolubility in water and solubility in non-polar organic solvents. Aside from this shared feature, lipids diverge dramatically in their structural organization and biological functions, serving vital structural, signaling, and energy storage roles. In this chapter, we will explore the structural and functional characteristics of each of the major categories of lipids tested on the MCAT.

As structural building blocks, we will investigate *phospholipids* and *sterols*, which make up vesicles, liposomes, and membranes. When it comes to signaling, we will note that lipids serve multiple roles, from enzyme cofactors to light-absorbing pigments, and from intracellular messengers to hormones. Finally, we will see that lipids are the workhorse of energy storage, giving the most "bang" for the metabolic "buck" by weight.

5.1 Structural Lipids ★★★

Lipids are the major component of the phospholipid bilayer, one of the most important structural parts of the cell. The unique ability of phospholipids to form a bilayer allows our cells to function as they do, separating the cell interior from the surrounding environment. We will first take a close look at the structure and role of phospholipids, glycerophospholipids, and sphingolipids. Finally, we will review the gross structural characteristics of the unique class called waxes.

Bridge

Although phospholipids are indeed the largest component of the phospholipid bilayer, nonphospholipids like glycolipids also play a role—and can be an important part of processes like cell recognition and signaling, discussed in Chapter 3 of *MCAT Biochemistry Review*.

Each of the membrane components is an **amphipathic** molecule, meaning that it has both hydrophilic and hydrophobic regions. For these membrane lipids, the polar head is the hydrophilic region, whereas the fatty acid tails are the hydrophobic region. When placed in aqueous solution, these molecules spontaneously form structures that allow the hydrophobic regions to group internally while the hydrophilic regions interact with water. This leads to the formation of various structures, including liposomes, micelles, and the phospholipid bilayer, shown in Figure 5.1.

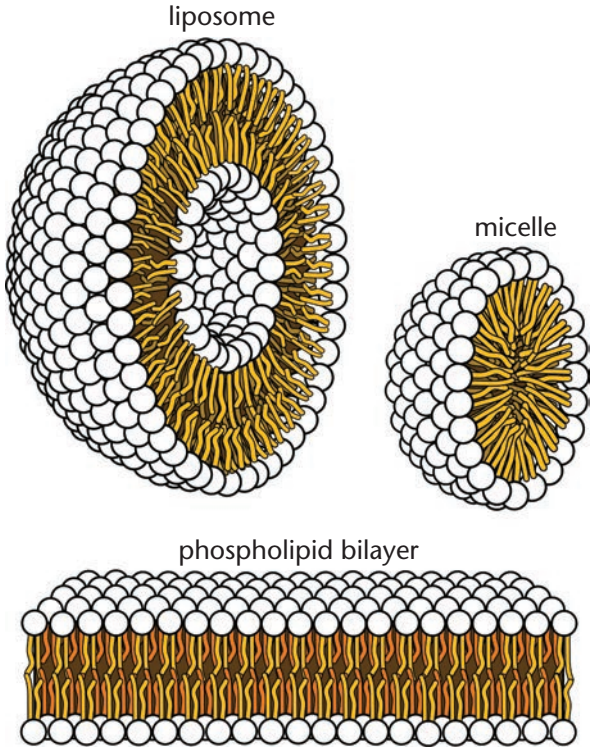

Figure 5.1. Membrane Lipids Form Various Structures in Aqueous Solutions

PHOSPHOLIPIDS

Phospholipids contain the following elements: a phosphate and alcohol that comprise the polar head group, joined to a hydrophobic fatty acid tail by phosphodiester

linkages. One or more fatty acids are attached to a backbone to form the hydrophobic tail region. Phospholipids can be further classified according to the backbone on which the molecule is built. For example, ***glycerol***, a three-carbon alcohol, forms *phosphoglycerides* or *glycerophospholipids*, and *sphingolipids* have a *sphingosine* backbone. One important thing to note, however, is that not all sphingolipids are phospholipids, as described later in this chapter.

One thing that these lipids do all share in common is a tail composed of long-chain fatty acids. These hydrocarbon chains vary by their degree of **saturation** and length. These two properties determine how the overall molecule will behave. Fully **saturated fatty acid** tails will have only single bonds; the carbon atom is considered saturated when it is bonded to four other atoms, with no π bonds. Saturated fatty acids, such as those in butter, have greater van der Waals forces and a more stable overall structure. Therefore, they form solids at room temperature. An **unsaturated fatty acid** includes one or more double bonds. Double bonds introduce kinks into the fatty acid chain, which makes it difficult for them to stack and solidify. Therefore, unsaturated fats—like olive oil—tend to be liquids at room temperature. The same rules apply in the phospholipid bilayer: phospholipids with unsaturated fatty acid tails make up more fluid regions of the phospholipid bilayer. Phospholipids, glycerophospholipids, and sphingolipids can have any of a variety of fatty acid tails and also different head groups, which determine their properties at the surface of the cell membrane. The next two sections—glycerophospholipids and sphingolipids—focus on the various polar head groups that different phospholipids may have.

Key Concept

Lipid properties—for all categories of lipids—are determined by the degree of saturation in fatty acid chains and the functional groups to which the fatty acid chains are bonded.

GLYCEROPHOSPHOLIPIDS

As mentioned in the last section, glycerophospholipids are all phospholipids; yet, not all phospholipids are glycerophospholipids! **Glycerophospholipids** (or **phosphoglycerides**) are specifically those phospholipids that contain a glycerol backbone bonded by ester linkages to two fatty acids and by a phosphodiester linkage to a highly polar head group, as shown in Figure 5.2. Because the head group determines the membrane surface properties, glycerophospholipids are named according to their head group. For example, ***phosphatidylcholine*** is the name of a glycerophospholipid with a *choline* head group, and ***phosphatidylethanolamine*** is one with an *ethanolamine* head group. The head group can be positively charged, negatively charged, or neutral. The membrane surface properties of these molecules make them very important to cell recognition, signaling, and binding. Within each subtype, the fatty acid chains can vary in length and saturation, resulting in an astounding variety of functions that are the focus of active scientific research.

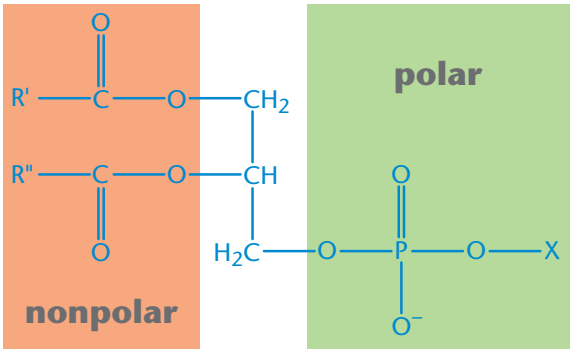

Figure 5.2. Structure of a Glycerophospholipid
X denotes the head group connected to the glycerol backbone by a phosphodiester linkage.

SPHINGOLIPIDS

Real World

Although experiments in blood transfusion are recorded as early as the 17th century, blood typing wasn't developed until the 20th century. With the advent of the ABO and Rh factor blood typing systems, blood transfusions could now be successfully administered to patients with hemophilia (a clotting disorder that causes significant bleeding), during surgery, and in a number of other applications.

Blood typing makes it possible to give life-saving blood transfusions without risking potentially fatal acute hemolytic reactions. The ABO blood typing system is based on cell-surface antigens on red blood cells. These cell-surface antigens are some of the most well-known sphingolipids. Like glycerophospholipids, sphingolipids are also sites of biological recognition at the cell surface and can be bonded to various head groups and fatty acids.

Sphingolipids have a **sphingosine** or **sphingoid** (sphingosine-like) backbone, as opposed to the glycerol backbone of glycerophospholipids. These molecules also have long-chain, nonpolar fatty acid tails and polar head groups. Many sphingolipids are also phospholipids because they contain a phosphodiester linkage. However, other sphingolipids contain glycosidic linkages to sugars; any lipid linked to a sugar can be termed a ***glycolipid***. Sphingolipids are divided into four major subclasses, differing by their head group.

The simplest sphingolipid is ***ceramide***, which has a single hydrogen atom as its head group.

Sphingomyelins are the major class of sphingolipids that are also phospholipids (**sphingophospholipids**). These molecules have either phosphatidylcholine or phosphatidylethanolamine as a head group, and thus contain a phosphodiester bond. Sphingomyelin head groups have no net charge. As the name implies, sphingomyelins are major components in the plasma membranes of cells producing myelin (oligodendrocytes and Schwann cells), the insulating sheath for axons.

Sphingolipids with head groups composed of sugars bonded by glycosidic linkages are considered glycolipids, as mentioned above, or, more specifically, ***glycosphingolipids***. These molecules are not phospholipids because they contain no phosphodiester linkage. Glycosphingolipids are found mainly on the outer surface of the plasma membrane and can be further classified as *cerebrosides* or *globosides*. **Cerebrosides**

have a single sugar, whereas **globosides** have two or more. These molecules are also referred to as neutral glycolipids because they have no net charge at physiological pH.

The final group is composed of the most complex sphingolipids. ***Gangliosides*** are glycolipids that have polar head groups composed of oligosaccharides with one or more ***N-acetylneuraminic acid*** (**NANA**; also called **sialic acid**) molecules at the terminus, and a negative charge. These molecules are also considered glycolipids because they have a glycosidic linkage and no phosphate group. Gangliosides play a major role in cell interaction, recognition, and signal transduction.

A summary of the different types of sphingolipids is provided in Figure 5.3.

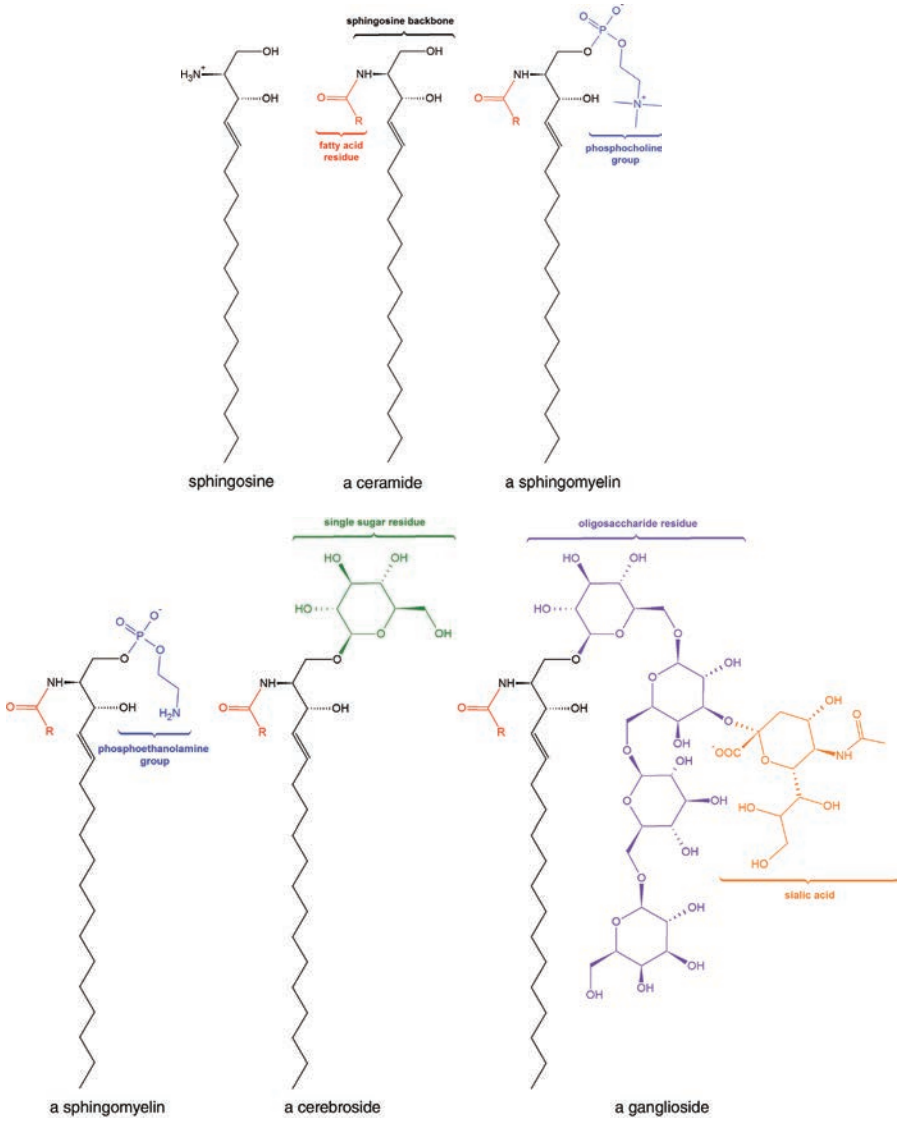

Figure 5.3. Types of Sphingolipids
Ceramide has a single hydrogen atom for a head group; sphingomyelins have phosphodiester linkages (phospholipids); cerebrosides have one sugar; globosides (not pictured) have multiple sugars; gangliosides have oligosaccharides and terminal sialic acids.

Mnemonic

Gangliosides are the **"gangly"** sphingolipids, with the most complex structure and functional groups (oligosaccharides and NANA) in all directions.

Real World

Sphingolipid accumulation is associated with numerous pathological conditions. Sphingomyelins found in the myelin sheath help in signal transduction. Accumulation of sphingomyelin, resulting from lack of the enzyme *sphingomyelinase*, can result in *Niemann–Pick disease*. Symptoms can include mental retardation and seizures. *Sulfatides* are sulfated cerebrosides associated with Alzheimer's disease.

WAXES

Waxes are esters of long-chain fatty acids with long-chain alcohols. As one might expect, they form pliable solids at room temperature (what we generally think of as *wax*). Biologically, they function as protection for both plants and animals. In plants, waxes are secreted as a surface coating to prevent excessive evaporation and to protect against parasites. In animals, waxes are secreted to prevent dehydration, as a water-repellant to keep skin and feathers dry, and as lubricant. For example, *carnauba wax* is made from the leaves of the *Copernicia prunifera* palm and is used to coat candies and wax cars. Bees secrete waxes to construct shelter, as shown in Figure 5.4.

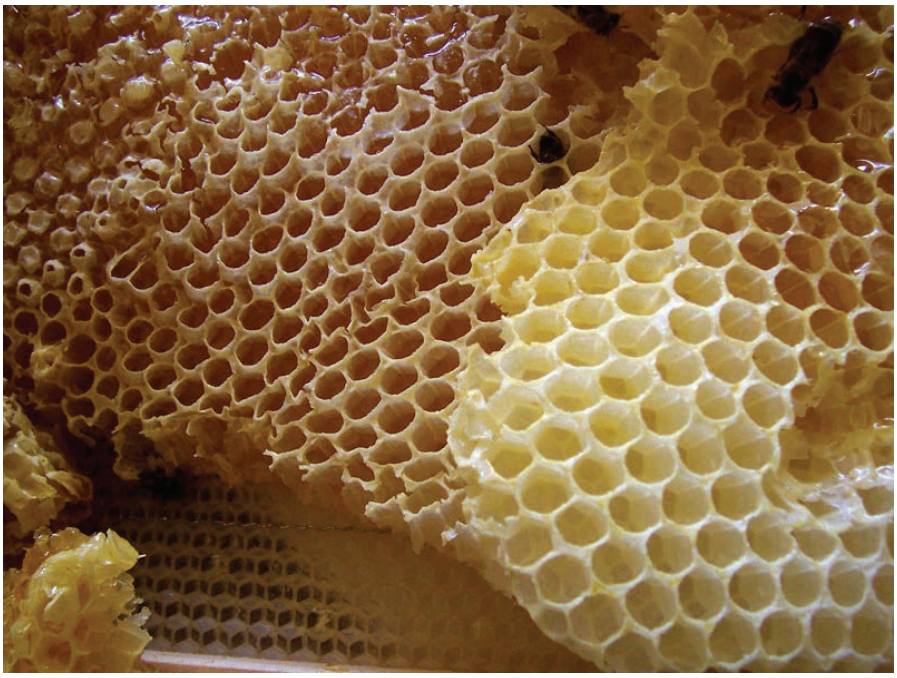

Figure 5.4. Honeycomb Structure Made from Beeswax
The solid and plastic nature of waxes, which contain esters with long alkyl chains, permits their use for structure building.

MCAT Concept Check 5.1:
Before you move on, assess your understanding of the material with these questions.

1. Which components of membrane lipids contribute to their structural role in membranes? Which components contribute to function?
   - Structure:

     _____

   - Function:

     _____

2. What is the difference between a sphingolipid that is also a phospholipid and one that is NOT?

_____

_____

_____

3. Name the three main types of sphingolipids and their characteristics.

Type	Phospholipid or Glycolipid?	Functional Group(s)

4. What would happen if an amphipathic molecule were placed in a nonpolar solvent rather than an aqueous solution?

_____

_____

_____

5.2 Signaling Lipids ★★

In addition to passive roles in structure, lipids also perform active roles in cellular signaling and as coenzymes. Lipids serve as coenzymes in the electron transport chain and in glycosylation reactions. Lipids also function as hormones that transmit signals over long distances and as intracellular messengers responding to extracellular signals. Certain special lipids with conjugated double bonds absorb light, which is extremely important for our ability to see; others act as pigments in plants and animals. Here, we will focus on three important categories of signaling lipids: steroids, prostaglandins, and fat-soluble vitamins, as well as important precursors like terpenes.

Bridge

Remember from Chapter 2 of *MCAT Biochemistry Review* that a coenzyme is an organic, nonprotein factor bound to an enzyme and required for its normal activity.

TERPENES AND TERPENOIDS

Before we delve into the details of downstream lipid signaling molecules, we must first turn our attention to *terpenes*. These odiferous chemicals are the metabolic precursors to steroids and other lipid signaling molecules, and have varied independent functions. **Terpenes** are a class of lipids built from ***isoprene*** (C_5H_8) moieties and

share a common structural pattern with carbons grouped in multiples of five, as shown in Figure 5.5.

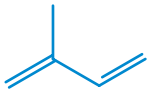

Figure 5.5. Isoprene

Terpenes are produced mainly by plants and also by some insects. They are generally strongly scented. In some cases, these pungent chemicals are part of the plant or insect's protective mechanism. The strong smell of turpentine, a derivative of resin, comes from the monoterpenes that are resin's major components; terpenes actually get their name from their original discovery in turpentine. Terpenes are also the primary components of much more pleasant-smelling essential oils extracted from plants.

Terpenes are grouped according to the number of isoprene units present; a single terpene unit contains two isoprene units. ***Monoterpenes*** ($C_{10}H_{16}$), which are abundant in both essential oils and turpentine as described above, contain two isoprene units. ***Sesquiterpenes*** (*sesqui–* meaning one-and-a-half) contain three isoprene units, and ***diterpenes*** contain four. Vitamin A, which will be discussed later in this chapter, is a diterpene from which *retinal*, a visual pigment vital for sight, is derived. ***Triterpenes***, with six isoprene units, can be converted to cholesterol and various steroids, also discussed later in this chapter. ***Carotenoids***, like *β-carotene* and *lutein*, are ***tetraterpenes*** and have eight isoprene units. Natural rubber has isoprene chains between 1000 and 5000 units long and is therefore considered a polyterpene.

Terpenoids, also sometimes referred to as isoprenoids, are derivatives of terpenes that have undergone oxygenation or rearrangement of the carbon skeleton. These compounds are further modified, as are terpenes, by the addition of an extensive variety of functional groups. Terpenoids share similar characteristics with terpenes in terms of both biological precursor function and aromatic properties, contributing to steroid biosynthesis as well as the scents of cinnamon, eucalyptus, camphor, turmeric, and numerous other compounds. Terpenoids are named in an analogous fashion, with diterpenoids deriving from four isoprene units and so on. Terpenes and terpenoids are precursor molecules that feed into various biosynthesis pathways that produce important products, including steroids, which have widespread effects on biological function, and vitamin A, which is vital to sight.

STEROIDS

The term steroid probably brings to mind muscle-bound body builders or home run-hitting professional athletes. In science, and on the MCAT, steroid refers not just to the infamously abused anabolic steroids, but also to a broader class of molecules defined by their structure.

Structurally, **steroids**, shown in Figure 5.6, are metabolic derivatives of terpenes and are very different from the lipids mentioned earlier in this chapter in both structure and function. Steroids are characterized by having four cycloalkane rings fused together: three cyclohexane and one cyclopentane. Steroid functionality is determined by the oxidation status of these rings, as well as the functional groups they carry. It is important to note that the large number of carbons and hydrogens make steroids nonpolar, like the other lipids mentioned.

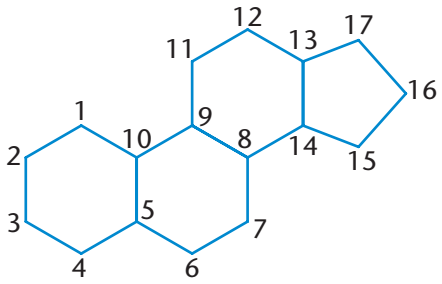

Figure 5.6. Common Steroid Structure

Keep in mind the terminology difference between steroids and steroid hormones. Steroid refers to a group defined by a particular chemical structure, demonstrated above. **Steroid hormones** are steroids that act as hormones, meaning that they are secreted by endocrine glands into the bloodstream and then travel on protein carriers to distant sites, where they can bind to specific high-affinity receptors and alter gene expression levels. Steroid hormones are potent biological signals that regulate gene expression and metabolism, affecting a wide variety of biological systems even at low concentrations. Some important steroid hormones include testosterone, various estrogens, cortisol, and aldosterone, which are discussed in Chapter 5 of *MCAT Biology Review*. Plants, like animals, also use steroids as signaling molecules.

Cholesterol, shown in Figure 5.7, is a steroid of primary importance. Cholesterol is a major component of the phospholipid bilayer, and is responsible for mediating membrane fluidity. Cholesterol, like a phospholipid, is an amphipathic molecule containing both hydrophilic and hydrophobic components. Interactions with both the hydrophobic tails and hydrophilic heads of phospholipids, allows cholesterol to maintain relatively constant fluidity in cell membranes. At low temperatures, it keeps the cell membrane from solidifying; at high temperatures, it holds the membrane intact and prevents it from becoming too permeable. Cholesterol also serves as a precursor to many important molecules, including steroid hormones, bile acids, and vitamin D.

Real World

Cholesterol can be produced *de novo* or absorbed from dietary sources. *Hypercholesterolemia,* or high cholesterol, is a condition that is strongly correlated with heart disease, in which the combination of these two cholesterol sources is excessive. Accumulation of cholesterol in arterial walls results in atherosclerosis, a hardening of the wall.

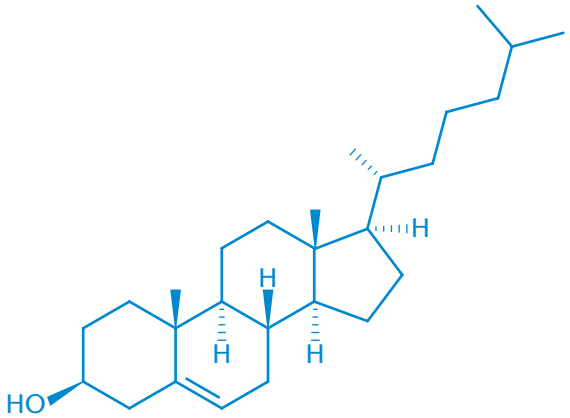

Figure 5.7. Cholesterol

PROSTAGLANDINS

Prostaglandins acquired their name because they were first thought to be produced by the prostate gland, but have since been determined to be produced by almost all cells in the body. These 20-carbon molecules are unsaturated carboxylic acids derived from ***arachidonic acid*** and contain one five-carbon ring. They act as paracrine or autocrine signaling molecules. In many tissues, the biological function of prostaglandins is to regulate the synthesis of cyclic adenosine monophosphate (cAMP), which is a ubiquitous intracellular messenger. In turn, cAMP mediates the actions of many other hormones. Downstream effects of prostaglandins include powerful effects on smooth muscle function, influence over the sleep–wake cycle, and the elevation of body temperature associated with fever and pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) like aspirin inhibit the enzyme *cyclooxygenase* (COX), which aids in the production of prostaglandins.

FAT-SOLUBLE VITAMINS

A **vitamin** is an essential nutrient that cannot be adequately synthesized by the body and therefore must be consumed in the diet. Vitamins are commonly divided into water-soluble and lipid-soluble categories. Lipid-soluble vitamins can accumulate in stored fat, whereas excess water-soluble vitamins are excreted through the urine. The fat-soluble vitamins include A, D, E, and K. Each of these has important and varied functions.

Vitamin A

Vitamin A, or ***carotene***, is an unsaturated hydrocarbon that is important in vision, growth and development, and immune function. The most significant metabolite of vitamin A is the aldehyde form, ***retinal***, which is a component of the light-sensing molecular system in the human eye. ***Retinol***, the storage form of vitamin

A, is also oxidized to ***retinoic acid***, a hormone that regulates gene expression during epithelial development.

Vitamin D

Vitamin D, or ***cholecalciferol***, can be consumed or formed in a UV light-driven reaction in the skin. In the liver and kidneys, vitamin D is converted to ***calcitriol*** ($1,25\text{-}(OH)_2D_3$), the biologically active form of vitamin D. Calcitriol increases calcium and phosphate uptake in the intestines, which promotes bone production. A lack of vitamin D can result in **rickets**, a condition seen in children and characterized by underdeveloped, curved long bones as well as impeded growth.

Vitamin E

Vitamin E characterizes a group of closely related lipids called ***tocopherols*** and ***tocotrienols***. These are characterized by a substituted aromatic ring with a long isoprenoid side chain and are characteristically hydrophobic. Tocopherols are biological antioxidants. The aromatic ring reacts with free radicals, destroying them. This, in turn, prevents oxidative damage, an important contributor to the development of cancer and aging.

Vitamin K

Vitamin K is actually a group of compounds, including ***phylloquinone*** (K_1) and the ***menaquinones*** (K_2). Vitamin K is vital to the posttranslational modifications required to form *prothrombin*, an important clotting factor in the blood. The aromatic ring of vitamin K undergoes a cycle of oxidation and reduction during the formation of prothrombin. Vitamin K is also required to introduce calcium-binding sites on several calcium-dependent proteins.

MCAT Concept Check 5.2:

Before you move on, assess your understanding of the material with these questions.

1. How many carbons are in a diterpene?

_____

_____

_____

2. What is the difference between a steroid and a steroid hormone?

_____

_____

_____

Mnemonic

One way to remember **carotene** is to remember that **carrots** are high in **vitamin A**, which is why eating carrots is colloquially suggested to improve **vision**. To remember that **vitamin D** regulates calcium, remember that it is frequently added to **milk** in order to aid in the absorption of **calcium**.

Mnemonic

Vitamin **K** is for **K**oagulation.

Real World

The anticoagulant *warfarin* works by blocking the recycling of vitamin K, causing a deficiency or lowering of the active amount of vitamin K. Therefore, patients taking warfarin are recommended to stay away from food containing high amounts of vitamin K, such as green leafy vegetables.

3. NSAIDs block prostaglandin production in order to reduce pain and inflammation. What do prostaglandins do to bring about these symptoms?

_____

_____

4. What are the names and functions of the four fat-soluble vitamins?

Name	Function

5.3 Energy Storage ★★

Triacylglycerols are a class of lipids specifically used for energy storage. From the body's point of view, lipids in general are a fantastic way to store energy. This is true for two major reasons. First, the carbon atoms of fatty acids are more reduced than those of sugars, which contain numerous alcohol groups. The result of this is that the oxidation of triacylglycerols yields twice the amount of energy per gram as carbohydrates, making this a far more energy-dense storage mechanism compared to polysaccharides like glycogen. Second, triacylglycerols are hydrophobic. They do not draw in water and do not require hydration for stability. This helps decrease their weight, especially in comparison to hydrophilic polysaccharides. One final perk for vertebrates surviving in colder temperatures (like penguins, polar bears, and arctic explorers) is that the layer of lipids serves a dual purpose of energy storage and insulation—it helps to retain body heat so that less energy is required to maintain a constant internal temperature.

TRIACYLGLYCEROLS

Triacylglycerols, also called **triglycerides**, are composed of three fatty acids bonded by ester linkages to glycerol, as shown in Figure 5.8. For most naturally occurring triacylglycerols, it is rare for all three fatty acids to be the same.

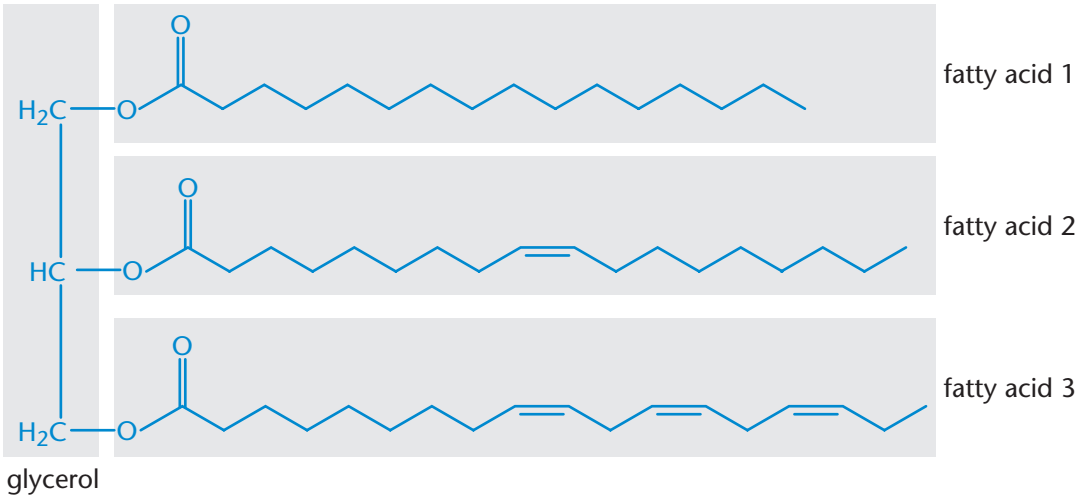

Figure 5.8. Triacylglycerol Structure
The fatty acids used here are palmitic acid, oleic acid, and α-linolenic acid.

Overall, these compounds are nonpolar and hydrophobic. This contributes to their insolubility in water, as the polar hydroxyl groups of the glycerol component and the polar carboxylates of fatty acids are bonded together, decreasing their polarity.

Triacylglycerol deposits can be observed in cells as oily droplets in the cytosol. These serve as depots of metabolic fuel that can be recruited when the cell needs additional energy to divide or survive when other fuel supplies are low. Special cells in animals, known as **adipocytes**, store large amounts of fat and are found primarily under the skin, around mammary glands, and in the abdominal cavity. In plants, triacylglycerol deposits are also found in seeds as oils. Triacylglycerols travel bidirectionally in the bloodstream between the liver and adipose tissue. The physical characteristics of triacylglycerols are primarily determined by the saturation (or unsaturation) of the fatty acid chains that make them up, much like phospholipids.

Real World

The two main methods of energy storage in the body are as triacylglycerols in adipose tissue or as carbohydrates in glycogen. Each method has its advantages and disadvantages. For example, glycogen offers access to metabolic energy in a faster water-soluble form; however, because of its low energy density, glycogen can only provide energy for a bit less than one day. In contrast, a moderately obese individual with 15 to 20 kg of stored triacylglycerols in adipocytes could draw upon fat stores for months, but it takes more time to mobilize this energy.

FREE FATTY ACIDS AND SAPONIFICATION

Free fatty acids are unesterified fatty acids with a free carboxylate group. In the body, these circulate in the blood bonded noncovalently to serum albumin. Fatty acids also make up what we know as soap, which can be produced through a process called saponification.

Saponification is the ester hydrolysis of triacylglycerols using a strong base. Traditionally, the base that is used is **lye**, the common name for sodium or potassium hydroxide. The result is the basic cleavage of the fatty acid, leaving the sodium salt of the fatty acid and glycerol, as shown in Figure 5.9. The fatty acid salt is what we know as soap.

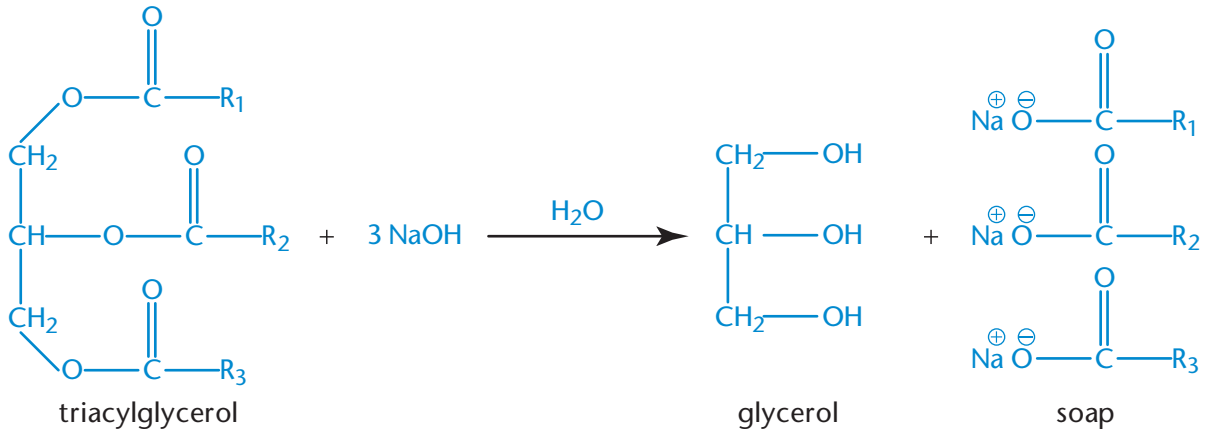

Figure 5.9. Saponification
Ester hydrolysis of a triacylglycerol using lye (NaOH).

Real World

Saponification also occurs naturally, although more slowly, in corpses and oil paintings, as the triacylglycerols are hydrolyzed by naturally occurring bases. In corpses, the result of this process is known as *adipocere*, or grave wax.

Soaps can act as surfactants. A **surfactant** lowers the surface tension at the surface of a liquid, serving as a detergent or emulsifier. This is important to how soap works. If we try to combine an aqueous solution and oil, as with vinegar and olive oil in salad dressing, these solutions will remain in separate phases. If we were to add a soap, however, the two phases would appear to combine into a single phase, forming a **colloid**. This occurs because of the formation of **micelles**: tiny aggregates of soap with the hydrophobic tails turned inward and the hydrophilic heads turned outward, thereby shielding the hydrophobic lipid tails and allowing for overall solvation, as shown in Figure 5.10. We saw these earlier when we discussed membrane lipids.

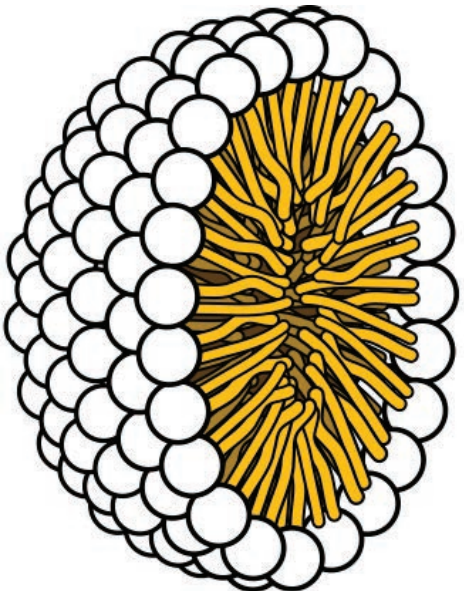

Figure 5.10. Cross-Section of a Micelle
Micelles organize in aqueous solution by forcing hydrophobic tails to the interior, allowing the hydrophilic heads to interact with water in the environment.

Nonpolar compounds can dissolve in the hydrophobic interior of the water-soluble micelle, meaning that our cleaning agents can dissolve both water-soluble and water-insoluble messes and then wash them all away together. Micelles are also important in the body for the absorption of fat-soluble vitamins (A, D, E, and K) and complicated lipids such as *lecithins*. Fatty acids and bile salts secreted by the gallbladder form micelles that can increase the surface area available for lipolytic enzymes.

MCAT Concept Check 5.3:

Before you move on, assess your understanding of the material with these questions.

1. How does the human body store spare energy? Why doesn't the human body store most energy as sugar?

_____

_____

_____

2. Describe the structure and function of triacylglycerols.

_____

_____

3. What bonds are broken during saponification?

_____

4. Why does soap appear to dissolve in water, and how is this fact important to cleaning?

_____

_____

_____

Conclusion

In this chapter, we examined the myriad biological functions performed by lipids. We first learned the structural functions of lipids, looking at the phospholipids that are the primary component of the phospholipid bilayer and other membrane lipids. Making our way through terpenes, we looked at the structure and function of signaling lipids, examining steroid hormones in particular. We looked into the fat-soluble vitamins and their downstream functions in the body. Finally, we summarized energy storage in the form of triacylglycerols and applied our acid–base chemistry knowledge to the formation of soap. In the next chapter, we turn our attention to the final class of biomolecules: nucleic acids.

CONCEPT SUMMARY

Structural Lipids

- Lipids are insoluble in water and soluble in nonpolar organic solvents.
- **Phospholipids** are amphipathic and form the bilayer of biological membranes.
  - They contain a hydrophilic (polar) head group and hydrophobic (nonpolar) tails.
  - The head group is attached by a **phosphodiester linkage** and, because it interacts with the environment, determines the function of the phospholipid.
  - The **saturation** of the fatty acid tails determines the fluidity of the membrane; saturated fatty acids are less fluid than unsaturated ones. Fatty acids form most of the structural thickness of the phospholipid bilayer.
  - **Glycerophospholipids** are phospholipids that contain a glycerol backbone.
- **Sphingolipids** contain a sphingosine or sphingoid backbone.
  - Many (but not all) sphingolipids are also phospholipids, containing a phosphodiester bond; these are termed **sphingophospholipids**.
  - **Sphingomyelins** are the major class of sphingophospholipids and contain a phosphatidylcholine or phosphatidylethanolamine head group. They are a major component of the myelin sheath.
  - **Glycosphingolipids** are attached to sugar moieties instead of a phosphate group. **Cerebrosides** have one sugar connected to sphingosine; **globosides** have two or more.
  - **Gangliosides** contain oligosaccharides with at least one terminal ***N*-acetylneuraminic acid** (**NANA**; also called **sialic acid**).
- **Waxes** contain long-chain fatty acids esterified to long-chain alcohols. They are used as protection against evaporation and parasites in plants and animals.

Signaling Lipids

- **Terpenes** are odiferous steroid precursors made from **isoprene**, a five-carbon molecule.
  - One terpene unit (a **monoterpene**) contains two isoprene units.
  - **Terpenoids** are derived from terpenes via oxygenation or backbone rearrangement. They have similar odorous characteristics.
- **Steroids** contain three cyclohexane rings and one cyclopentane ring. Their oxidation state and functional groups may vary.
  - **Steroid hormones** have high-affinity receptors, work at low concentrations, and affect gene expression and metabolism.
  - **Cholesterol** is a steroid important to membrane fluidity and stability; it serves as a precursor to a host of other molecules.

- **Prostaglandins** are autocrine and paracrine signaling molecules that regulate cAMP levels. They have powerful effects on smooth muscle contraction, body temperature, the sleep–wake cycle, fever, and pain.
- The fat-soluble vitamins include vitamins A, D, E, and K.
  - **Vitamin A** (**carotene**) is metabolized to **retinal** for vision and **retinoic acid** for gene expression in epithelial development.
  - **Vitamin D** (**cholecalciferol**) is metabolized to **calcitriol** in the kidneys and regulates calcium and phosphorus homeostasis in the intestines (increasing calcium and phosphate absorption), promoting bone formation. A deficiency of vitamin D causes **rickets**.
  - **Vitamin E** (**tocopherols**) act as biological antioxidants. Their aromatic rings destroy free radicals, preventing oxidative damage.
  - **Vitamin K** (**phylloquinone** and **menaquinones**) is important for formation of prothrombin, a clotting factor. It performs posttranslational modifications on a number of proteins, creating calcium-binding sites.

Energy Storage

- **Triacylglycerols** (**triglycerides**) are the preferred method of storing energy for long-term use.
  - They contain one glycerol attached to three fatty acids by ester bonds. The fatty acids usually vary within the same triacylglycerol.
  - The carbon atoms in lipids are more reduced than carbohydrates, giving twice as much energy per gram during oxidation.
  - Triacylglycerols are very hydrophobic, so they are not hydrated by body water and do not carry additional water weight.
- Animal cells specifically used for storage of large triacylglycerol deposits are called **adipocytes**.
- Free fatty acids are unesterified fatty acids that travel in the bloodstream. Salts of free fatty acids are **soaps**, and can be synthesized in saponification.
  - **Saponification** is the ester hydrolysis of triacylglycerols using a strong base, like sodium or potassium hydroxide.
  - Soaps act as surfactants, forming micelles. A **micelle** can dissolve a lipid-soluble molecule in its fatty acid core, and washes away with water because of its shell of carboxylate head groups.

ANSWERS TO CONCEPT CHECKS

5.1

1. Membrane lipids are amphipathic: they have hydrophilic heads and hydrophobic tails, allowing for the formation of bilayers in aqueous solution. The fatty acid tails form the bulk of the phospholipid bilayer, and play a predominantly structural role. On the other hand, the functional differences between membrane lipids are determined by the polar head group, due to its constant exposure to the exterior environment of the phospholipid bilayer (remember, this can be either the inside or outside of the cell). The degree of unsaturation of fatty acid tails can also play a small role in function.
2. The difference is the bond between the sphingosine backbone and the head group. When this is a phosphodiester bond, it's a phospholipid (note the *phospho–* prefixes). Nonphospholipid sphingolipids include glycolipids, which contain a glycosidic linkage to a sugar.
3.

Type	Phospholipid or Glycolipid?	Functional Group(s)
Sphingomyelin	Phospholipid	Phosphatidylethanolamine/ phosphatidylcholine
Glycosphingolipid	Glycolipid	Sugars (mono- or polysaccharide)
Ganglioside	Glycolipid	Oligosaccharides and *N*-acetylneuraminic acid (NANA)

4. In a nonpolar solvent, we would see the opposite of what happens in a polar solvent like water: The hydrophilic, polar part of the molecules would be sequestered inside, while the nonpolar, hydrophobic part of the molecules would be found on the exterior and exposed to the solvent.

5.2

1. A diterpene has 20 carbon molecules in its backbone. One terpene unit is made from two isoprene units, each of which has five carbons.
2. A steroid is defined by its structure: it includes three cyclohexane rings and a cyclopentane ring. A steroid hormone is a molecule within this class that also functions as a hormone, meaning that it travels in the bloodstream, is active at low concentrations, has high-affinity receptors, and affects gene expression and metabolism.
3. Prostaglandins regulate the synthesis of cAMP, which is involved in many pathways, including those that drive pain and inflammation.

4.

Name	Function
A (carotene)	As retinal: vision; as retinoic acid: epithelial development
D (cholecalciferol)	As calcitriol: calcium and phosphate regulation
E (tocopherols)	Antioxidants, using aromatic ring
K (phylloquinone and menaquinones)	Posttranslational modification of prothrombin, addition of calcium-binding sites on many proteins

5.3

1. The human body stores energy as glycogen and triacylglycerols. Triacylglycerols are preferred because their carbons are more reduced, resulting in a larger amount of energy yield per unit weight. In addition, due to their hydrophobic nature, triacylglycerols do not need to carry extra weight from hydration.
2. Triacylglycerols, also called triglycerides, are composed of a glycerol backbone esterified to three fatty acids. They are used for energy storage.
3. The ester bonds of triacylglycerols are broken to form a glycerol molecule and the salts of fatty acids (soap).
4. Soap appears to dissolve in water because amphipathic free fatty acid salts form micelles, with hydrophobic fatty acid tails toward the center and carboxylate groups facing outward toward the water. Fat-soluble particles can then dissolve inside micelles in the soap–water solution and wash away. Water-soluble compounds can freely dissolve in the water.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following is NOT a type of glycolipid?

A. Cerebroside
B. Globoside
C. Ganglioside
D. Sphingomyelin

2. During saponification:

A. triacylglycerols undergo a condensation reaction.
B. triacylglycerols undergo ester hydrolysis.
C. fatty acid salts are produced using a strong acid.
D. fatty acid salts are bound to albumin.

3. Which of the following best describes the structure of steroids?

A. Three cyclopentane rings, one cyclohexane ring
B. Three cyclohexane rings, one cyclopentane ring
C. Four carbon rings, differing in structure for each steroid
D. Three cyclic carbon rings and a functional group

4. Soap bubbles form because fatty acid salts organize into:

A. lysosomes.
B. micelles.
C. phospholipid bilayers.
D. hydrogen bonds.

5. Steroid hormones are steroids that:

I. have specific high-affinity receptors.
II. travel in the bloodstream from endocrine glands to distant sites.
III. effect gene transcription by binding directly to DNA.

A. I only
B. III only
C. I and II only
D. I and III only

6. Why are triacylglycerols used in the human body for energy storage?

A. They are highly hydrated, and therefore can store lots of energy.
B. They always have short fatty acid chains for easy access by metabolic enzymes.
C. The carbon atoms of the fatty acid chains are highly reduced, and therefore yield more energy upon oxidation.
D. Polysaccharides, which would actually be a better energy storage form, would dissolve in the body.

7. Which of the following is correct about fat-soluble vitamins?

I. Vitamin E is important for calcium regulation.
II. Vitamin D protects against cancer because it is a biological antioxidant.
III. Vitamin K is necessary for the posttranslational introduction of calcium-binding sites.
IV. Vitamin A is metabolized to retinal, which is important for sight.

A. III only
B. I and II only
C. III and IV only
D. II, III, and IV only

8. Which of the following is true of amphipathic molecules?

A. They form protective spheres in any solvent, with hydrophobic molecules interior and hydrophilic molecules exterior.
B. They have two fatty acid chains and a polar head group.
C. They are important to the formation of the phospholipid bilayer and soap bubbles.
D. They have a glycerol base.

9. Which of the following is/are true about sphingolipids?

I. They are all phospholipids.
II. They all contain a sphingosine backbone.
III. They can have either phosphodiester or glycosidic linkages to their polar head groups.

A. I only
B. III only
C. II and III only
D. I, II, and III

10. Which of the following statements about saturation is FALSE?

A. It can describe the number of double or triple bonds in a fatty acid tail.
B. It determines at least one of the properties of membranes.
C. More saturated fatty acids make for a more fluid solution.
D. Fully saturated fatty acids have only single bonds.

11. Which of the following is true about glycerophospholipids?

A. Glycerophospholipids can sometimes be sphingolipids, depending on the bonds in their head groups.
B. Glycerophospholipids are merely a subset of phospholipids.
C. Glycerophospholipids are used in the ABO blood typing system.
D. Glycerophospholipids have one glycerol, one polar head group, and one fatty acid tail.

12. Which of the following statements about terpenes is FALSE?

A. Terpenes are strongly scented molecules that sometimes serve protective functions.
B. Terpenes are steroid precursors.
C. A triterpene is made of three isoprene moieties, and therefore has 15 carbons.
D. Terpenes are made by plants and insects.

13. Which of the following is true about cholesterol?

A. Cholesterol always increases membrane fluidity in cells.
B. Cholesterol is a steroid hormone precursor.
C. Cholesterol is a precursor for vitamin A, which is produced in the skin.
D. Cholesterol interacts only with the hydrophobic tails of phospholipids.

14. Which of the following statements regarding prostaglandins is FALSE?

A. Prostaglandins regulate the synthesis of cAMP.
B. Prostaglandin synthesis is inhibited by NSAIDs.
C. Prostaglandins affect pain, inflammation, and smooth muscle function.
D. Prostaglandins are endocrine hormones, like steroid hormones.

15. Which of the statements regarding waxes is FALSE?

A. Waxes generally have melting points above room temperature.
B. Waxes are produced only in plants and insects and therefore must be consumed by humans.
C. Waxes protect against dehydration and parasites.
D. Waxes are esters of long-chain fatty acids and long-chain alcohols.

Explanations to Discrete Practice Questions

1. D

Glycolipids contain sugar moieties connected to their backbone. Sphingomyelin is not a glycolipid, but rather a phospholipid. This class can either have phosphatidylcholine or phosphatidylethanolamine as a head group and therefore contains a phosphodiester, not glycosidic, bond.

2. B

Saponification is the ester hydrolysis of triacylglycerol using a strong base like sodium or potassium hydroxide to form glycerol and fatty acid salts. This is not a condensation reaction, as in **choice (A)**, but a cleavage reaction. Fatty acids do travel in the body bonded to serum albumin, as in **choice (D)**, but that is unrelated to the process of saponification.

3. B

The basic backbone of steroid structure contains three cyclohexane rings and one cyclopentane ring. Although the oxidation status of these rings varies for different steroids, the overall structure does not, as in **choice (C)**.

4. B

Fatty acid salt micelles are responsible for the formation of soap bubbles. While phospholipids can form bilayers, as in **choice (C)**, the fatty acids in soap are free fatty acids, not phospholipids.

5. C

Steroid hormones are produced in endocrine glands and travel in the bloodstream to bind high-affinity receptors in the nucleus. The hormone's receptor binds to DNA as part of the hormone–receptor complex, but the hormone itself does not.

6. C

Triacylglycerols are highly hydrophobic and therefore not highly hydrated (which would add extra weight from the water of hydration, taking away from the energy density of these molecules), eliminating **choice (A)**. The fatty acid chains produce twice as much energy as polysaccharides during oxidation because they are highly reduced. The fatty acid chains vary in length and saturation.

7. C

Vitamin A is metabolized to retinal, which is important for sight. Vitamin D is metabolized to calcitriol, which is important for calcium regulation. Vitamin E is made up of tocopherols, which are biological antioxidants. Vitamin K is necessary for the introduction of calcium binding sites, such as during the posttranslational modification of prothrombin.

8. C

Phospholipids are amphipathic, as are fatty acid salts. Although amphipathic molecules take spherical forms with hydrophobic molecules interior in aqueous solution, as in **choice (A)**, the opposite would be true in a nonpolar solvent. **Choice (B)** describes phospholipids and sphingolipids, and **choice (D)** describes triacylglycerols and phospholipids; both groups do not include fatty acid salts.

9. B

Sphingolipids can either have a phosphodiester bond, and therefore be phospholipids, or have a glycosidic linkage and therefore be glycolipids. Not all sphingolipids have a sphingosine backbone, as in statement II; some have related (sphingoid) compounds as backbones instead.

10. C

More saturated fatty acids make for a less fluid solution. This is because they can pack more tightly and form more noncovalent bonds, resulting in more energy being needed to disrupt the overall structure.

11. B

Glycerophospholipids are a subset of phospholipids, as are sphingomyelins. Glycerophospholipids are never sphingolipids because they contain a glycerol backbone (rather than sphingosine or a sphingoid backbone), eliminating **choice (A)**. Sphingolipids are used in the ABO blood typing system, eliminating **choice (C)**. Glycerophospholipids have a polar head group, glycerol, and two fatty acid tails, not one, as in **choice (D)**.

12. C

A triterpene is made of six isoprene moieties (remember, one terpene unit contains two isoprene units), and therefore has a 30-carbon backbone.

13. B

Cholesterol is a steroid hormone precursor that has variable effects on membrane fluidity depending on temperature, eliminating **choice (A)**. It interacts with both the hydrophobic tails and the hydrophilic heads of membrane lipids, nullifying **choice (D)**. It is also a precursor for vitamin D (not vitamin A), which can be produced in the skin in a UV-driven reaction, eliminating **choice (C)**.

14. D

Prostaglandins are paracrine or autocrine signaling molecules, not endocrine—they affect regions close to where they are produced, rather than affecting the entire body. Think of the swelling that happens when you bash your knee into your desk: your knee will swell, turn red, and possibly bruise. Luckily, however, your entire body won't swell as well.

15. B

Waxes are also produced in animals for similar protective functions. Cerumen, or earwax, is a prime example in humans.

Concept Summary 200

Introduction

How do all of the cells of our body know what job to do? The cells that make up the human body have nucleic acids that instruct the cell on how to function. The nucleic acid *deoxyribonucleic acid* (DNA) stores the information in our cells and selectively shares that information when appropriate. DNA is a molecule that can be passed from generation to generation. DNA can be replicated in a carefully regulated process designed to keep the genome safe from degradation and free from errors. Seemingly small changes in the genetic code can result in life-threatening and even life-incompatible alterations to protein structure and function. In this chapter, the unique structure of DNA will be discussed, along with replication and repair processes. The primary focus will be on eukaryotic processes, but there will be some review of prokaryotic genetics to help us better understand the molecular basis of life.

Much of the advancement of medicine in the past two decades has been due to our increased understanding of molecular genetics, which has led to the creation of an entire biotechnology industry centered around genomics and the utilization of nucleic acids for various diagnostic tests and therapeutic interventions. We will also take a look at some of these important principles in this chapter.

6.1 DNA Structure

There are two chemically distinct forms of nucleic acids within eukaryotic cells. **Deoxyribonucleic acid** (**DNA**) and **ribonucleic acid** (**RNA**) are polymers, each with distinct roles, that together create the molecules integral to life in all living organisms. DNA is the focus of this chapter and RNA will be discussed in more detail in Chapter 7 of *MCAT Biochemistry Review*. The bulk of DNA is found in chromosomes in the nucleus of eukaryotic cells, although some is also present in mitochondria and chloroplasts.

NUCLEOSIDES AND NUCLEOTIDES

DNA is a macromolecule and it is essential to understand how this molecule is constructed. DNA is a *polydeoxyribonucleotide* that is composed of many *mono-deoxyribonucleotides* linked together. The nomenclature of nucleic acids can be complicated, so the terms have been defined here:

- **Nucleosides** are composed of a five-carbon sugar (*pentose*) bonded to a nitrogenous base and are formed by covalently linking the base to C-1′ of the sugar, as shown in Figure 6.1. Note that the carbon atoms in the sugar are labeled with a prime symbol to distinguish them from the carbon atoms in the nitrogenous base.
- **Nucleotides** are formed when one or more phosphate groups are attached to C-5′ of a nucleoside. Often these molecules are named according to the number of phosphates present. Adenosine di- and triphosphate (ADP and ATP), for example, gain their name from the number of phosphate groups attached to the nucleoside adenosine. These are high-energy compounds because of the energy associated with the repulsion between closely associated negative charges on the phosphate groups, as shown in Figure 6.2. Nucleotides are the building blocks of DNA.

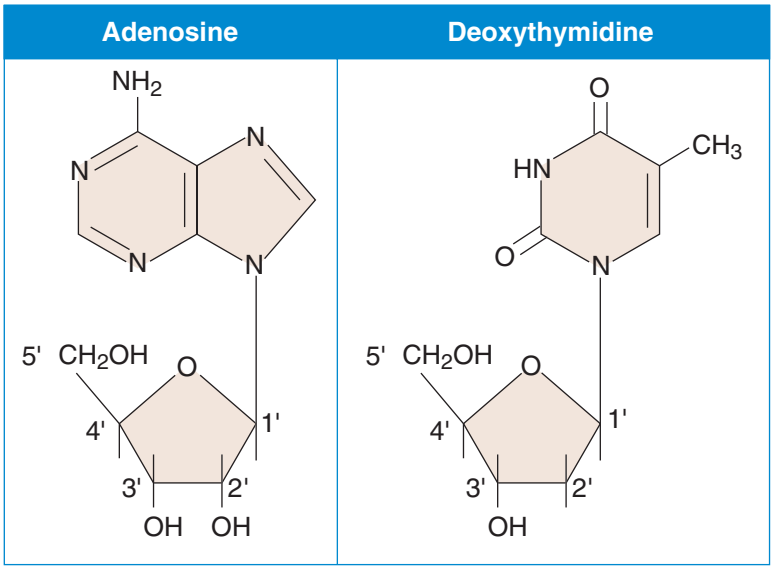

Figure 6.1. Examples of Nucleosides

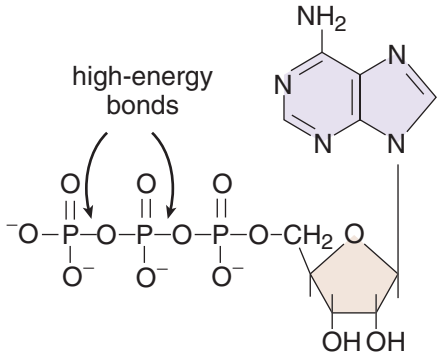

Figure 6.2. High-Energy Bonds in Adenosine Triphosphate, a Nucleotide

Bridge

In Chapter 3 of *MCAT General Chemistry Review*, we learned that bond breaking is usually endothermic and bond making is usually exothermic. ATP offers a biologically relevant—and MCAT tested—exception to this rule. Due to all the negative charges in close proximity, removing the terminal phosphate from ATP actually releases energy, which powers our cells.

Nucleic acids are classified according to the pentose they contain, as shown in Figure 6.3. If the pentose is **ribose**, the nucleic acid is RNA; if the pentose is **deoxyribose** (ribose with the 2′ –OH group replaced by –H), then it is DNA.

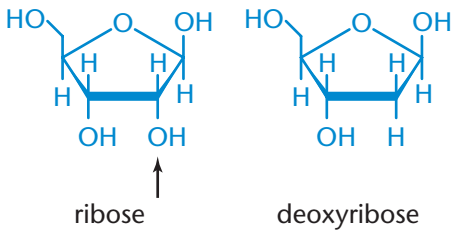

Figure 6.3. Ribose and Deoxyribose
Ribose has an –OH group at C-2; deoxyribose has –H.

The nomenclature for the common bases, nucleosides, and nucleotides is shown in Table 6.1. Note that there is no *thymidine* listed (only *deoxythymidine*) because thymine appears almost exclusively in DNA.

Base	Nucleoside	Nucleotides		
Adenine	Adenosine (Deoxyadenosine)	AMP (dAMP)	ADP (dADP)	ATP (dATP)
Guanine	Guanosine (Deoxyguanosine)	GMP (dGMP)	GDP (dGDP)	GTP (dGTP)
Cytosine	Cytidine (Deoxycytidine)	CMP (dCMP)	CDP (dCDP)	CTP (dCTP)
Uracil	Uridine (Deoxyuridine)	UMP (dUMP)	UDP (dUDP)	UTP (dUTP)
Thymine	(Deoxythymidine)	(dTMP)	(dTDP)	(dTTP)

Names of nucleosides and nucleotides attached to deoxyribose are shown in parentheses.

Table 6.1. Nomenclature of Important Bases, Nucleosides, and Nucleotides

SUGAR–PHOSPHATE BACKBONE

The backbone of DNA is composed of alternating sugar and phosphate groups; it determines the directionality of the DNA and is always read from 5′ to 3′. It is formed as nucleotides are joined by 3′–5′ phosphodiester bonds. That is, a phosphate group links the 3′ carbon of one sugar to the 5′ phosphate group of the next incoming sugar in the chain. Phosphates carry a negative charge; thus, DNA and RNA strands have an overall negative charge.

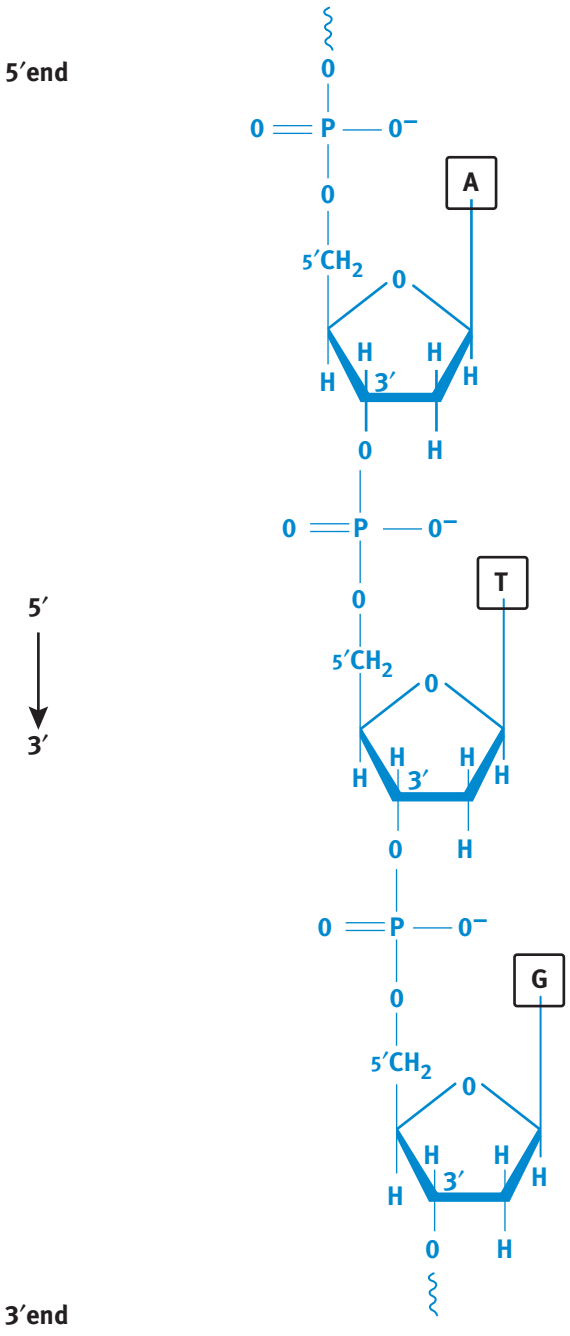

Figure 6.4. DNA Strand Polarity
DNA strands run antiparallel to one another; enzymes that replicate and transcribe DNA only work in the 5′ to 3′ direction.

Each strand of DNA has distinct 5′ and 3′ ends, creating polarity within the backbone, as shown in Figure 6.4. The 5′ end of DNA, for instance, will have an –OH or phosphate group bonded to C-5′ of the sugar, while the 3′ end has a free –OH on C-3′ of the sugar. The base sequence of a nucleic acid strand is both written and read in the

MCAT Expertise

On the MCAT, always check nucleic acids for polarity. One of the easiest ways to generate incorrect answers is to simply reverse the reading frame: 3′—GATTACA—5′ is not the same as 3′—ACATTAG—5′.

5′ to 3′ direction. Thus, the DNA strand in Figure 6.4 must be written: 5′—ATG—3′ (or simply ATG). DNA sequences can also be written in slightly different ways:

- If written backwards, the ends must be labeled: 3′—GTA—5′
- The position of phosphates may be shown: pApTpG
- "d" may be used as shorthand for deoxyribose: dAdTdG

DNA is generally double-stranded (dsDNA) and RNA is generally single-stranded (ssRNA). Exceptions to this rule may be seen, especially in viruses, as described in Chapter 1 of *MCAT Biology Review*.

PURINES AND PYRIMIDINES

There are two families of nitrogen-containing bases found in nucleotides: purines and pyrimidines. The bases described below, and shown in Figure 6.5, represent the common bases in eukaryotes; however, it should be noted that exceptions may be seen in tRNA and in some prokaryotes and viruses. **Purines** contain two rings in their structure. The two purines found in nucleic acids are **adenine** (**A**) and **guanine** (**G**); both are found in DNA and RNA. **Pyrimidines** contain only one ring in their structure. The three pyrimidines are **cytosine** (**C**), **thymine** (**T**), and **uracil** (**U**); while cytosine is found in both DNA and RNA, thymine is only found in DNA and uracil is only found in RNA.

Mnemonic

To remember the types and structures of these two classes of nitrogenous bases, remember to **CUT** the **PY**e (as **C**, **U**, and **T** are **py**rimidines). You can also note that pie has one ring of crust, and pyrimidines have only one ring in their structure. You can also remember **PUR**e **A**s **G**old (as **A** and **G** are **pur**ines); think of gold wedding rings. It takes two gold rings at a wedding, just like purines have two rings in their structure.

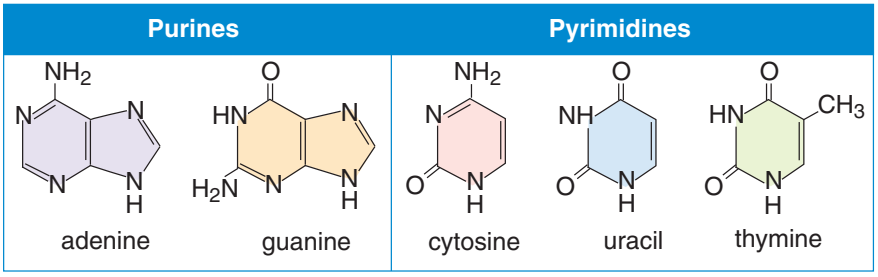

Figure 6.5. Bases Commonly Found in Nucleic Acids

Purines and pyrimidines are examples of biological aromatic heterocycles. In chemistry, the term **aromatic** describes any unusually stable ring system that adheres to the following four specific rules:

1. The compound is cyclic
2. The compound is planar
3. The compound is conjugated (has alternating single and multiple bonds, or lone pairs, creating at least one unhybridized *p*-orbital for each atom in the ring)
4. The compound has $4n + 2$ (where n is any integer) π electrons. This is called **Hückel's rule**

The most common example of an aromatic compound is benzene, but many different structures obey these rules. In an aromatic compound, the extra stability is due to the delocalized π electrons, which can travel throughout the entire compound using available molecular orbitals. All six of the carbon atoms in benzene are sp^2-hybridized, and each of the six orbitals overlaps equally with its two neighbors. As a result, the delocalized electrons form two π electron clouds (one above and one below the plane of the ring), as shown in Figure 6.6. This delocalization is characteristic of all aromatic molecules, and because of this, aromatic molecules are fairly unreactive.

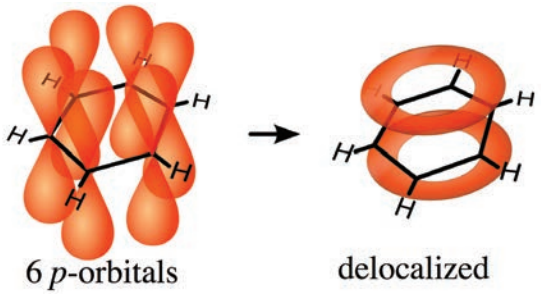

Figure 6.6. Delocalization of π Electrons in Benzene

Heterocycles are ring structures that contain at least two different elements in the ring. As shown in Figure 6.5 earlier, both purines and pyrimidines contain nitrogen in their aromatic rings. Nucleic acids are thus imbued with exceptional stability. This helps to explain the utility of nucleotides as the molecule for storing genetic information.

WATSON–CRICK MODEL

Putting this information together, we can start looking at the **Watson–Crick model** of DNA structure. In 1953, James Watson and Francis Crick presented one of the landmark findings of modern biology and medicine: the three-dimensional structure of DNA. They were able to deduce the double-helical nature of DNA and propose specific base-pairing that would be the basis of a copying mechanism. In the **double helix**, two linear polynucleotide chains of DNA are wound together in a spiral orientation along a common axis. The key features of the model—some of which have already been mentioned—are:

- The two strands of DNA are antiparallel; that is, the strands are oriented in opposite directions. When one strand has polarity 5′ to 3′ *down* the page, the other strand has 5′ to 3′ polarity *up* the page.
- The sugar–phosphate backbone is on the outside of the helix with the nitrogenous bases on the inside.
- There are specific base-pairing rules, often referred to as **complementary base-pairing**, as shown in Figure 6.7. An adenine (A) is always base-paired with a thymine (T) via two hydrogen bonds. A guanine (G) always pairs with

Key Concept

When writing a complementary strand of DNA, it is important to not only remember the base-pairing rules but to also keep track of the 5′ and 3′ ends. Remember that the sequences need to be both complementary and antiparallel. For example, 5′—ATCG—3′ will be complementary to 5′—CGAT—3′.

MCAT Expertise

Using Chargaff's rules:
In double-stranded DNA, purines = pyrimidines:
- %A = %T
- %G = %C

If a sample of DNA has 10% G, what is the % of T?
10% G = 10% C, thus %G + %C = 20%
%A + %T = 80%, thus %T = 40%.

cytosine (C) via three hydrogen bonds. The three hydrogen bonds make the G–C base pair interaction stronger. These hydrogen bonds, and the hydrophobic interactions between bases, provide stability to the double helix structure. Thus, the base sequence on one strand defines the base sequence on the other strand.

- Because of the specific base-pairing, the amount of A equals the amount of T, and the amount of G equals the amount of C. Thus, total purines will be equal to total pyrimidines overall. These properties are known as **Chargaff's rules**.

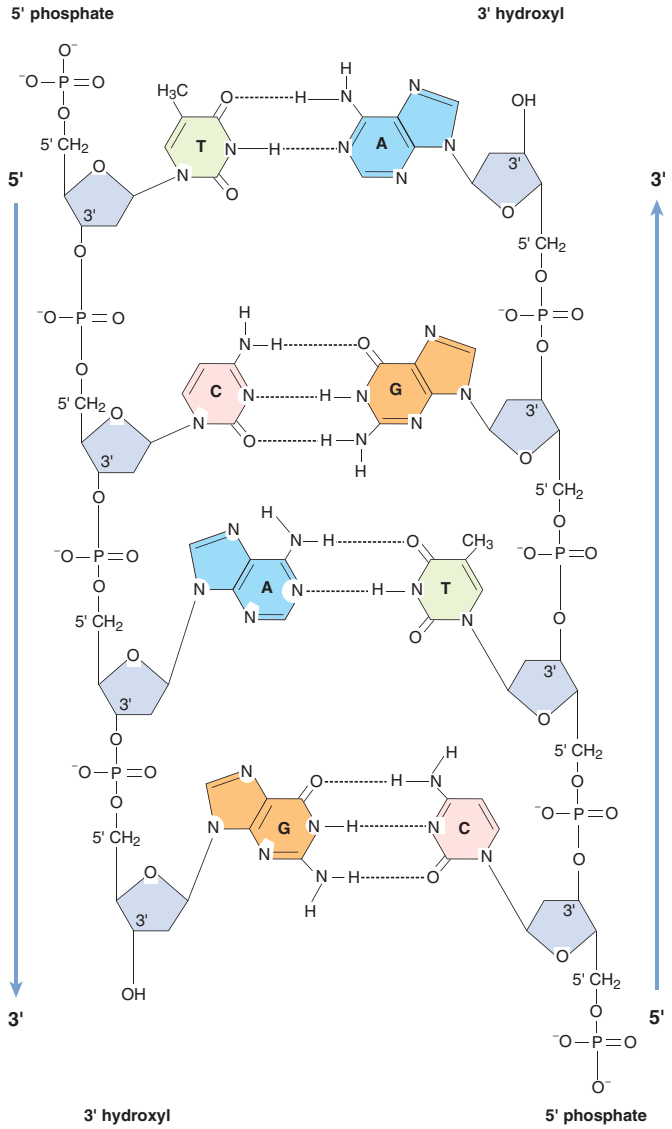

Figure 6.7. Base-Pairing in DNA

The double helix of most DNA is a right-handed helix, forming what is called **B-DNA**, as shown in Figure 6.8. The helix in B-DNA makes a turn every 3.4 nm and contains

about 10 bases within that span. Major and minor grooves can be identified between the interlocking strands and are often the site of protein binding. Another form of DNA is called **Z-DNA** for its zigzag appearance; it is a left-handed helix that has a turn every 4.6 nm and contains 12 bases within each turn. A high GC-content or a high salt concentration may contribute to the formation of this form of DNA. No biological activity has been attributed to Z-DNA partly because it is unstable and difficult to research.

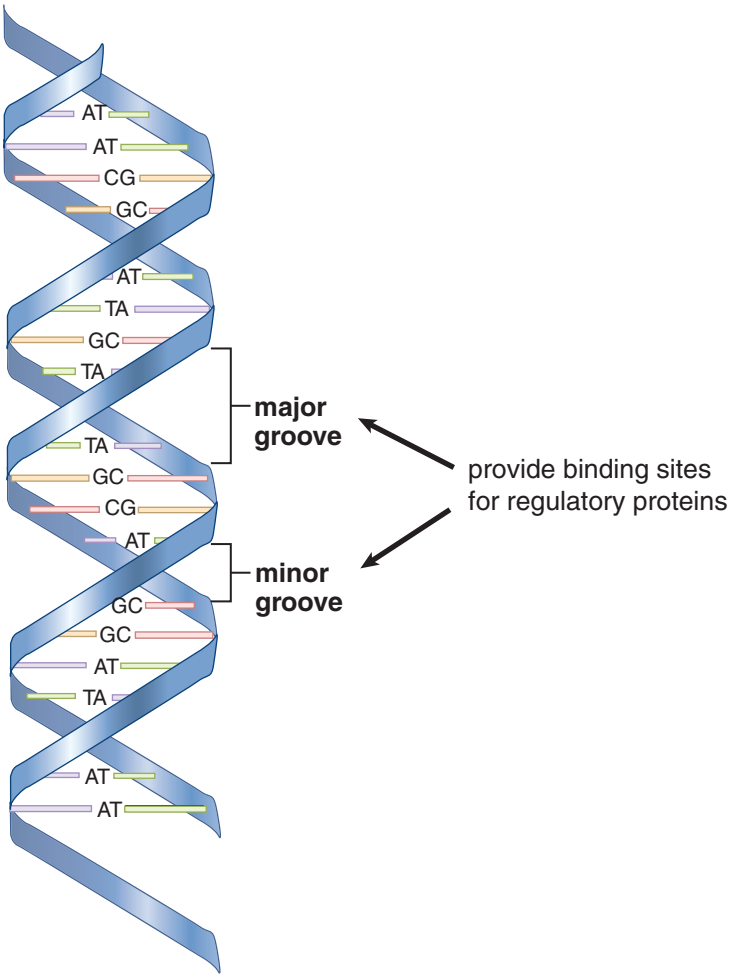

Figure 6.8. The B-DNA Double Helix

DENATURATION AND REANNEALING

During processes such as replication and transcription, it is necessary to gain access to the DNA. The double helical nature of DNA can be **denatured** by conditions that disrupt hydrogen bonding and base-pairing, resulting in the "melting" of the double helix into two single strands that have separated from each other. Notably, none of the covalent links between the nucleotides in the backbone of the DNA break during this process. Heat, alkaline pH, and chemicals like formaldehyde and urea are commonly used to denature DNA.

Denatured, single-stranded DNA can be **reannealed** (brought back together) if the denaturing condition is slowly removed. If a solution of heat-denatured DNA is slowly cooled, for example, then the two complementary strands can become paired again, as shown in Figure 6.9.

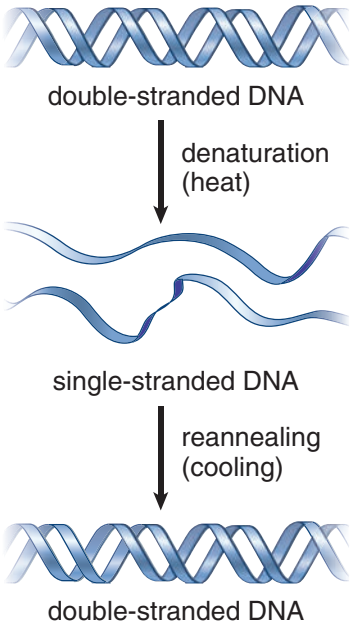

Figure 6.9. Denaturation and Reannealing of DNA

Such annealing of complementary DNA strands is also an important step in many laboratory processes, such as polymerase chain reactions (PCR) and in the detection of specific DNA sequences. In these techniques, a well-characterized **probe DNA** (DNA with known sequence) is added to a mixture of target DNA sequences. When probe DNA binds to target DNA sequences, this may provide evidence of the presence of a gene of interest. This binding process is called hybridization and is described in further detail later in this chapter.

MCAT Concept Check 6.1:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between a nucleoside and a nucleotide?

_____

_____

2. What are the base-pairing rules according to the Watson–Crick model?

_____

_____

3. What are the three major structural differences between DNA and RNA?

   1. _____

   2. _____

   3. _____

4. How does the aromaticity of purines and pyrimidines underscore their genetic function?

_____

_____

5. If a strand of RNA contained 15% cytosine, 15% adenine, 35% guanine, and 35% uracil, would this violate Chargaff's rules? Why or why not?

_____

_____

6.2 Eukaryotic Chromosome Organization ★★★

There are over 6 billion bases of DNA in each human cell. It is important for the cell to organize these bases effectively. These bases must be replicated during the cell cycle and also utilized in gene expression for normal cellular functions. In humans, DNA is divided up among the 46 **chromosomes** found in the nucleus of the cell. The supercoiling of the DNA double helix does provide some compaction, but much more is necessary.

HISTONES

The DNA that makes up a chromosome is wound around a group of small basic proteins called **histones**, forming **chromatin**. There are five histone proteins found in eukaryotic cells. Two copies each of the histone proteins *H2A*, *H2B*, *H3*, and *H4* form a histone core and about 200 base pairs of DNA are wrapped around this protein complex, forming a **nucleosome**, as shown in Figure 6.10. Under an electron microscope, the nucleosomes look like beads on a string. The last histone, *H1*, seals off the DNA as it enters and leaves the nucleosome, adding stability to the structure. Together, the nucleosomes create a much more organized and compacted DNA.

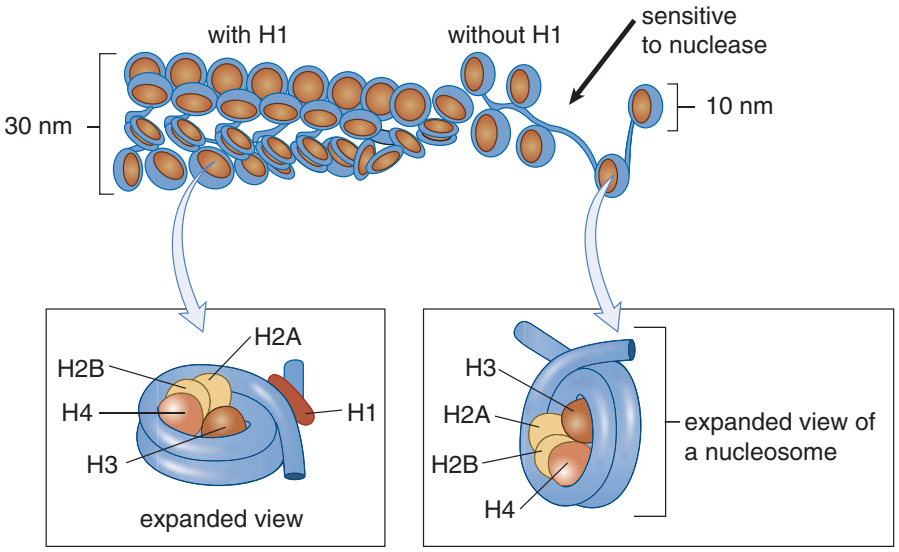

Figure 6.10. Nucleosome Structure
Nucleosomes are composed of DNA wrapped around histone proteins.

Histones are one example of **nucleoproteins** (proteins that associate with DNA). Most other nucleoproteins are acid-soluble and tend to stimulate processes such as transcription.

HETEROCHROMATIN AND EUCHROMATIN

The chromosomes have a diffuse configuration during interphase of the cell cycle. The cell will undergo DNA replication during the S phase of interphase and having the DNA uncondensed and accessible makes the process more efficient. A small percentage of the chromatin remains compacted during interphase and is referred to as **heterochromatin**. Heterochromatin appears dark under light microscopy and is transcriptionally silent. Heterochromatin often consists of DNA with highly repetitive sequences. In contrast, the dispersed chromatin is called **euchromatin**, which appears light under light microscopy. Euchromatin contains genetically active DNA. Both heterochromatin and euchromatin can be seen in the nucleus in Figure 6.11.

Key Concept

Heterochromatin is dark, dense, and silent. Euchromatin is light, uncondensed, and expressed.

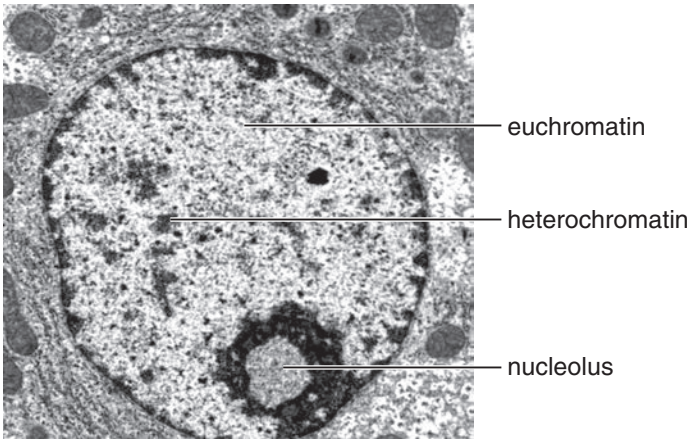

Figure 6.11. Euchromatin and Heterochromatin in an Interphase Nucleus

TELOMERES AND CENTROMERES

As described later in this chapter, DNA replication cannot extend all the way to the end of a chromosome. This will result in losing sequences and information with each round of replication. The solution for our cells is a simple repeating unit (TTAGGG) at the end of the DNA, forming a **telomere**. Some of the sequence is lost in each round of replication and can be replaced by the enzyme ***telomerase***. Telomerase is more highly expressed in rapidly dividing cells. Animal studies indicate that there are a set number of replications possible, and that the progressive shortening of telomeres contributes to aging. Telomeres also serve a second function: their high GC-content creates exceptionally strong strand attractions at the end of chromosomes to prevent unraveling; think of telomeres as "knotting off" the end of the chromosome.

Centromeres, as their name suggests, are a region of DNA found in the center of chromosomes. They are often referred to as sites of constriction because they form noticeable indentations. This part of the chromosome is composed of heterochromatin, which is in turn composed of tandem repeat sequences that also contain high GC-content. During cell division, the two sister chromatids can therefore remain connected at the centromere until microtubules separate the chromatids during anaphase.

MCAT Concept Check 6.2:

Before you move on, assess your understanding of the material with these questions.

1. What are the five histone proteins in eukaryotic cells? Which one is not part of the histone core around which DNA wraps to form chromatin?

_____

_____

2. Compare and contrast heterochromatin and euchromatin based on the following characteristics:

Characteristic	Heterochromatin	Euchromatin
Density of chromatin packing		
Appearance under light microscopy		
Transcriptional activity		

3. What property of telomeres and centromeres allows them to stay tightly raveled, even when the rest of DNA is uncondensed?

_____

6.3 DNA Replication ★★★

The DNA is an organism's "blueprint" that provides not only the ability to sustain activities of life but also insight into our evolutionary past. The process of DNA replication is highly regulated to ensure as close to 100 percent perfection when making a copy of our genome as possible. DNA replication is necessary for the reproduction of a species and for any dividing cell.

STRAND SEPARATION AND ORIGINS OF REPLICATION

The human genome has about 3 billion base pairs packed into multiple chromosomes. The **replisome** or **replication complex** is a set of specialized proteins that assist the DNA polymerases. To begin the process of replication, DNA unwinds at points called **origins of replication**. The generation of new DNA proceeds in both directions, creating **replication forks** on both sides of the origin, as shown in Figure 6.12.

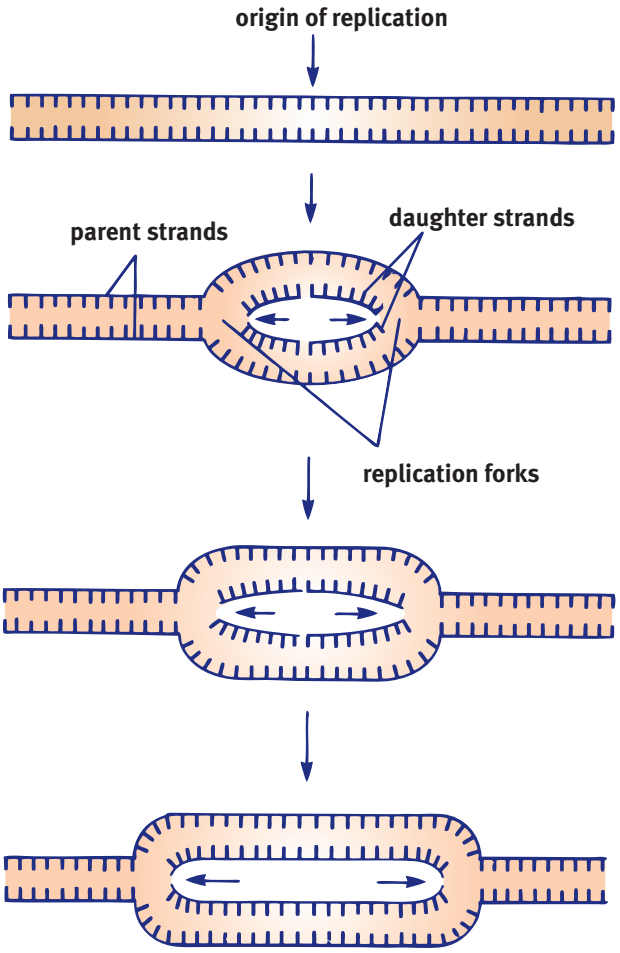

Figure 6.12. Origins of Replication
Replication forks form on both sides of the origin, increasing the efficiency of replication.

The bacterial chromosome is a closed, double-stranded circular DNA molecule with a single origin of replication. Thus, there are two replication forks that move away from each other in opposite directions around the circle. The two replication forks eventually meet, resulting in the production of two identical circular molecules of DNA.

Eukaryotic replication must copy many more bases compared to prokaryotes and is a slower process. In order to duplicate all of the chromosomes efficiently, each eukaryotic chromosome contains one linear molecule of double-stranded DNA having multiple origins of replication. As the replication forks move toward each other and **sister chromatids** are created, the chromatids will remain connected at the **centromere**. The differences between prokaryotic and eukaryotic replication patterns are shown in Figure 6.13.

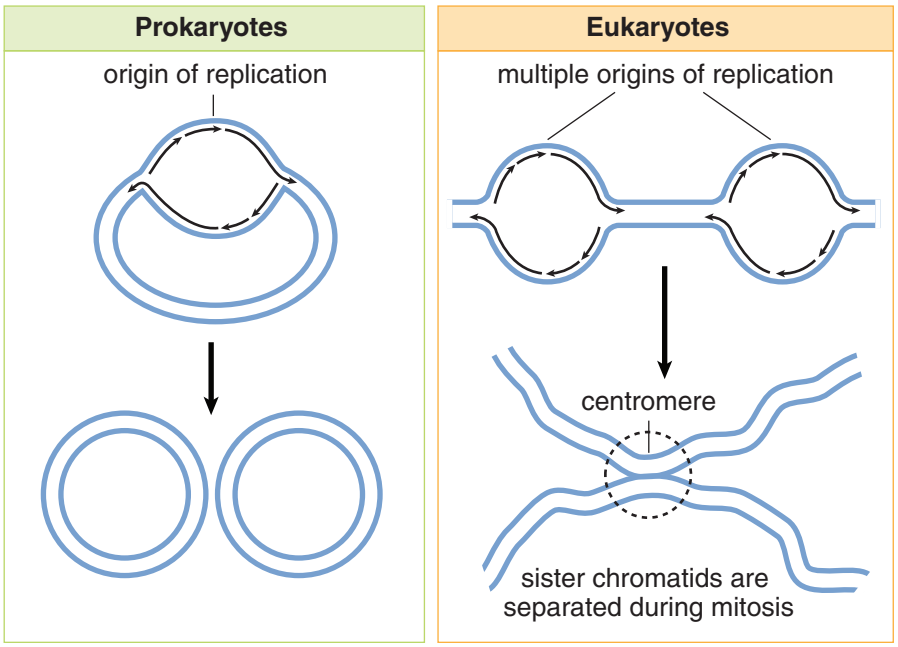

Figure 6.13. DNA Replication in Prokaryotes and Eukaryotes

Helicase is the enzyme responsible for unwinding the DNA, generating two single-stranded template strands ahead of the polymerase. Once opened, the unpaired strands of DNA are very sticky, in a molecular sense. The free purines and pyrimidines seek out other molecules with which to hydrogen bond. Proteins are therefore required to hold the strands apart: **single-stranded DNA-binding proteins** will bind to the unraveled strand, preventing both the reassociation of the DNA strands and the degradation of DNA by ***nucleases***. As the helicase unwinds the DNA, it will cause positive supercoiling that strains the DNA helix. **Supercoiling** is a wrapping of DNA on itself as its helical structure is pushed ever further toward the telomeres during replication; picture an old-fashioned telephone cord that's become tangled on itself. To alleviate this torsional stress and reduce the risk of strand breakage, ***DNA topoisomerases*** introduces negative supercoils. They do so by working ahead of helicase, nicking one or both strands, allowing relaxation of the torsional pressure, and then resealing the cut strands.

During replication, these **parental strands** will serve as templates for the generation of new **daughter strands**. The replication process is termed **semiconservative** because one parental strand is retained in each of the two resulting identical double-stranded DNA molecules, as shown in Figure 6.14.

Real World

Any antibiotic ending with *–floxacin* (ciprofloxacin, moxifloxacin, and so on) is called a *fluoroquinolone* and targets the prokaryotic topoisomerase *DNA gyrase*. This stops bacterial replication and slows the infection. Fluoroquinolones are routinely used for pneumonia and certain infections of the genitourinary system.

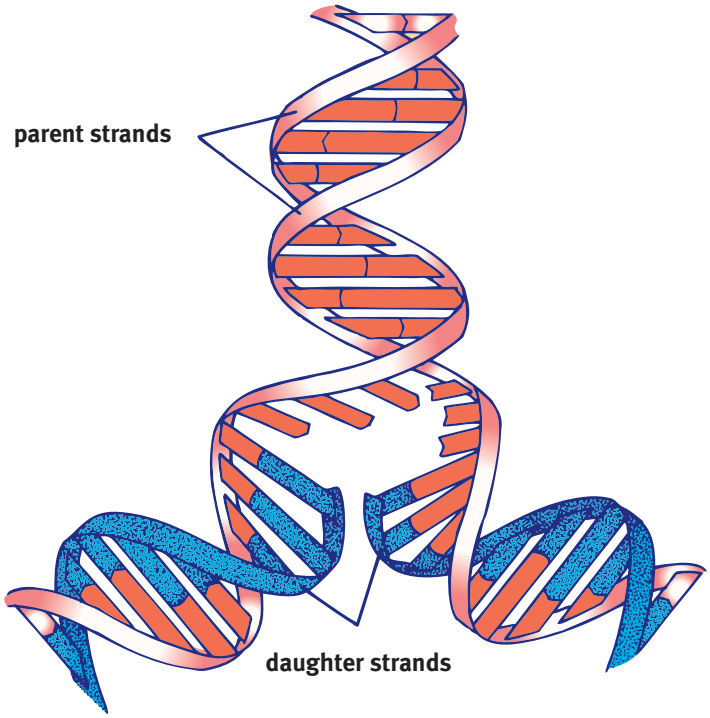

Figure 6.14. Semiconservative Replication
A new double helix is made of one old parent strand and one new daughter strand.

SYNTHESIS OF DAUGHTER STRANDS

DNA polymerases are responsible for reading the DNA template, or parental strand, and synthesizing the new daughter strand. The DNA polymerase can read the template strand in a 3′ to 5′ direction while synthesizing the complementary strand in the 5′ to 3′ direction. This will result in a new double helix of DNA that has the required antiparallel orientation. Due to this directionality of the DNA polymerase, certain constraints arise. Remember that the two separated parental strands of the helix are also antiparallel to each other. Thus, at each replication fork, one strand is oriented in the correct direction for DNA polymerase; the other strand is antiparallel.

The **leading strand** in each replication fork is the strand that is copied in a continuous fashion, in the same direction as the advancing replication fork. This parental strand will be read 3′ to 5′ and its complement will be synthesized in a 5′ to 3′ manner, as discussed above.

The **lagging strand** is the strand that is copied in a direction opposite the direction of the replication fork. On this side of the replication fork, the parental strand has 5′ to 3′ polarity. DNA polymerase cannot simply read and synthesize on this strand. How does it solve this problem? Because DNA polymerase can only synthesize in the

Key Concept

With the exception of DNA polymerase's *reading* direction (and a few untested endonucleases), everything in molecular biology is 5′ to 3′. DNA polymerase reads 3′ to 5′, but the following processes occur 5′ to 3′:

- DNA synthesis
- DNA repair
- RNA transcription
- RNA translation (reading of codons)

5′ to 3′ direction from a 3′ to 5′ template, small strands called **Okazaki fragments** are produced. As the replication fork continues to move forward, it clears additional space that DNA polymerase must fill in. Each time DNA polymerase completes an Okazaki fragment, it turns around to find another gap that needs to be filled in.

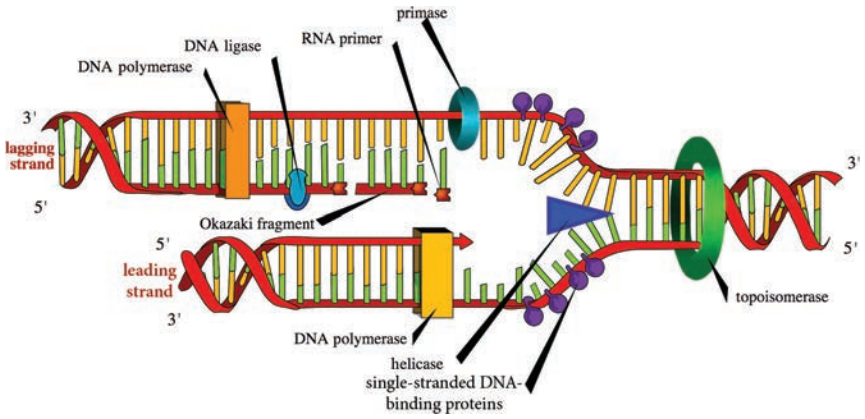

Figure 6.15. Enzymes of DNA Replication
This process involves the action of DNA helicase, gyrase, polymerase, and ligase to create two identical molecules of DNA.

The process of DNA replication is shown in Figure 6.15. The first step in the replication of DNA is actually to lay down an RNA primer. DNA cannot be synthesized *de novo*; that is, it needs another molecule to "hook on" to. RNA, on the other hand, can be directly paired with the parent strand. Thus, ***primase*** synthesizes a short primer (roughly 10 nucleotides) in the 5′ to 3′ direction to start replication on each strand. These short RNA sequences are constantly being added to the lagging strand because each Okazaki fragment must start with a new primer. In contrast, the leading strand requires only one, in theory (in reality, there are usually a few primers on the leading strand). ***DNA polymerase III*** (prokaryotes) or ***DNA polymerases α, δ,*** and ***ε*** (eukaryotes) will then begin synthesizing the daughter strands of DNA in the 5′ to 3′ manner. The incoming nucleotides are 5′ deoxyribonucleotide triphosphates: dATP, dCTP, dGTP, and dTTP. As the new phosphodiester bond is made, a free *pyrophosphate* (PP_i) is released.

The RNA must eventually be removed to maintain sanctity of the genome. This is accomplished by the enzyme ***DNA polymerase I*** (prokaryotes) or ***RNase H*** (eukaryotes). Then, ***DNA polymerase I*** (prokaryotes) or ***DNA polymerase δ*** (eukaryotes) adds DNA nucleotides where the RNA primer had been. ***DNA ligase*** seals the ends of the DNA molecules together, creating one continuous strand of DNA.

While prokaryotic DNA synthesis has been worked out in great detail, and eukaryotic synthesis is considered to be very similar, there are a few differences in the enzymes involved. There are five "classic" DNA polymerases in eukaryotic cells, which are

designated with the Greek letters α, β, γ, δ, and ε. Further research has revealed more polymerases named ζ through μ, but these are outside the scope of the MCAT. Table 6.2 highlights differences in the names of the enzymes associated with DNA replication in prokaryotic *vs*. eukaryotic cells; special attention should be paid to the eukaryotic DNA polymerases:

- DNA polymerases α, δ, and ε work together to synthesize both the leading and lagging strands; DNA polymerase δ also fills in the gaps left behind when RNA primers are removed
- DNA polymerase γ replicates mitochondrial DNA
- DNA polymerases β and ε are important to the process of DNA repair
- DNA polymerases δ and ε are assisted by the PCNA protein, which assembles into a trimer to form the **sliding clamp**. The clamp helps to strengthen the interaction between these DNA polymerases and the template strand

Step in Replication	Prokaryotic Cells	Eukaryotic Cells (Nuclei)
Origin of replication	One per chromosome	Multiple per chromosome
Unwinding of DNA double helix	Helicase	Helicase
Stabilization of unwound template strands	Single-stranded DNA-binding protein	Single-stranded DNA-binding protein
Synthesis of RNA primers	Primase	Primase
Synthesis of DNA	DNA polymerase III	DNA polymerases α, δ, and ε
Removal of RNA primers	DNA polymerase I ($5' \rightarrow 3'$ exonuclease)	RNase H ($5' \rightarrow 3'$ exonuclease)
Replacement of RNA with DNA	DNA polymerase I	DNA polymerase δ
Joining of Okazaki fragments	DNA ligase	DNA ligase
Removal of positive supercoils ahead of advancing replication forks	DNA topoisomerases (DNA gyrase)	DNA topoisomerases
Synthesis of telomeres	Not applicable	Telomerase

Table 6.2. Steps and Proteins Involved in DNA Replication

REPLICATING THE ENDS OF CHROMOSOMES

While DNA polymerase does a excellent job of synthesizing DNA, it unfortunately cannot complete synthesis of the $5'$ end of the strand. Thus, each time DNA synthesis is carried out, the chromosome becomes a little shorter. To lengthen the

time that cells can replicate and synthesize DNA before necessary genes are damaged, chromosomes contain **telomeres**. As described earlier, telomeres are located at the very tips of the chromosome and consist of repetitive sequences with a high GC-content. This repetition means that telomeres can be slightly degraded between replication cycles without loss of function.

MCAT Concept Check 6.3:

Before you move on, assess your understanding of the material with these questions.

1. For each of the enzymes listed below, list the function of the enzyme and if they are found in prokaryotes, eukaryotes, or both.

Enzyme	Prokaryotes/ Eukaryotes/Both	Function
Helicase		
Single-stranded DNA-binding protein		
Primase		
DNA polymerase III		
DNA polymerase α		
DNA polymerase I		
RNase H		
DNA ligase		
DNA topoisomerases		

2. Between the leading strand and lagging strand, which is more prone to mutations? Why?

_____

_____

3. What is the function of a telomere?

_____

_____

6.4 DNA Repair ★★

The structure of DNA can be damaged in a number of ways such as exposure to chemicals or radiation. DNA is very susceptible to damage and if the damage is not

corrected, it will subsequently be copied and passed on to daughter cells. Damage can include breaking of the DNA backbone, structural or spontaneous alterations of bases, or incorporation of the incorrect base during replication. Any defect in the genetic code can cause an increased risk of cancer, so the cell has multiple processes in place to catch and correct genetic errors. This helps maintain the integrity and stability of the genome from cell to cell, and from generation to generation.

ONCOGENES AND TUMOR SUPPRESSOR GENES

Certain genes, when mutated, can lead to cancer. **Cancer** cells proliferate excessively because they are able to divide without stimulation from other cells and are no longer subject to the normal controls on cell proliferation. By definition, cancer cells are able to migrate by local invasion or **metastasis**, a migration to distant tissues by the bloodstream or lymphatic system. Over time, cancer cells tend to accumulate mutations.

Mutated genes that cause cancer are termed **oncogenes**. Oncogenes primarily encode cell cycle-related proteins. Before these genes are mutated, they are often referred to as **proto-oncogenes**. The first gene in this category to be discovered was *src* (named after *sarcoma*, a category of connective tissue cancers). The abnormal alleles encode proteins that are more active than normal proteins, promoting rapid cell cycle advancement. Typically, a mutation in only one copy is sufficient to promote tumor growth and is therefore considered dominant.

Tumor suppressor genes, like *p53* or *Rb* (*retinoblastoma*), encode proteins that inhibit the cell cycle or participate in DNA repair processes. They normally function to stop tumor progression, and are sometimes called **antioncogenes**. Mutations of these genes result in the loss of tumor suppression activity, and therefore promote cancer. Inactivation of both alleles is necessary for the loss of function because, in most cases, even one copy of the normal protein can function to inhibit tumor formation. In this example, multiple mutations or "hits" are required.

Key Concept

While the outcome of oncogenes and mutated tumor suppressor genes is the same (cancer), the actual cause is different. Oncogenes promote the cell cycle while mutated tumor suppressors can no longer slow the cell cycle. Oncogenes are like stepping on the gas pedal; mutated tumor suppressors are like cutting the brakes.

PROOFREADING AND MISMATCH REPAIR

DNA polymerase moves along a single strand of DNA, building the complementary strand as it goes. While DNA polymerase is almost 100 percent accurate, it does occasionally make errors.

Proofreading

During synthesis, the two double-stranded DNA molecules will pass through a part of the DNA polymerase enzyme for **proofreading**. When the complementary strands have incorrectly paired bases, the hydrogen bonds between the strands can be unstable, and this lack of stability is detected as the

DNA passes through this part of the polymerase. The incorrect base is excised and can be replaced with the correct one, as shown in Figure 6.16. If both the parent and daughter strands are simply DNA, how does the enzyme discriminate which is the template strand, and which is the incorrectly paired daughter strand? It looks at the level of methylation: the template strand has existed in the cell for a longer period of time, and therefore is more heavily methylated. Methylation also plays a role in the transcriptional activity of DNA, as described in Chapter 7 of *MCAT Biochemistry Review*. This system is very efficient, correcting most of the errors put into the sequence during replication. DNA ligase, which closes the gaps between Okazaki fragments, lacks proofreading ability. Thus, the likelihood of mutations in the lagging strand is considerably higher than the leading strand.

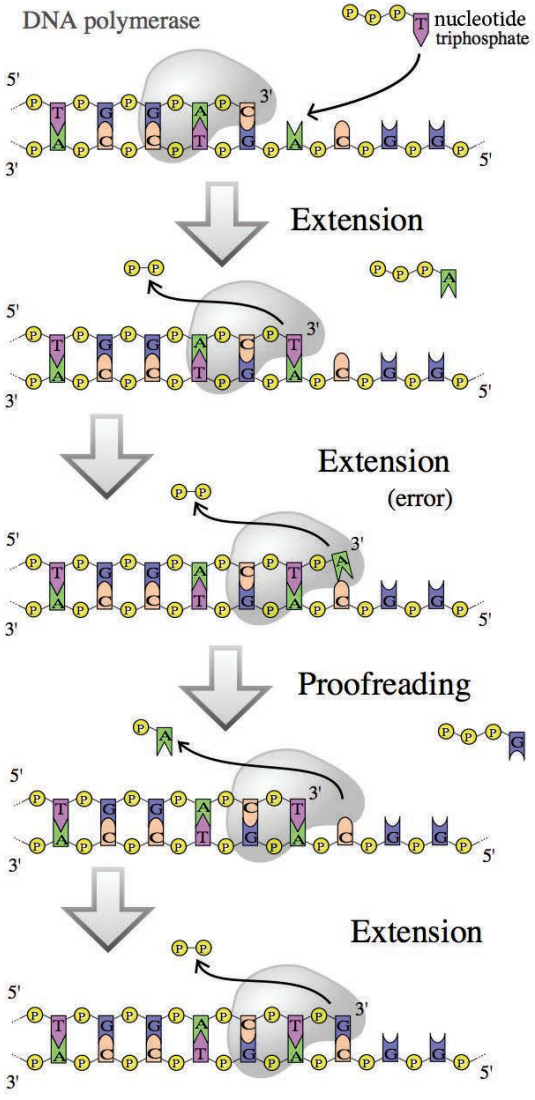

Figure 6.16. Proofreading by DNA Polymerase

Mismatch Repair

Cells also have machinery in the G_2 phase of the cell cycle for **mismatch repair**; these enzymes are encoded by genes *MSH2* and *MLH1*, which detect and remove errors introduced in replication that were missed during the S phase of the cell cycle. These enzymes are homologues of *MutS* and *MutL* in prokaryotes, which serve a similar function.

NUCLEOTIDE AND BASE EXCISION REPAIR

Most of the repair mechanisms involve proteins that recognize damage or a lesion, remove the damage, and then use the complementary strand as a template to fill in the gap. Our cell machinery recognizes two specific types of DNA damage in the G_1 and G_2 cell cycle phases and fixes them through nucleotide excision repair or base excision repair.

Nucleotide Excision Repair

Ultraviolet light induces the formation of dimers between adjacent thymine residues in DNA. The formation of thymine dimers interferes with DNA replication and normal gene expression, and distorts the shape of the double helix. Thymine dimers are eliminated from DNA by a **nucleotide excision repair** (**NER**) mechanism, which is a cut-and-patch process, as shown in Figure 6.17. First, specific proteins scan the DNA molecule and recognize the lesion because of a bulge in the strand. An ***excision endonuclease*** then makes nicks in the phosphodiester backbone of the damaged strand on both sides of the thymine dimer and removes the defective oligonucleotide. DNA polymerase can then fill in the gap by synthesizing DNA in the 5′ to 3′ direction, using the undamaged strand as a template. Finally, the nick in the strand is sealed by DNA ligase.

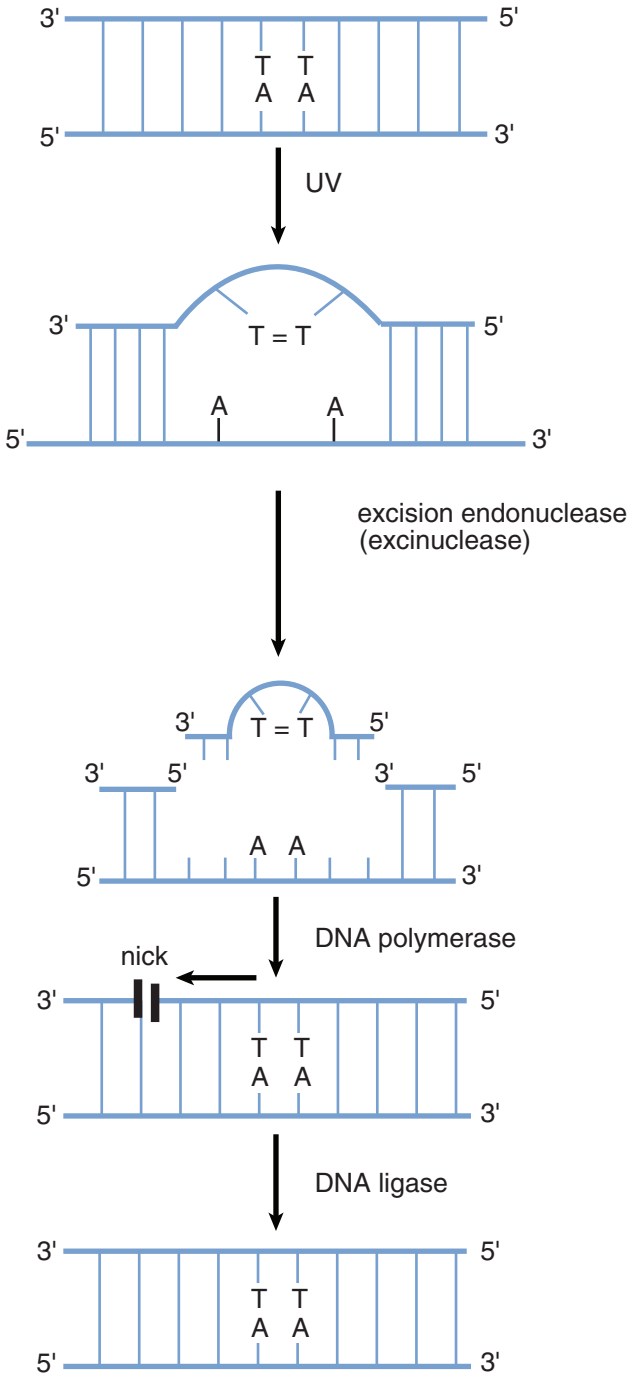

Figure 6.17. Thymine Dimer Formation and Nucleotide Excision Repair

Base Excision Repair

Alterations to bases can occur with other cellular insults. For example, thermal energy can be absorbed by DNA and may lead to cytosine deamination. This is the

loss of an amino group from cytosine and results in the conversion of cytosine to uracil. Uracil should not be found in a DNA molecule and is thus easily detected as an error; however, detection systems exist for small, non-helix-distorting mutations in other bases as well. These are repaired by **base excision repair**. First, the affected base is recognized and removed by a glycosylase enzyme, leaving behind an **apurinic/apyrimidinic** (**AP**) **site**, also called an **abasic site**. The AP site is recognized by an ***AP endonuclease*** that removes the damaged sequence from the DNA. DNA polymerase and DNA ligase can then fill in the gap and seal the strand, as described above.

MCAT Concept Check 6.4:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between an oncogene and a tumor suppressor gene?

_____

_____

2. How does DNA polymerase recognize which strand is the template strand once the daughter strand is synthesized?

_____

_____

3. For each of the repair mechanisms below, in which phase of the cell cycle does the repair mechanism function? What are the key enzymes or genes specifically associated with each mechanism?

Repair mechanism	Phase of Cell Cycle	Key Enzymes/Genes
DNA polymerase (proofreading)		
Mismatch repair		
Nucleotide excision repair		
Base excision repair		

4. What is the key structural difference in the types of lesions corrected by nucleotide excision repair *vs*. those corrected by base excision repair?

_____

_____

6.5 Recombinant DNA and Biotechnology

Now that we have reviewed the basics of DNA structure and function, we can discuss how this knowledge has been harnessed for a variety of research and treatment innovations. **Recombinant DNA** technology allows a DNA fragment from any source to be multiplied by either gene cloning or polymerase chain reaction (PCR). This provides a means of analyzing and altering genes and proteins. It also provides the reagents necessary for genetic testing, such as carrier detection (detecting heterozygote status for a particular disease) and prenatal diagnosis of genetic diseases; it is also useful for gene therapy. Additionally, this technology can provide a source of a specific protein, such as recombinant human insulin, in almost unlimited quantities. The process of creating recombinant DNA (by gene cloning) and its benefits are shown in Figure 6.18.

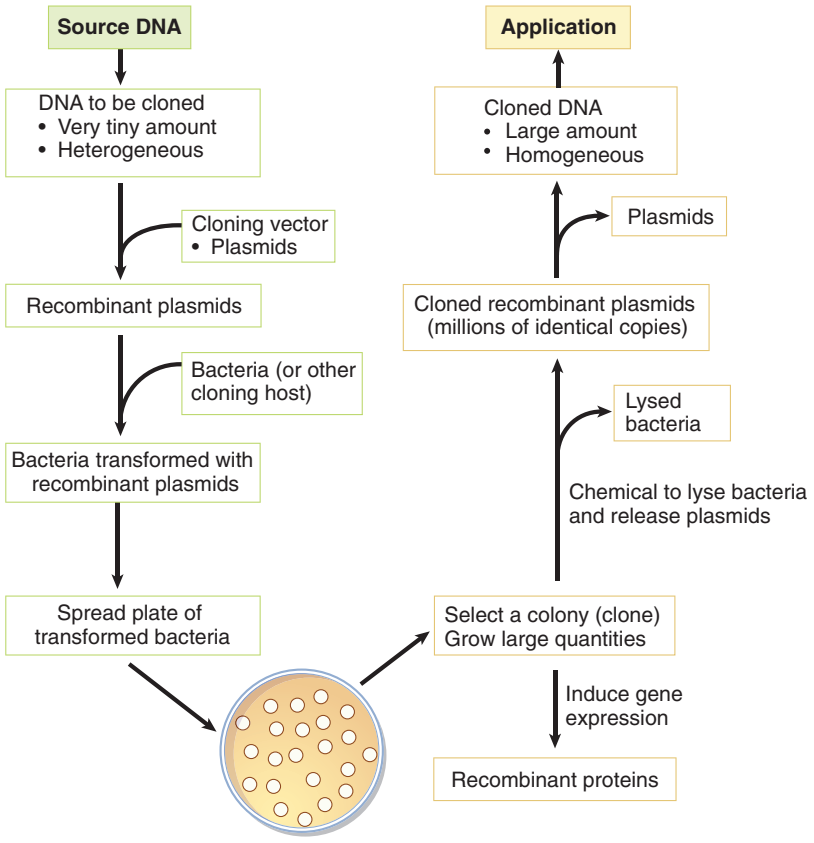

Figure 6.18. Cloning Recombinant DNA
Cloning allows for production of recombinant proteins, or identification and characterization of DNA by increasing its volume and purity.

DNA CLONING AND RESTRICTION ENZYMES

DNA cloning is a technique that can produce large amounts of a desired sequence. Often, the DNA to be cloned is present in a small quantity and is part of a heterogeneous mixture containing other DNA sequences. The goal is to produce a large quantity of homogeneous DNA for other applications. Cloning requires that the investigator ligate the DNA of interest into a piece of nucleic acid referred to as a **vector**, forming a **recombinant vector**. Vectors are usually bacterial or viral plasmids that can be transferred to a host bacterium after insertion of the DNA of interest. The bacteria are then grown in colonies, and a colony containing the recombinant vector is isolated. This can be accomplished by ensuring that the recombinant vector also includes a gene for antibiotic resistance; antibiotics can then kill off all of the colonies that do not contain the recombinant vector. The resulting colony can then be grown in large quantities. Depending on the investigator's goal, the bacteria can then be made to express the gene of interest (generating large quantities of recombinant protein), or can be lysed to reisolate the replicated recombinant vectors (which can be processed by restriction enzymes to release the cloned DNA from the vector).

Restriction enzymes (**restriction endonucleases**) are enzymes that recognize specific double-stranded DNA sequences. These sequences are palindromic, meaning that the 5′ to 3′ sequence of one strand is identical to the 5′ to 3′ sequence of the other strand (in antiparallel orientation). Restriction enzymes are isolated from bacteria, which are their natural source. In bacteria, they act as part of a restriction and modification system that protects the bacteria from infection by DNA viruses. Once a specific sequence has been identified, the restriction enzyme can cut through the backbones of the double helix. Thousands of restriction enzymes have been studied and many are commercially available to laboratories, allowing us to process DNA in very specific ways. Some restriction enzymes produce offset cuts, yielding sticky ends on the fragments, as shown in Figure 6.19. Sticky ends are advantageous in facilitating the recombination of a restriction fragment with the vector DNA. The vector of choice can also be cut with the same restriction enzyme, allowing for the fragments to be inserted directly into the vector.

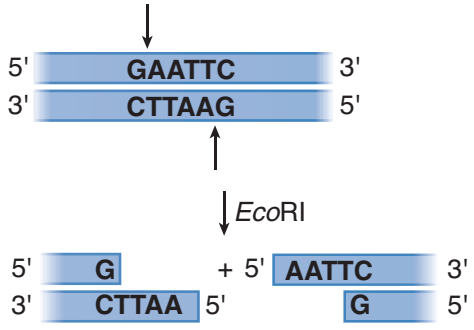

Figure 6.19. A Restriction Enzyme (*Eco*RI) Creating Sticky Ends
Restriction enzymes cut at palindromic sequences, such as GAATTC.

DNA vectors contain at least one sequence, if not many, recognized by restriction enzymes. A vector also requires an origin of replication and at least one gene for antibiotic resistance to allow for selection of colonies with recombinant plasmids, as described above. The formation of a recombinant plasmid is shown in Figure 6.20.

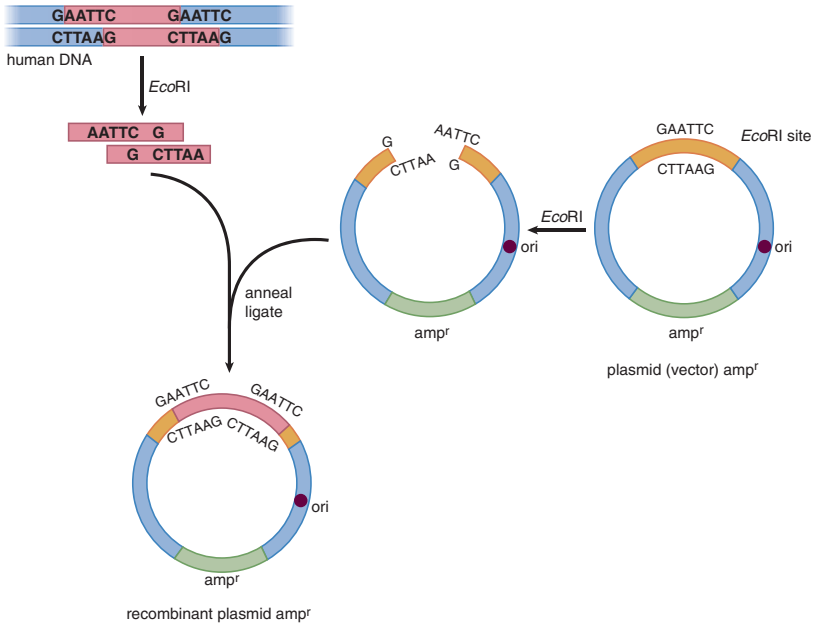

Figure 6.20. Formation of a Recombinant Plasmid Vector
ori: origin of replication; amp^r: gene for resistance to ampicillin (an antibiotic).

DNA LIBRARIES AND cDNA

DNA cloning can be used to produce DNA libraries. **DNA libraries** are large collections of known DNA sequences; in sum, these sequences could equate to the genome of an organism. To make a DNA library, DNA fragments, often digested randomly, are cloned into vectors and can be utilized for further study. Libraries can consist of either genomic DNA or cDNA. **Genomic libraries** contain large fragments of DNA, and include both coding (exon) and noncoding (intron) regions of the genome. **cDNA** (**complementary DNA**) libraries are constructed by reverse-transcribing processed mRNA, as shown in Figure 6.21. As such, cDNA lacks noncoding regions, such as introns, and only includes the genes that are expressed in the tissue from which the mRNA was isolated. For that reason, these libraries are sometimes called **expression libraries**. While genomic libraries contain the entire genome of an organism, genes may by chance be split into multiple vectors. Therefore, only cDNA libraries can be used to reliably sequence specific genes and identify disease-causing mutations, produce recombinant proteins (such as insulin, clotting factors, or vaccines), or produce transgenic animals. Several of these applications are discussed in more detail in subsequent sections of this chapter. Table 6.3 contrasts some of the characteristics of genomic and cDNA libraries.

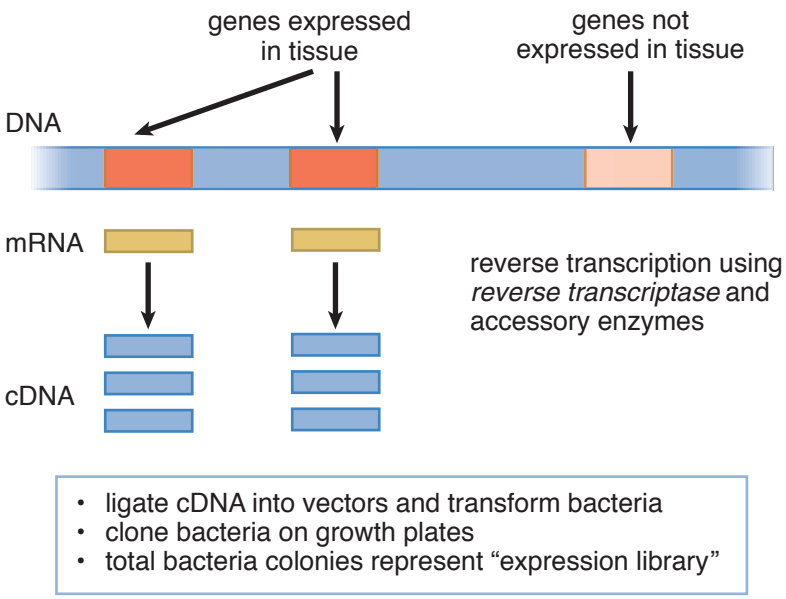

Figure 6.21. Cloning Expressed Genes by Producing cDNA

	Genomic Libraries	cDNA (Expression) Library
Source of DNA	Chromosomal DNA	mRNA (cDNA)
Enzymes to make library	Restriction endonuclease DNA ligase	Reverse transcriptase DNA ligase
Contains nonexpressed sequences of chromosomes	Yes	No
Cloned genes are complete sequences	Not necessarily	Yes
Cloned genes contain introns	Yes	No
Promoter and enhancer sequences present	Yes, but not necessarily in same clone	No
Gene can be expressed in cloning host (recombinant proteins)	No	Yes
Can be used for gene therapy or constructing transgenic animals	No	Yes

Table 6.3. Comparison of Genomic and cDNA (Expression) Libraries

HYBRIDIZATION

Another tool often used by researchers is called hybridization. **Hybridization** is the joining of complementary base pair sequences. This can be DNA–DNA recognition or DNA–RNA recognition. This technique uses two single-stranded sequences and is a vital part of polymerase chain reaction and Southern blotting.

Polymerase Chain Reaction

Polymerase chain reaction (**PCR**) is an automated process that can produce millions of copies of a DNA sequence without amplifying the DNA in bacteria. PCR is used to identify criminal suspects, familial relationships, and disease-causing bacteria and viruses. Knowing the sequences that flank the desired region of DNA allows for the amplification of the sequence in between. A PCR reaction requires **primers** that are complementary to the DNA that flanks the region of interest, nucleotides (dATP, dTTP, dCTP, and dGTP), and DNA polymerase. The reaction also needs heat to cause the DNA double helix to melt apart (denature). Unfortunately, the DNA polymerase found in the human body does not work at high temperatures. Thus, the DNA polymerase from *Thermus aquaticus*, a bacteria that thrives in the hot springs of Yellowstone National Park at 70°C, is used instead. During PCR, the DNA of interest is denatured, replicated, and then cooled to allow reannealing of the daughter strands with the parent strands. This process is repeated several times, doubling the amount of DNA with each cycle, until enough copies of the DNA sequence are available for further testing.

Bridge

PCR provides a great example of the temperature dependence of enzymes. While human DNA polymerase denatures at the high temperatures required in PCR, the DNA polymerase from *T. aquaticus* functions optimally at these temperatures. Refer to Chapter 2 of *MCAT Biochemistry Review* for more on the link between temperature and enzyme activity.

Gel Electrophoresis and Southern Blotting

Gel electrophoresis is a technique used to separate macromolecules, such as DNA and proteins, by size and charge. Electrophoresis of proteins was discussed in detail in Chapter 3 of *MCAT Biochemistry Review*, but DNA can be separated in a similar way. All molecules of DNA are negatively charged because of the phosphate groups in the backbone of the molecule, so all DNA strands will migrate toward the anode of an electrochemical cell. The preferred gel for DNA electrophoresis is **agarose gel**, and—just like proteins in polyacrylamide gel—the longer the DNA strand, the slower it will migrate in the gel.

Gel electrophoresis is often used while performing a Southern blot. A **Southern blot** is used to detect the presence and quantity of various DNA strands in a sample. DNA is cut by restriction enzymes and then separated by gel electrophoresis. The DNA fragments are then carefully transferred to a membrane, retaining their separation. The membrane is then probed with many copies of a single-stranded DNA sequence. The probe will bind to its complementary sequence and form double-stranded DNA. Probes are labeled with radioisotopes or indicator proteins, both of which can be used to indicate the presence of a desired sequence.

DNA SEQUENCING

DNA sequencing has revolutionized the world that we live in. The applications of this technique are far-reaching, from the medical field to criminal courts. A basic sequencing reaction contains the main players from replication, including template DNA, primers, an appropriate DNA polymerase, and all four deoxyribonucleotide triphosphates. In addition, a modified base called a ***dideoxyribonucleotide*** is

added in lower concentrations. Dideoxyribonucleotides (ddATP, ddCTP, ddGTP, and ddTTP) contain a hydrogen at C-3′, rather than a hydroxyl group; thus, once one of these modified bases has been incorporated, the polymerase can no longer add to the chain. Eventually the sample will contain many fragments (as many as the number of nucleotides in the desired sequence), each one of which terminates with one of the modified bases. These fragments are then separated by size using gel electrophoresis. The last base for each fragment can be read, and because gel electrophoresis separates the strands by size, the bases can easily be read in order.

Real World

The Human Genome Project, initiated in 1991, involved the identification of all 3 billion base pairs of the human DNA sequence. The first draft of this project was completed in 2000. This project demonstrated that although humans appear to be quite different from each other, the sequence of our DNA is, in reality, highly conserved. On average, two unrelated individuals still share over 99.9% of their DNA sequences.

APPLICATIONS OF DNA TECHNOLOGY

In addition to its utility as a research tool, DNA biotechnology has led to a number of therapeutic breakthroughs, ranging from gene therapy—described in this section—to development of personalized chemotherapeutic regimens in cancer by genotyping the tumor cells. DNA technology is also used in industry, including the development of genetically modified foods that are enriched with specific nutrients and testing of the environment for risk assessment and cleanup procedures. As mentioned previously, DNA technology also plays a key role in forensic pathology and crime scene investigation. This is likely only the beginning, as biotechnology continues to be an active area of research.

Gene Therapy

Gene therapy now offers potential cures for individuals with inherited diseases. Gene therapy is intended for diseases in which a given gene is mutated or inactive, giving rise to pathology. By transferring a normal copy of the gene into the affected tissues, the pathology should be fixed, essentially curing the individual. For instance, about half of children with *severe combined immunodeficiency* (SCID) have a mutation in the gene encoding the γ chain common to several of the interleukin receptors. By placing a working copy of the gene for the γ chain into a virus, one can transmit the functional gene into human cells. The first successful case of gene therapy was for SCID (caused by a different mutation) in 1990.

For gene replacement therapy to be a realistic possibility, efficient gene delivery vectors must be used to transfer the cloned gene into the target cells' DNA. Because viruses naturally infect cells to insert their own genetic material, most gene delivery vectors in use are modified viruses. A portion of the viral genome is replaced with the cloned gene such that the virus can infect but not complete its replication cycle, as shown in Figure 6.22. Randomly integrated DNA poses a risk of integrating near and activating a host oncogene. Among the children treated for SCID, a small number have developed leukemias (cancers of white blood cells).

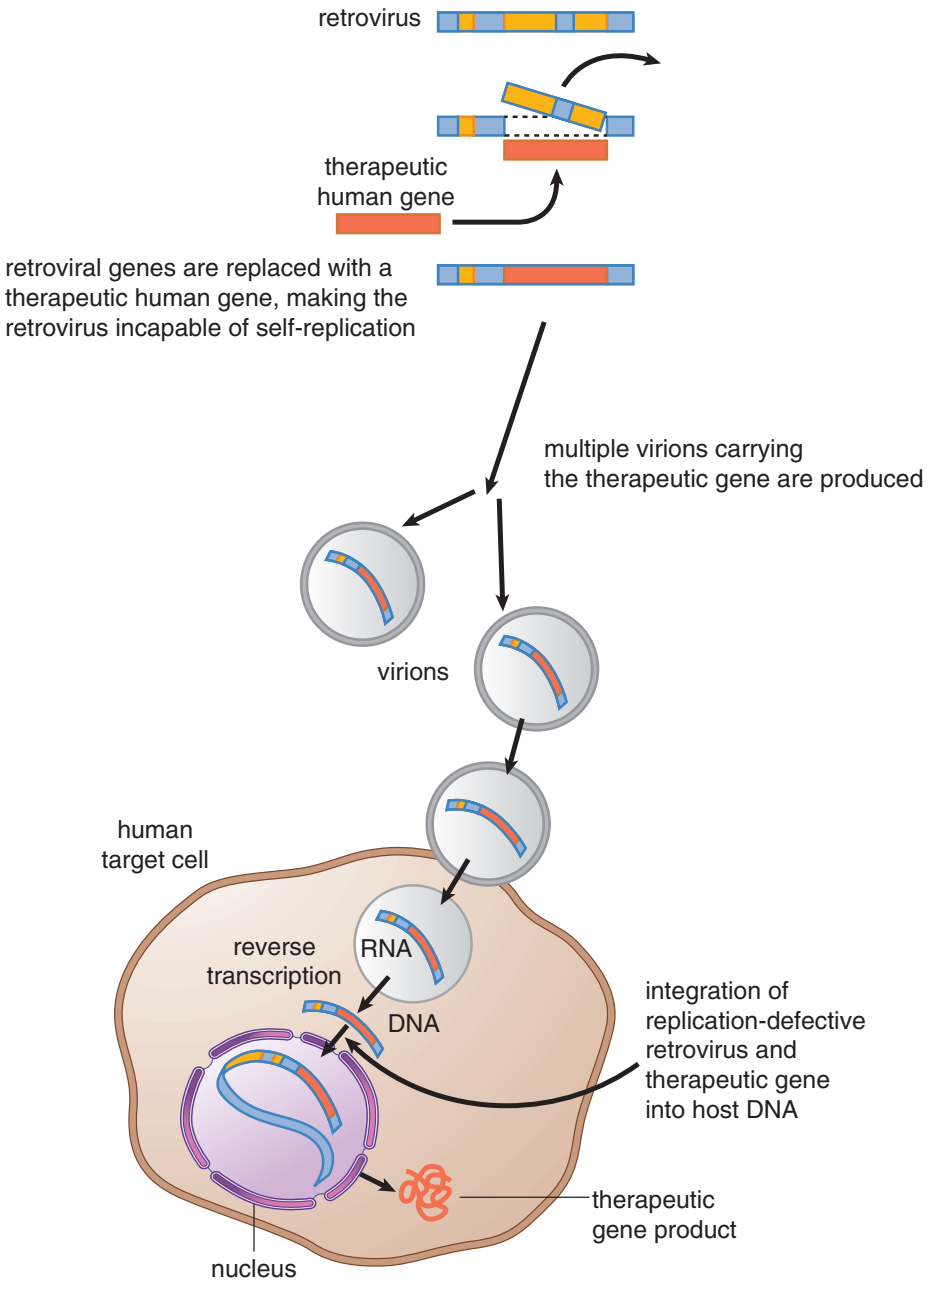

Figure 6.22. Retroviral Gene Therapy
The example given here uses a retrovirus, but other viruses may also be used for gene therapy.

Transgenic and Knockout Mice

Once DNA has been isolated, it can be introduced into eukaryotic cells. **Transgenic mice** are altered at their **germ line** by introducing a cloned gene into fertilized ova or into embryonic stem cells. The cloned gene that is introduced is referred to as a **transgene**. If the transgene is a disease-producing

allele, the transgenic mice can be used to study the disease process from early embryonic development through adulthood. A similar approach can be used to produce **knockout mice**, in which a gene has been intentionally deleted (knocked out). These mice provide valuable models in which to study human diseases.

There are different approaches to developing transgenic mice. A cloned gene may be microinjected into the nucleus of a newly fertilized ovum. Rarely, the gene may subsequently incorporate into the nuclear DNA of the zygote. The ovum is implanted into a surrogate mother, and, if successful, the resulting offspring will contain the transgene in all of their cells, including their germ line cells (gametes). Consequently, the transgene will also be passed to *their* offspring. The transgene coexists in the animals with their own copies of the gene, which have not been deleted. This approach is useful for studying dominant gene effects but is less useful as a model for recessive disease because the number of copies of the gene that insert into the genome cannot be controlled; the transgenic mice may each contain a different number of copies of the transgene. This method is demonstrated in Figure 6.23.

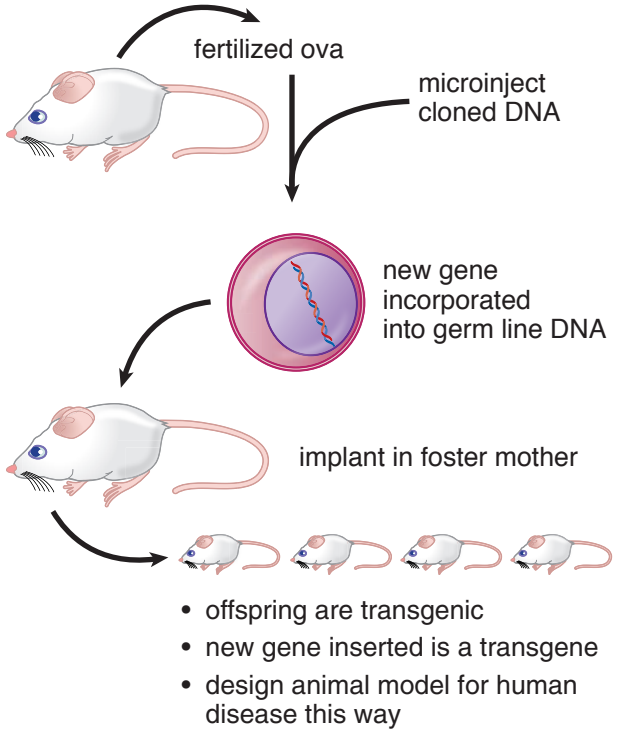

Figure 6.23. Creation of a Transgenic Mouse

Embryonic stem cell lines can also be used for developing transgenic mice. Advantages of using stem cell lines are that the cloned genes can be introduced in cultures, and that one can select for cells with the transgene successfully inserted. The altered stem cells are injected into developing blastocysts and implanted into surrogate mothers. The blastocyst itself is thus composed of two types of stem cells: the ones containing the transgene and the original blastocyst cells that lack the transgene. The resulting offspring is a ***chimera***, meaning that it has patches of cells, including germ cells, derived from each of the two lineages. This is evident if the two cell lineages (transgenic cells and host blastocyst) come from mice with different coat colors. The chimeras will have patchy coats of two colors, allowing them to be easily identified. These chimeras can then be bred to produce mice that are heterozygous for the transgene and mice that are homozygous for the transgene.

SAFETY AND ETHICS

The different procedures and techniques that have been reviewed provide great insight for researchers in many different fields of study. However, it is also important to acknowledge the potential risks associated with these technologies. Safety concerns such as increased resistance in viruses and bacteria can impact both humans and the environment in which we live. Ethical dilemmas arise: is it ethical to test for life-threatening genetic diseases and potentially terminate a pregnancy based on the results? What about testing for eye or hair color? What are the ethical questions around choosing human test subjects? If a disease-causing gene were found in one individual of a family, does this need to be communicated to other relatives at risk, potentially violating principles of privacy? Is it permissible to carry out potentially risky therapy in an individual whose illness makes him or her unable to communicate? The medical community and bioethicists at large continue to wrestle with this question: how much should we meddle with our own genetic makeup?

Real World

The story of Jesse Gelsinger is one particularly harrowing example of the problems that biotechnology can create. Diagnosed with mild *ornithine transcarbamylase* (OTC) deficiency, a defect of the urea cycle, Gelsinger volunteered for a clinical trial of gene therapy. During the trial (which was also fraught with questionable consent practices), Gelsinger died from a massive immune response to the viral vector, leading to multiple organ failure and brain death. He was 18 years old.

MCAT Concept Check 6.5:

Before you move on, assess your understanding of the material with these questions.

1. When creating a DNA library, what are some of the advantages of genomic libraries? What about cDNA libraries?
   - Genomic:

     _____
   - cDNA:

     _____

2. What does PCR accomplish for a researcher? What about Southern blotting?
   - PCR:

     _____

   - Southern blotting:

     _____

3. During DNA sequencing, why does the DNA polymer stop growing once a dideoxyribonucleotide is added?

_____

_____

4. What is the difference between a transgenic and a knockout mouse?

_____

_____

Conclusion

In this chapter, the DNA molecule was discussed. The importance of this molecule as an archive in the cell was highlighted. The unique structure of the DNA double helix and complementary base-pairing are integral to DNA molecules' ability to replicate and pass information from cell to cell and from generation to generation. Replication of DNA is a complex process involving many enzymes and proteins that are highly coordinated to ensure efficiency. The discoveries of DNA structure and function aid us in understanding how cellular processes take place but also provide us with many tools to exploit in the laboratory.

DNA is one of the most heavily tested concepts on the MCAT. This makes sense because not only has our understanding of the molecule increased exponentially over the last few decades, but also our ability to manipulate DNA. This has led to the creation of an entire industry of biotechnology that will assuredly grow during your career as a medical student and physician. In the next chapter, we turn to DNA's counterpart, RNA. We'll explore how the genes discussed in this chapter can actually turn into functional proteins through the key processes of transcription and translation.

CONCEPT SUMMARY

DNA Structure

- **Deoxyribonucleic acid** (**DNA**) is a macromolecule that stores genetic information in all living organisms.
- **Nucleosides** contain a five-carbon sugar bonded to a nitrogenous base; **nucleotides** are nucleosides with one to three phosphate groups added.
  - Nucleotides in DNA contain **deoxyribose**; in RNA, they contain **ribose**.
  - Nucleotides are abbreviated by letter: **adenine** (**A**), **cytosine** (**C**), **guanine** (**G**), **thymine** (**T**), and **uracil** (**U**).
- DNA is organized according to the **Watson–Crick model**.
  - The backbone is composed of alternating sugar and phosphate groups, and is always read **5′** to **3′**.
  - There are two strands with **antiparallel** polarity, wound into a **double helix**.
  - **Purines** (A and G) always pair with **pyrimidines** (C, U, and T). In DNA, A pairs with T (via two hydrogen bonds) and C pairs with G (via three hydrogen bonds). RNA does not contain thymine, but contains uracil instead; thus, in RNA, A pairs with U (via two hydrogen bonds).
  - Purines and pyrimidines are biological aromatic heterocycles. **Aromatic** compounds are cyclic, planar, and **conjugated**, and contain $4n + 2\ \pi$ electrons (where n is any integer; **Hückel's rule**). Heterocycles are ring structures that contain at least two different elements in the ring.
  - **Chargaff's rules** state that purines and pyrimidines are equal in number in a DNA molecule, and that because of base-pairing, the amount of adenine equals the amount of thymine, and the amount of cytosine equals the amount of guanine.
  - Most DNA is B-DNA, forming a right-handed helix. Low concentrations of Z-DNA, with a zigzag shape, may be seen with high GC-content or high salt concentration.
- DNA strands can be pulled apart (**denatured**) and brought back together (**reannealed**). Heat, alkaline pH, and chemicals like formaldehyde and urea can cause denaturation of DNA; removal of these conditions may result in reannealing of the strands.

Eukaryotic Chromosome Organization

- DNA is organized into 46 chromosomes in human cells.
- In eukaryotes, DNA is wound around **histone proteins** (H2A, H2B, H3, and H4) to form **nucleosomes**, which may be stabilized by another histone protein (H1). As a whole, DNA and its associated histones make up **chromatin** in the nucleus.

- **Heterochromatin** is dense, transcriptionally silent DNA that appears dark under light microscopy.
- **Euchromatin** is less dense, transcriptionally active DNA that appears light under light microscopy.

- **Telomeres** are the ends of chromosomes. They contain high GC-content to prevent unraveling of the DNA. During replication, telomeres are slightly shortened, although this can be (partially) reversed by the enzyme telomerase.
- **Centromeres** are located in the middle of chromosomes and hold sister chromatids together until they are separated during anaphase in mitosis. They also contain a high GC-content to maintain a strong bond between chromatids.

DNA Replication

- The **replisome** (**replication complex**) is a set of specialized proteins that assist the DNA polymerases.
- To replicate DNA, it is first unwound at an **origin of replication** by **helicases**. This produces two **replication forks** on either side of the origin.
  - Prokaryotes have a circular chromosome that contains only one origin of replication.
  - Eukaryotes have linear chromosomes that contain many origins of replication.
- Unwound strands are kept from reannealing or being degraded by **single-stranded DNA-binding proteins**.
- **Supercoiling** causes torsional strain on the DNA molecule, which can be released by **DNA topoisomerases**, which create nicks in the DNA molecule.
- DNA replication is **semiconservative**: one old **parent strand** and one new **daughter strand** is incorporated into each of the two new DNA molecules.
- DNA cannot be synthesized without an adjacent nucleotide to hook onto, so a small RNA primer is put down by **primase**.
- **DNA polymerase III** (prokaryotes) or **DNA polymerase α**, **δ**, and **ε** (eukaryotes) can then synthesize a new strand of DNA; they read the template DNA 3′ to 5′ and synthesize the new strand 5′ to 3′.
  - The **leading strand** requires only one primer and can then be synthesized continuously in its entirety.
  - The **lagging strand** requires many primers and is synthesized in discrete sections called **Okazaki fragments**.
- RNA primers can later be removed by **DNA polymerase I** (prokaryotes) or **RNase H** (eukaryotes), and filled in with DNA by DNA polymerase I (prokaryotes) or DNA polymerase δ (eukaryotes). **DNA ligase** can then fuse the DNA strands together to create one complete molecule.

DNA Repair

- **Oncogenes** develop from mutations of **proto-oncogenes**, and promote cell cycling. They may lead to **cancer**, which is defined by unchecked cell proliferation with the ability to spread by local invasion or **metastasize** (migrate to distant sites via the bloodstream or lymphatic system).
- **Tumor suppressor genes** code for proteins that reduce cell cycling or promote DNA repair; mutations of tumor suppressor genes can also lead to cancer.
- During replication, DNA polymerase **proofreads** its work and excises incorrectly matched bases. The daughter strand is identified by its lack of methylation and corrected accordingly.
- **Mismatch repair** also occurs during the G_2 phase of the cell cycle, using the genes *MSH2* and *MLH1*.
- **Nucleotide excision repair** fixes helix-deforming lesions of DNA (such as thymine dimers) via a cut-and-patch process that requires an **excision endonuclease**.
- **Base excision repair** fixes nondeforming lesions of the DNA helix (such as cytosine deamination) by removing the base, leaving an **apurinic/apyrimidinic (AP) site**. An **AP endonuclease** then removes the damaged sequence, which can be filled in with the correct bases.

Recombinant DNA and Biotechnology

- **Recombinant DNA** is DNA composed of nucleotides from two different sources.
- **DNA cloning** introduces a fragment of DNA into a **vector plasmid**. **A restriction enzyme** (**restriction endonuclease**) cuts both the plasmid and the fragment, which are left with **sticky ends**. Once the fragment binds to the plasmid, it can be introduced into a bacterial cell and permitted to replicate, generating many copies of the fragment of interest.
  - Vectors contain an origin of replication, the fragment of interest, and at least one gene for antibiotic resistance (to permit for selection of that colony after replication).
  - Once replicated, the bacterial cells can be used to create a protein of interest, or can be lysed to allow for isolation of the fragment of interest from the vector.
- **DNA libraries** are large collections of known DNA sequences.
  - **Genomic libraries** contain large fragments of DNA, including both coding and noncoding regions of the genome. They cannot be used to make recombinant proteins or for gene therapy.
  - **cDNA libraries** (**expression libraries**) contain smaller fragments of DNA, and only include the exons of genes expressed by the sample tissue. They can be used to make recombinant proteins or for gene therapy.

- **Hybridization** is the joining of complementary base pair sequences.
  - **Polymerase chain reaction** (**PCR**) is an automated process by which millions of copies of a DNA sequence can be created from a very small sample by hybridization.
  - DNA molecules can be separated by size using **agarose gel electrophoresis.**
  - **Southern blotting** can be used to detect the presence and quantity of various DNA strands in a sample. After electrophoresis, the sample is transferred to a membrane that can be **probed** with single-stranded DNA molecules to look for a sequence of interest.
- **DNA sequencing** uses **dideoxyribonucleotides**, which terminate the DNA chain because they lack a 3′ –OH group. The resulting fragments can be separated by gel electrophoresis, and the sequence can be read directly from the gel.
- **Gene therapy** is a method of curing genetic deficiencies by introducing a functional gene with a viral vector.
- **Transgenic mice** are created by integrating a gene of interest into the germ line or embryonic stem cells of a developing mouse.
  - Organisms that contain cells from two different lineages (such as mice formed by integration of transgenic embryonic stem cells into a normal mouse blastocyst) are called **chimeras.**
  - Transgenic mice can be mated to select for the transgene.
- **Knockout mice** are created by deleting a gene of interest.
- Biotechnology brings up a number of safety and ethical issues, including pathogen resistance and the ethics of choosing individuals for specific traits.

ANSWERS TO CONCEPT CHECKS

6.1

1. Nucleosides contain a five-carbon sugar (pentose) and nitrogenous base. Nucleotides are composed of a nucleoside plus one to three phosphate groups.
2. A pairs with T (in DNA) or U (in RNA), using two hydrogen bonds. C pairs with G, using three hydrogen bonds.
3. DNA contains deoxyribose, while RNA contains ribose. DNA contains thymine, while RNA contains uracil. Usually, DNA is double-stranded, while RNA is single-stranded.
4. The aromaticity of nucleic acids makes these compounds very stable and unreactive. Stability is important for storing genetic information and avoiding spontaneous mutations.
5. This does not violate Chargaff's rules. RNA is single-stranded, and thus the complementarity seen in DNA does not hold true. For single-stranded RNA, %C does not necessarily equal %G; %A does not necessarily equal %U.

6.2

1. The five histone proteins are H1, H2A, H2B, H3, and H4. H1 is the only one not in the histone core.
2.

Characteristic	Heterochromatin	Euchromatin
Density of chromatin packing	Dense	Not dense (uncondensed)
Appearance under light microscopy	Dark	Light
Transcriptional activity	Silent	Active

3. High GC-content increases hydrogen bonding, making the association between DNA strands very strong at telomeres and centromeres.

6.3

1.

Enzyme	Prokaryotes/Eukaryotes/ Both	Function
Helicase	Both	Unwinds DNA double helix
Single-stranded DNA-binding protein	Both	Prevents reannealing of DNA double helix during replication

Primase	Both	Places ~10-nucleotide RNA primer to begin DNA replication
DNA polymerase III	Prokaryotes	Adds nucleotides to growing daughter strand
DNA polymerase α	Eukaryotes	Adds nucleotides to growing daughter strand
DNA polymerase I	Prokaryotes	Fills in gaps left behind after RNA primer excision
RNase H	Eukaryotes	Excises RNA primer
DNA ligase	Both	Joins DNA strands (especially between Okazaki fragments)
DNA topoisomerases	Both	Reduces torsional strain from positive supercoils by introducing nicks in DNA strand

2. The lagging strand is more prone to mutations because it must constantly start and stop the process of DNA replication. Additionally, it contains many more RNA primers, all of which must be removed and filled in with DNA.
3. Telomeres are the ends of eukaryotic chromosomes and contain repetitive sequences of noncoding DNA. These protect the chromosome from losing important genes from the incomplete replication of the 5′ end of the DNA strand.

6.4

1. Oncogenes (or, more properly, proto-oncogenes) code for cell cycle-promoting proteins; when mutated, a proto-oncogene becomes an oncogene, promoting rapid cell cycling. Tumor suppressor genes code for repair or cell cycle-inhibiting proteins; when mutated, the cell cycle is allowed to proceed unchecked. Oncogenes are like stepping on the gas pedal, mutated tumor suppressor genes are like cutting the brakes.
2. The parent strand is more heavily methylated, whereas the daughter stand is barely methylated at all. This allows DNA polymerase to distinguish between the two strands during proofreading.

3.

Repair Mechanism	Phase of Cell Cycle	Key Enzymes/Genes
DNA polymerase (proofreading)	S	DNA polymerase
Mismatch repair	G_2	*MSH2*, *MLH1* (*MutS* and *MutL* in prokaryotes)
Nucleotide excision repair	G_1, G_2	Excision endonuclease
Base excision repair	G_1, G_2	Glycosylase, AP endonuclease

4. Nucleotide excision repair corrects lesions that are large enough to distort the double helix; base excision repair corrects lesions that are small enough not to distort the double helix.

6.5

1. Genomic libraries include all of the DNA in an organism's genome, including noncoding regions. This may be useful for studying DNA in introns, centromeres, or telomeres. cDNA libraries only include expressed genes from a given tissue, but can be used to express recombinant proteins or to perform gene therapy.
2. PCR increases the number of copies of a given DNA sequence and can be used for a sample containing very few copies of the DNA sequence. Southern blotting is useful when searching for a particular DNA sequence because it separates DNA fragments by length and then probes for a sequence of interest.
3. Dideoxyribonucleotides lack the 3′ –OH group that is required for DNA strand elongation. Thus, once a dideoxyribonucleotide is added to a growing DNA molecule, no more nucleotides can be added because dideoxyribonucleotides have no 3′ –OH group with which to form a bond.
4. Transgenic mice have a gene introduced into their germ line or embryonic stem cells to look at the effects of that gene; they are therefore best suited for studying the effects of dominant alleles. Knockout mice are those in which a gene of interest has been removed, rather than added.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. In a single strand of a nucleic acid, nucleotides are linked by:

A. hydrogen bonds.
B. phosphodiester bonds.
C. ionic bonds.
D. van der Waals forces.

2. Which of the following statements regarding differences between DNA and RNA is FALSE?

A. In cells, DNA is double-stranded, whereas RNA is single-stranded.
B. DNA uses the nitrogenous base thymine; RNA uses uracil.
C. The sugar in DNA is deoxyribose; the sugar in RNA is ribose.
D. DNA strands replicate in a 5′ to 3′ direction, whereas RNA is synthesized in a 3′ to 5′ direction.

3. Which of the following DNA sequences would have the highest melting temperature?

A. CGCAACCATCCG
B. CGCAATAATACA
C. CGTAATAATACA
D. CATAACAAATCA

4. Which of the following biomolecules is LEAST likely to contain an aromatic ring?

A. Proteins
B. Purines
C. Carbohydrates
D. Pyrimidines

5. For a compound to be aromatic, all of the following must be true EXCEPT:

A. the molecule is cyclic.
B. the molecule contains $4n + 2\ \pi$ electrons.
C. the molecule contains alternating single and double bonds.
D. the molecule is planar.

6. Which of the following enzymes is NOT involved in DNA replication?

A. Primase
B. DNA ligase
C. RNA polymerase
D. Telomerase

7. How is cDNA best characterized?

A. cDNA results from a DNA transcript with noncoding regions removed.
B. cDNA results from the reverse transcription of processed mRNA.
C. cDNA is the abbreviation for deoxycytosine.
D. cDNA is the circular DNA molecule that forms the bacterial genome.

8. Which of the following statements regarding polymerase chain reaction is FALSE?

A. Human DNA polymerase is used because it is the most accurate.
B. A primer must be prepared with a complementary sequence to part of the DNA of interest.

C. Repeated heating and cooling cycles allow the enzymes to act specifically and replaces helicase.
D. Each cycle of the polymerase chain reaction doubles the amount of DNA of interest.

9. Restriction endonucleases are used for which of the following?

I. Gene therapy
II. Southern blotting
III. DNA repair

A. I only
B. II only
C. II and III only
D. I, II, and III

10. How does prokaryotic DNA differ from eukaryotic DNA?

I. Prokaryotic DNA lacks nucleosomes.
II. Eukaryotic DNA has telomeres.
III. Prokaryotic DNA is replicated by a different DNA polymerase.
IV. Eukaryotic DNA is circular when not restricted by centromeres.

A. I only
B. IV only
C. II and III only
D. I, II, and III only

11. Why might uracil be excluded from DNA but NOT RNA?

A. Uracil is much more difficult to synthesize than thymine.
B. Uracil binds adenine too strongly for replication.
C. Cytosine degradation results in uracil.
D. Uracil is used as a DNA synthesis activator.

12. Tumor suppressor genes are most likely to result in cancer through:

A. loss of function mutations.
B. gain of function mutations.
C. overexpression.
D. proto-oncogene formation.

13. Which of the following is an ethical concern of gene sequencing?

A. Gene sequencing is invasive, thus the potential health risks must be thoroughly explained.
B. Gene sequencing impacts relatives, thus privacy concerns may be raised.
C. Gene sequencing is very inaccurate, which increases anxiety related to findings.
D. Gene sequencing can provide false-negative results, giving a false sense of security.

14. Which of the following is NOT a difference between heterochromatin and euchromatin?

A. Euchromatin has areas that can be transcribed, whereas heterochromatin is silent.
B. Heterochromatin is tightly packed, whereas euchromatin is less dense.
C. Heterochromatin stains darkly, whereas euchromatin stains lightly.
D. Heterochromatin is found in the nucleus, whereas euchromatin is in the cytoplasm.

15. During which phase of the cell cycle are DNA repair mechanisms least active?

A. G_1
B. S
C. G_2
D. M

Explanations to Discrete Practice Questions

1. B

Nucleotides bond together to form polynucleotides. The 3′ hydroxyl group of one nucleotide's sugar joins the 5′ hydroxyl group of the adjacent nucleotide's sugar by a phosphodiester bond. Hydrogen bonding, **choice (A)**, is important for holding complementary strands together, but does not play a role in the bonds formed between adjacent nucleotides on a single strand.

2. D

Because we are looking for the false statement, we have to read each choice to eliminate those that are true or find one that is overtly false. Let's quickly review the main differences between DNA and RNA. In cells, DNA is double-stranded, with a deoxyribose sugar and the nitrogenous bases A, T, C, and G. RNA, on the other hand, is usually single-stranded, with a ribose sugar and the bases A, U, C, and G. **Choice (D)** is false because both DNA replication and RNA synthesis proceed in a 5′ to 3′ direction.

3. A

The melting temperature of DNA is the temperature at which a DNA double helix separates into two single strands (denatures). To do this, the hydrogen bonds linking the base pairs must be broken. Cytosine binds to guanine with three hydrogen bonds, whereas adenine binds to thymine with two hydrogen bonds. The amount of heat needed to disrupt the bonding is proportional to the number of bonds. Thus, the higher the GC-content in a DNA segment, the higher the melting point.

4. C

Aromatic rings must contain conjugated π electrons, which require alternating single and multiple bonds, or lone pairs. In carbohydrate ring structures, only single bonds are present, thus preventing aromaticity. Nucleic acids contain aromatic heterocycles, while proteins will generally contain at least one aromatic amino acid (tryptophan, phenylalanine, or tyrosine).

5. C

For a compound to be aromatic, it must be cyclic, planar, and conjugated, and contain $4n + 2$ π electrons, where n is any integer. Conjugation requires that every atom in the ring have at least one unhybridized *p*-orbital. While most examples of aromatic compounds have alternating single and double bonds, compounds can be aromatic if they contain triple bonds as well; this would still permit at least one unhybridized *p*-orbital.

6. C

During DNA replication, the strands are separated by DNA helicase. At the replication fork, primase, **choice (A)**, creates a primer for the initiation of replication, which is followed by DNA polymerase. On the lagging strand, Okazaki fragments form and are joined by DNA ligase, **choice (B)**. After the chromosome has been processed, the ends, called telomeres, are replicated with the assistance of the enzyme telomerase, **choice (D)**. RNA polymerase, distinct from primase, is responsible for transcription.

7. B

cDNA (complementary DNA) is formed from a processed mRNA strand by reverse transcription. cDNA is used in DNA libraries and contains only the exons of genes that are transcriptionally active in the sample tissue.

8. A

The polymerase chain reaction is used to clone a sequence of DNA using a DNA sample, a primer, free nucleotides, and enzymes. The polymerase from *Thermus aquaticus* is used because the reaction is regulated by thermal cycling, which would denature human enzymes.

9. D

Endonucleases are enzymes that cut DNA. They are used by the cell for DNA repair. They are also used by scientists during DNA analysis, as restriction enzymes are endonucleases. Restriction enzymes are used to cleave DNA before electrophoresis and Southern blotting, and to introduce a gene of interest into a viral vector for gene therapy.

10. D

Prokaryotic DNA is circular and lacks histone proteins, and thus does not form nucleosomes. Both prokaryotic and eukaryotic DNA are replicated by DNA polymerases, although these polymerases differ in identity. Eukaryotic DNA is organized into chromatin, which can condense to form linear chromosomes; only prokaryotes have circular chromosomes. Only eukaryotic DNA has telomeres.

11. C

One common DNA mutation is the transition from cytosine to uracil in the presence of heat. DNA repair enzymes recognize uracil and correct this error by excising the base and inserting cytosine. RNA exists only transiently in the cell, such that cytosine degradation is insignificant. Were uracil to be used in DNA under normal circumstances, it would be impossible to tell if a base *should* be uracil or if it is a damaged cytosine nucleotide.

12. A

Oncogenes are most likely to result in cancer through activation, **choice (B)**, while tumor suppressor genes are most likely to result in cancer through inactivation.

13. B

One of the primary ethical concerns related to gene sequencing is the issue of consent and privacy. Because genetic screening provides information on direct relatives, there are potential violations of privacy in communicating this information to family members who may be at risk. There are not significant physical risks, eliminating **choice (A)**, and gene sequencing is fairly accurate, eliminating **choices (C)** and **(D)**.

14. D

Euchromatin has a classic "beads on a string" appearance that stains lightly, while heterochromatin is tightly packed and stains darkly. Heterochromatin is primarily composed of inactive genes or untranslated regions, while euchromatin is able to be expressed. All chromatin is found in the nucleus, not the cytoplasm.

15. D

Mismatch repair mechanisms are active during S phase (proofreading) and G_2 phase (*MSH2* and *MLH1*), eliminating **choices (B)** and **(C)**. Nucleotide and base excision repair mechanisms are most active during the G_1 and G_2 phases, also eliminating **choice (A)**. These mechanisms exist during interphase because they are aimed at *preventing* propagation of the error into daughter cells during M phase (mitosis).

Concept Summary 243

Introduction

Hepatitis C virus (HCV) continues to be a major cause of cirrhosis and liver failure in the United States. Usually associated with intravenous drug use, hepatitis C causes ongoing damage and inflammation in the liver, leading to the formation of scar tissue that replaces the normal cells of the organ. Over time, this buildup of scar tissue makes the liver unable to keep up with the metabolic demands of the body, and liver failure ensues. To fight this virus, infected hepatocytes release interferon, a peptide signal that—as the name suggests—interferes with viral replication. Because viruses must hijack the host cell's machinery to replicate, one way the body can limit the spread of the virus is by shutting off the processes of transcription and translation. Interferon not only curtails these processes in virally infected cells, but also induces the production of *RNAse L*, which cleaves RNA in cells to further reduce the ability of the virus to replicate. Coupled with other immune defenses, interferon thus serves as an efficient mechanism to protect the body from viral pathogens.

Even in normal, healthy cells, the first step in expressing genetic information is transcription of the information in the base sequence of a double-stranded DNA molecule to form a single-stranded molecule of RNA. The second step is translating that nucleotide sequence into a protein. Not every cell, though, expresses every gene product, and control of gene expression leads to the differentiation of the totipotent zygote into all of the tissues of the body. In this chapter, we will discuss the process through which proteinxs are produced along with the controls that modulate each step of the path.

7.1 The Genetic Code

An organism must be able to store and preserve its genetic information, pass that information along to future generations, and express that information as it carries out all the processes of life. We know that DNA and RNA share the same language: they both code using nitrogenous bases. Proteins, however, are composed of amino acids, which constitute a different language altogether. Therefore, we use the genetic code to translate this genetic information into proteins.

While nucleotides play a crucial role in maintaining our genetic identity from generation to generation, it is the proteins they encode that help organisms develop and perform the necessary functions of life. The major steps involved in the transfer of genetic information are illustrated in the **central dogma of molecular biology**, as shown in Figure 7.1. Classically, a **gene** is a unit of DNA that encodes a specific protein or RNA molecule, and through transcription and translation, that gene can be expressed. Although this sequence is now complicated by our increased knowledge of the ways in which genes and nucleic acids may be expressed, it is still useful as a general working definition of the processes of DNA replication, transcription, and translation. We have already discussed DNA synthesis, but will continue learning more about gene expression in the rest of this chapter.

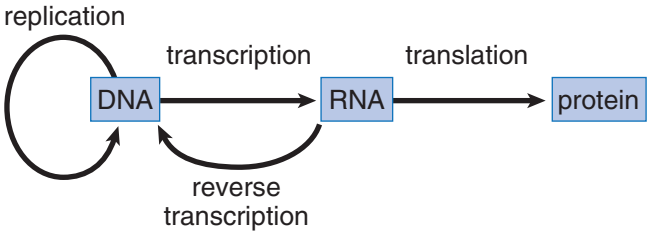

Figure 7.1. The Central Dogma of Molecular Biology

The relationship between the sequence found in double-stranded DNA, single-stranded RNA, and protein is illustrated in Figure 7.2 for a prototypical gene. Messenger RNA is synthesized in the $5' \rightarrow 3'$ direction and is complementary and antiparallel to the DNA template strand. The ribosome translates the mRNA in the $5' \rightarrow 3'$ direction, as it synthesizes the protein from the amino terminus (N-terminus) to the carboxy terminus (C-terminus).

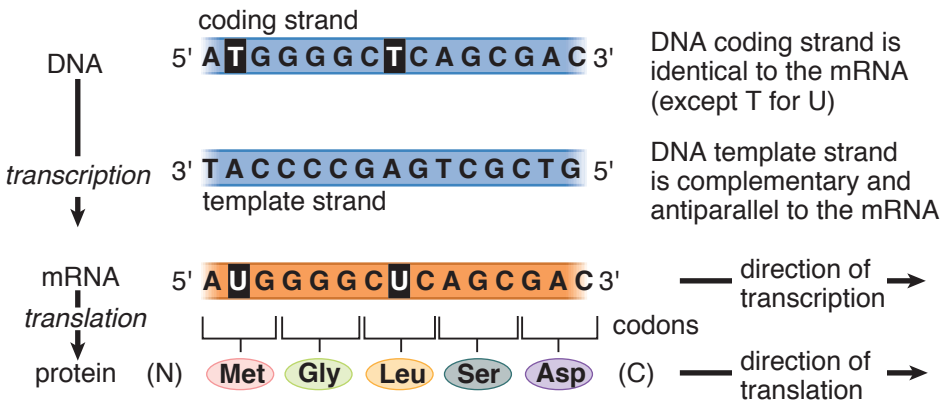

Figure 7.2. Flow of Genetic Information from DNA to Protein

TYPES OF RNA

There are three main types of RNA found in cells: mRNA, tRNA, and rRNA. Each of the main types is described below, but regulatory and specialized forms of RNA are also described later in the chapter.

Messenger RNA (mRNA)

Messenger RNA (**mRNA**) carries the information specifying the amino acid sequence of the protein to the ribosome. mRNA is transcribed from template DNA strands by *RNA polymerase* enzymes in the nucleus of cells. Then, mRNA may undergo a host of posttranscriptional modifications prior to its release from the nucleus. mRNA is the only type of RNA that contains information that is translated into protein; to do so, it is read in three-nucleotide segments termed **codons**. In eukaryotes, mRNA is **monocistronic**, meaning that each mRNA molecule translates into only one protein product. Thus, in eukaryotes, the cell has a different mRNA molecule for each of the thousands of different proteins made by that cell. In prokaryotes, mRNA may be **polycistronic**, and starting the process of translation at different locations in the mRNA can result in different proteins. The process of creating mature mRNA will be discussed in the next section of this chapter.

Key Concept

mRNA is the messenger of genetic information. DNA codes for proteins but cannot perform any of the important enzymatic reactions that proteins are responsible for in cells. mRNA takes the information from the DNA to the ribosomes, where creation of the primary protein structure occurs.

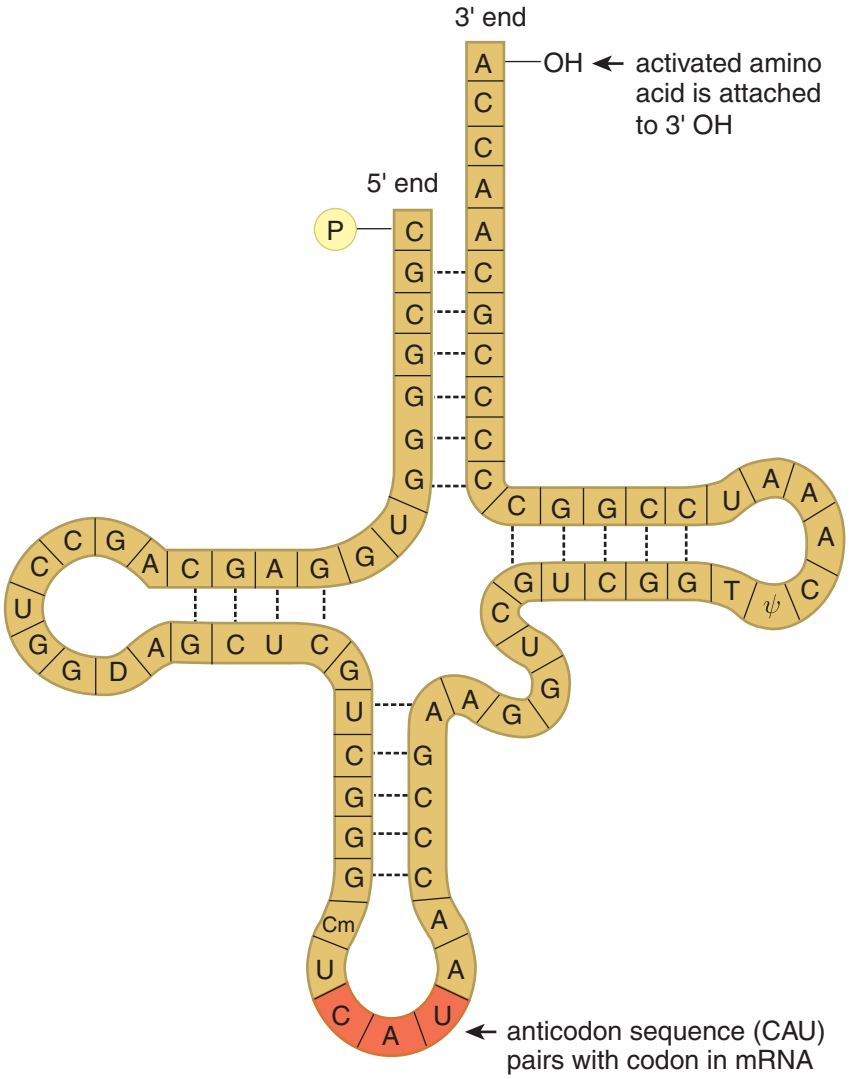

Figure 7.3. The Structure of tRNA

Transfer RNA (tRNA)

Transfer RNA (**tRNA**) is responsible for converting the language of nucleic acids to the language of amino acids and peptides. Each tRNA molecule contains a folded strand of RNA that includes a three-nucleotide anticodon, as shown in Figure 7.3. This anticodon recognizes and pairs with the appropriate codon on an mRNA molecule while in the ribosome. There are 20 amino acids in eukaryotic proteins, each of which is represented by at least one codon. To become part of a nascent polypeptide in the ribosome, amino acids are connected to a specific tRNA molecule; such tRNA molecules are said to be **charged** or **activated** with an amino acid, as shown in Figure 7.4. Mature tRNA is found in the cytoplasm.

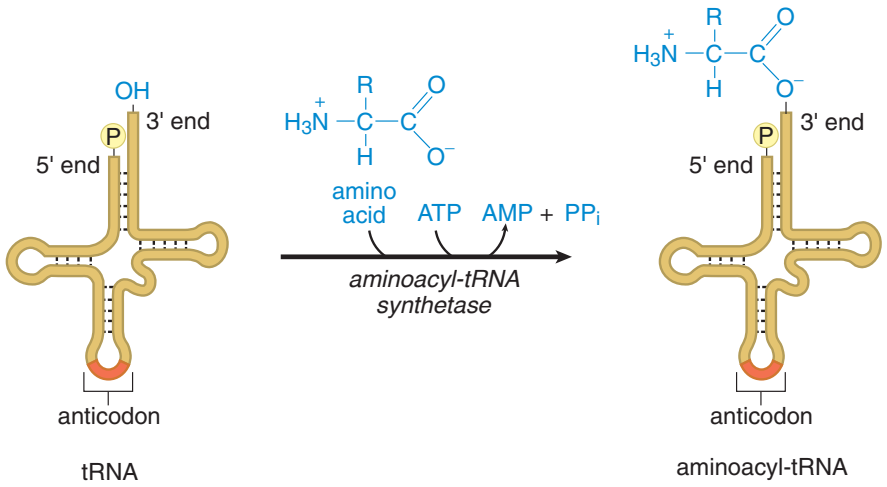

Figure 7.4. Activation of Amino Acid for Protein Synthesis

Each type of amino acid is activated by a different ***aminoacyl-tRNA synthetase*** that requires two high-energy bonds from ATP, implying that the attachment of the amino acid is an energy-rich bond. The aminoacyl-tRNA synthetase transfers the activated amino acid to the 3′ end of the correct tRNA. Each tRNA has a CCA nucleotide sequence where the amino acid binds. The high-energy aminoacyl-tRNA bond will be used to supply the energy needed to create a peptide bond during translation.

Ribosomal RNA (rRNA)

Ribosomal RNA (**rRNA**) is synthesized in the nucleolus and functions as an integral part of the ribosomal machinery used during protein assembly in the cytoplasm. Many rRNA molecules function as **ribozymes**; that is, enzymes made of RNA molecules instead of peptides. rRNA helps catalyze the formation of peptide bonds and is also important in splicing out its own introns within the nucleus. The complex structure of the ribosome is described later in this chapter.

CODONS

If a gene sequence is a "sentence" describing a protein, then its basic unit is a three-letter "word" known as the **codon**, which is translated into an amino acid. Genetic code tables, such as the one in Figure 7.5, serve as an easy way to determine the amino acid that is translated from each mRNA codon. Each codon consists of three bases; thus, there are 64 codons. Note how all codons are written in the 5′ → 3′ direction, and the code is unambiguous, in that each codon is specific for one and only one amino acid.

First Nucleotide Position	Second Nucleotide Position: U	C	A	G
U	UUU Phenylalanine	UCU Serine	UAU Tyrosine	UGU Cysteine
	UUC Phenylalanine	UCC Serine	UAC Tyrosine	UGC Cysteine
	UUA Leucine	UCA Serine	UAA STOP	UGA STOP
	UUG Leucine	UCG Serine	UAG STOP	UGG Tryptophan
C	CUU Leucine	CCU Proline	CAU Histidine	CGU Arginine
	CUC Leucine	CCC Proline	CAC Histidine	CGC Arginine
	CUA Leucine	CCA Proline	CAA Glutamine	CGA Arginine
	CUG Leucine	CCG Proline	CAG Glutamine	CGG Arginine
A	AUU Isoleucine	ACU Threonine	AAU Asparagine	AGU Serine
	AUC Isoleucine	ACC Threonine	AAC Asparagine	AGC Serine
	AUA Isoleucine	ACA Threonine	AAA Lysine	AGA Arginine
	AUG Methionine	ACG Threonine	AAG Lysine	AGG Arginine
G	GUU Valine	GCU Alanine	GAU Aspartate	GGU Glycine
	GUC Valine	GCC Alanine	GAC Aspartate	GGC Glycine
	GUA Valine	GCA Alanine	GAA Glutamate	GGA Glycine
	GUG Valine	GCG Alanine	GAG Glutamate	GGG Glycine

Figure 7.5. The Genetic Code

Key Concept

Each codon represents only one amino acid; however, most amino acids are represented by multiple codons.

Note that 61 of the codons code for one of the 20 amino acids, while three codons encode for the termination of translation. This code is universal across species (although there are some exceptions in the mitochondria that are not necessary to know for the MCAT).

During translation, the codon of the mRNA is recognized by a complementary **anticodon** on a transfer RNA (tRNA). The anticodon sequence allows the tRNA to pair with the codon in the mRNA. Because base-pairing is involved, the orientation of this interaction will be antiparallel. For example, the aminoacyl tRNA Ile-tRNA^{Ile} has an anticodon sequence 5′—GAU—3′, allowing it to pair with the isoleucine codon 5′—AUC—3′, as seen in Figure 7.6.

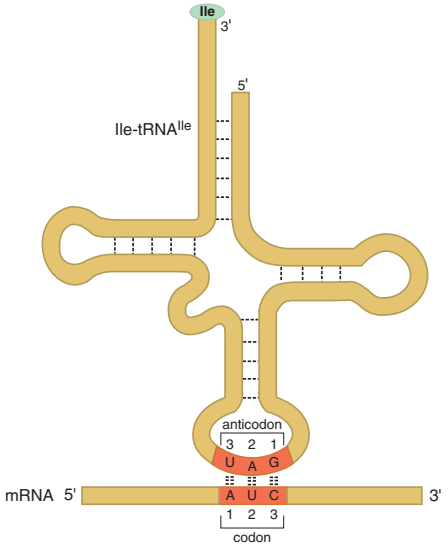

Figure 7.6. Base Pairing of an Aminoacyl-tRNA with a Codon in mRNA

Every preprocessed eukaryotic protein starts with the exact same amino acid: methionine. Because every protein begins with methionine, the codon for methionine (AUG) is considered the **start codon** for translation of the mRNA into protein. There are also 3 codons that encode for termination of protein translation; there are no charged tRNA molecules that recognize these codons, which leads to the release of the protein from the ribosome. The three **stop codons** are UGA, UAA, and UAG.

Mnemonic

Stop codons:

- **UAA—U A**re **A**nnoying
- **UGA—U G**o **A**way
- **UAG—U A**re **G**one

MUTATIONS

Degeneracy and Wobble

The genetic code is **degenerate** because more than one codon can specify a single amino acid. In fact, all amino acids, except for methionine and tryptophan, are encoded by multiple codons. Referring back to Figure 7.5, we can see that for the amino acids with multiple codons, the first two bases are usually the same, and the third base in the codon is variable. We refer to this variable third base in the codon as the **wobble position**. Wobble is an evolutionary development designed to protect against mutations in the coding regions of our DNA. Mutations in the wobble position tend to be called **silent** or **degenerate**, which means there is no effect on the expression of the amino acid and therefore no adverse effects on the polypeptide sequence. The amino acid glycine, for example, requires that only the first two nucleotides of the codon be GG. The third nucleotide could be A, C, G, or U, and the amino acid composition of the protein would remain the same.

Key Concept

The degeneracy of the genetic code allows for mutations in DNA that do not always result in altered protein structure or function. Usually, a mutation within an intron will also not change the protein sequence because introns are cleaved out of the mRNA transcript prior to translation.

Missense and Nonsense Mutations

If a mutation occurs and it affects one of the nucleotides in a codon, it is known as a **point mutation**. Although we've already discussed the silent point mutation in the wobble position, other point mutations can have a severe detrimental effect depending on where the mutation occurs in the genome. Because these point mutations can affect the primary amino acid sequence of the protein, they are called **expressed mutations**. Expressed point mutations fall into two categories: missense and nonsense.

- **Missense mutation**—a mutation where one amino acid substitutes for another
- **Nonsense mutation**—a mutation where the codon now encodes for a premature stop codon (also known as a **truncation mutation**)

Frameshift Mutations

The three nucleotides of a codon are referred to as the **reading frame**. Point mutations occur when one nucleotide is changed, but a **frameshift mutation** occurs when some number of nucleotides are added to or deleted from the mRNA sequence. Insertion or deletion of nucleotides will shift the reading frame, usually resulting in changes

Real World

Cystic fibrosis is most commonly caused by a frameshift mutation: a deletion at codon 508 in the polypeptide chain of the CFTR chloride channel gene. The subsequent loss of a phenylalanine residue at this position results in a defective chloride ion channel. This altered protein never reaches the cell membrane, leading to blocked passage of salt and water into and out of cells. As a result of this blockage, cells that line the passageways of the lungs, pancreas, and other organs produce an abnormally thick, sticky mucus that traps bacteria, increasing the likelihood of infection in patients.

in the amino acid sequence or premature truncation of the protein. The effects of frameshift mutations are typically more serious than point mutations, although it is heavily dependent on where within the DNA sequence the mutation actually occurred. A synopsis of the different types of mutations can be found in Figure 7.7.

Figure 7.7. Some Common Types of Mutations in DNA

MCAT Concept Check 7.1:

Before you move on, assess your understanding of the material with these questions.

1. What are the roles of the three main types of RNA?
   - mRNA: _____
   - tRNA: _____
   - rRNA: _____

2. The three-base sequences listed below are DNA sequences. Using Figure 7.5, which amino acid is encoded by each of these sequences, after transcription and translation?
   - GAT: _____
   - ATT: _____

- CGC:

_____

- CCA:

_____

3. Which mRNA codon is the start codon, and what amino acid does it code for? Which mRNA codons are the stop codons?
   - Start codon: _____; codes for: _____
   - Stop codons: _____

4. What is wobble, and what role does it serve?

_____

_____

_____

5. For each of the mutations listed below, what changes in DNA sequence are observed, and what effect do they have on the encoded peptide?

Type of Mutation	Change in DNA Sequence	Effect on Encoded Protein
Silent (degenerate)		
Missense		
Nonsense		
Frameshift		

7.2 Transcription

Although DNA contains the actual coding sequence for a protein, the machinery to generate that protein is located in the cytoplasm. DNA cannot leave the nucleus, as it will be quickly degraded, so it must use RNA to transmit genetic information. The creation of mRNA from a DNA template is known as **transcription**, and while mRNA is the only type of RNA that carries information from DNA directly, there are many other types of RNA that exist, two of which will play important roles during protein translation: transfer RNA (tRNA) and ribosomal RNA (rRNA).

Mnemonic

When we transcribe information, we use the same language to write it down (like in court, when the judge asks the court reporter to read back the transcript—the reporter speaks the same language as written). Translation is exactly what it says: we are changing the language. RNA translation changes the language from nucleotides to amino acids.

MECHANISM OF TRANSCRIPTION

Transcription produces a copy of only one of the two strands of DNA. During initiation of transcription, several enzymes, including ***helicase*** and ***topoisomerase***, are involved in unwinding the double-stranded DNA and preventing formation of supercoils, as described in Chapter 6 of *MCAT Biochemistry Review*. This step is important in allowing the transcriptional machinery access to the DNA and the particular gene of interest. Transcription results in a single strand of mRNA, synthesized from one of the two nucleotide strands of DNA called the **template strand** (or the **antisense strand**). The newly synthesized mRNA strand is both antiparallel and complementary to the DNA template strand.

RNA is synthesized by a *DNA-dependent RNA polymerase*; RNA polymerase locates genes by searching for specialized DNA regions known as **promoters**. In eukaryotes, ***RNA polymerase II*** is the main player in transcribing mRNA, and its binding site in the promoter region is known as the **TATA box**, named for its high concentration of thymine and adenine bases. **Transcription factors** help the RNA polymerase locate and bind to this promoter region of the DNA, helping to establish where transcription will start. Unlike *DNA polymerase III*, which we reviewed during DNA replication, RNA polymerase does not require a primer to start generating a transcript.

In eukaryotes, there are three types of RNA polymerases, but only one is involved in the transcription of mRNA:

- *RNA polymerase I* is located in the nucleolus and synthesizes rRNA
- *RNA polymerase II* is located in the nucleus and synthesizes hnRNA (preprocessed mRNA) and some small nuclear RNA (snRNA)
- *RNA polymerase III* is located in the nucleus and synthesizes tRNA and some rRNA

Key Concept

Transcription is subject to the 5′ → 3′ rule, just like DNA synthesis. Synthesis of nucleic acids always occurs in the 5′ → 3′ direction.

RNA polymerase travels along the template strand in the 3′ → 5′ direction, which allows for the construction of transcribed mRNA in the 5′ → 3′ direction. Unlike DNA polymerase, RNA polymerase does not proofread its work, so the synthesized transcript will not be edited. The **coding strand** (or **sense strand**) of DNA is not used as a template during transcription. Because the coding strand is also complementary to the template strand, it is identical to the mRNA transcript except that all the thymine nucleotides in DNA have been replaced with uracil in the mRNA molecule.

In the vicinity of a gene, a numbering system is used to identify the location of important bases in the DNA strand, as shown in Figure 7.8. The first base transcribed from DNA to RNA is defined as the +1 base of that gene region. Bases to the left of this start point (upstream, or toward the 5′ end) are given negative numbers:

–1, –2, –3, and so on. Bases to the right (downstream, or toward the 3′ end) are denoted with positive numbers: +2, +3, +4, and so on. Thus, no nucleotide in the gene is numbered 0. The TATA box, where RNA polymerase II binds, usually falls around –25.

Transcription will continue along the DNA coding region until the RNA polymerase reaches a termination sequence or stop signal, which results in the termination of transcription. The DNA double helix then reforms, and the primary transcript formed is termed **heterogeneous nuclear RNA** (**hnRNA**). mRNA is derived from hnRNA via posttranscriptional modifications, as described below.

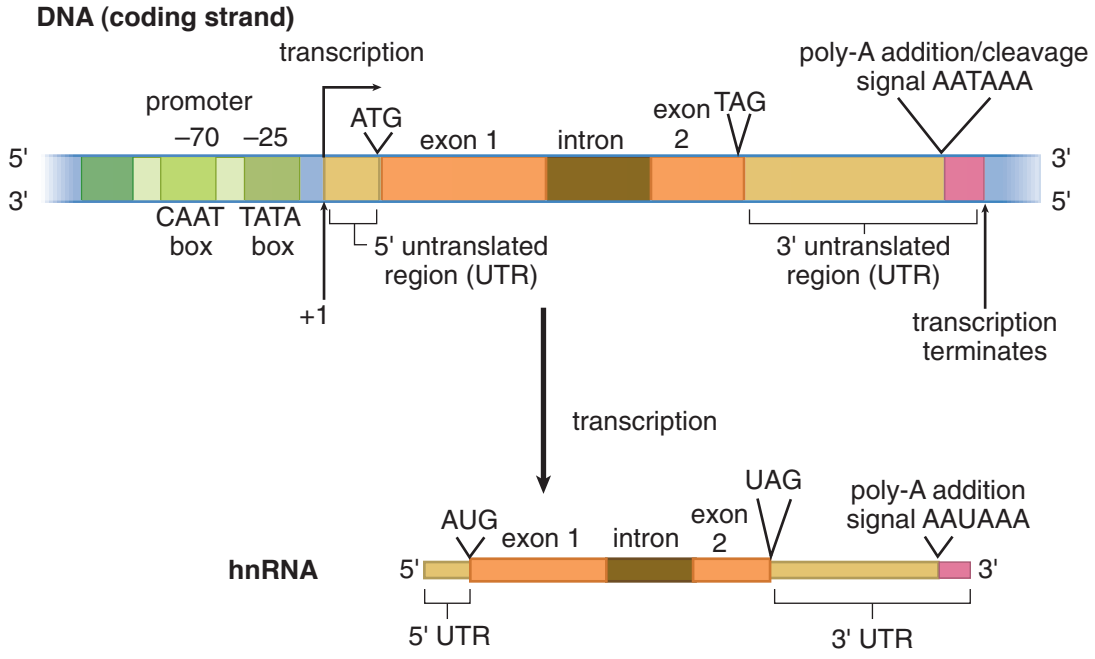

Figure 7.8. Transcription of DNA to hnRNA

POSTTRANSCRIPTIONAL PROCESSING

Before the hnRNA can leave the nucleus and be translated to protein, it must undergo three specific processes to allow it to interact with the ribosome and survive the conditions of the cytoplasm, as demonstrated in Figure 7.9. You can think of the nucleus as the happy home of the cell; the DNA strands are the parents, and the hnRNA is their child. The child must mature if he or she is to survive.

Key Concept

The MCAT commonly tests post-transcriptional processing:

- Intron/exon splicing
- 5′ cap
- 3′ poly-A tail

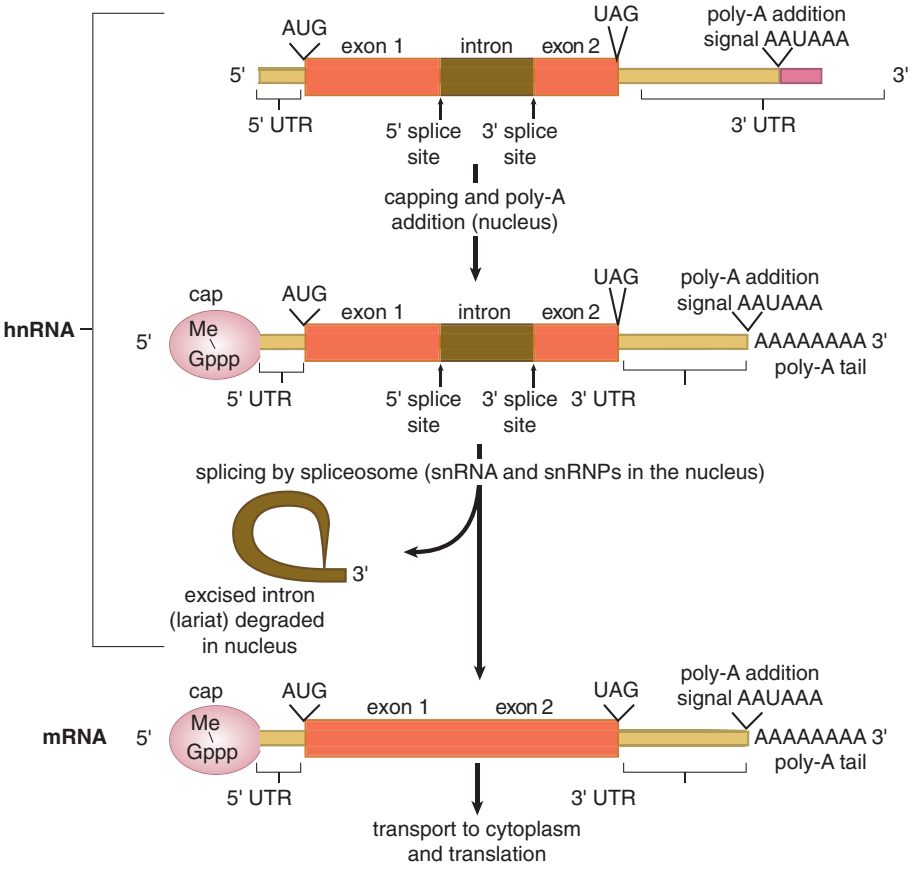

Figure 7.9. Processing Eukaryotic hnRNA to Form mRNA

Splicing: Introns and Exons

Maturation of the hnRNA includes splicing of the transcript to remove noncoding sequences (**introns**) and ligate coding sequences (**exons**) together. Splicing is accomplished by the **spliceosome**. In the spliceosome, **small nuclear RNA** (**snRNA**) molecules couple with proteins known as **small nuclear ribonucleoproteins** (also known as **snRNPs**, or "snurps"). The snRNP/snRNA complex recognizes both the 5′ and 3′ splice sites of the introns. These noncoding sequences are excised in the form of a **lariat** (lasso-shaped structure) and then degraded.

The evolutionary function of introns in eukaryotic cells is not currently well-understood; however, scientists hypothesize that introns play an important role in the regulation of cellular gene expression levels and in maintaining the size of our genome. The existence of introns has also been hypothesized to allow for rapid protein evolution. Many eukaryotic proteins share peptide sequences in common, suggesting that the genes encoding for these particular peptides may employ a modular function; that is, they contain standard sequences that can be swapped in and out, depending on the needs of the cell.

5′ Cap

At the 5′ end of the hnRNA molecule, a **7-methylguanylate triphosphate cap** is added. The cap is actually added during the process of transcription and is recognized by the ribosome as the binding site. It also protects the mRNA from degradation in the cytoplasm.

3′ Poly-A Tail

A **polyadenosyl** (**poly-A**) **tail** is added to the 3′ end of the mRNA transcript and protects the message against rapid degradation. It is composed of adenine bases. Think of the poly-A tail as a fuse for a "time bomb" for the mRNA transcript: as soon as the mRNA leaves the nucleus, it will start to get degraded from its 3′ end. The longer the poly-A tail, the more time the mRNA will be able to survive before being digested in the cytoplasm. The poly-A tail also assists with export of the mature mRNA from the nucleus.

At this point, when only the exons remain and the cap and tail have been added, the cell has created the mature mRNA that can now be transported into the cytoplasm for protein translation. Untranslated regions of the mRNA (UTRs) will still exist at the 5′ and 3′ edges of the transcript because the ribosome initiates translation at the start codon (AUG) and will end at a stop codon (UAA, UGA, UAG).

For some genes in eukaryotic cells, however, the primary transcript of hnRNA may be spliced together in different ways to produce multiple variants of proteins encoded by the same original gene. This process is known as **alternative splicing**, and it is illustrated in Figure 7.10. By utilizing alternative splicing, an organism can make many more different proteins from a limited number of genes. For reference, humans are estimated to make at least 100,000 proteins, but the number of human genes is only about 20,000–25,000. Don't worry about memorizing these numbers, though; they are constantly changing with new research. Alternative splicing is also known to function in the regulation of gene expression, in addition to generating protein diversity.

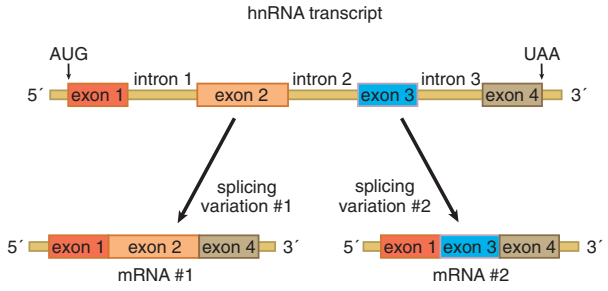

Figure 7.10. Alternative Splicing of Eukaryotic hnRNA to Produce Different Proteins

Mnemonic

Introns stay **in** the nucleus; **ex**ons will **ex**it the nucleus as part of the mRNA.

Real World

Mutations in splice sites can lead to abnormal proteins. For example, mutations that interfere with proper splicing of β-globulin mRNA are responsible for some cases of *β-thalassemia*, a group of blood disorders that hinder the production and efficacy of hemoglobin in the blood. Splice site mutations are one of the few mutations in noncoding DNA that may still have an effect on the translated protein.

MCAT Concept Check 7.2:

Before you move on, assess your understanding of the material with these questions.

1. What is the role of each eukaryotic RNA polymerase?
   - RNA polymerase I:

     _____
   - RNA polymerase II:

     _____
   - RNA polymerase III:

     _____
2. When starting transcription, where does RNA polymerase bind?

   _____
3. What are the three major posttranscriptional modifications that turn hnRNA into mature mRNA?

   1. _____
   2. _____
   3. _____
4. What is alternative splicing, and what does it accomplish?

   _____

   _____

7.3 Translation

Once the mRNA transcript is created and processed, it can exit the nucleus through **nuclear pores**. Once in the cytoplasm, mRNA finds a ribosome to begin the process of **translation**—converting the mRNA transcript into a functional protein. Translation is a complex process that requires mRNA, tRNA, ribosomes, amino acids, and energy in the form of GTP.

THE RIBOSOME

As mentioned earlier, the anticodon of the tRNA binds to the codon on the mature mRNA in the ribosome. The **ribosome** is composed of proteins and rRNA. In both prokaryotes and eukaryotes, there are large and small

Key Concept

Terminology and 5′ ⟶ 3′

- DNA ⟶ DNA = replication: new DNA synthesized in 5′ ⟶ 3′ direction
- DNA ⟶ RNA = transcription: new RNA synthesized in 5′ ⟶ 3′ direction (template is read 3′ ⟶ 5′)
- RNA ⟶ protein = translation: mRNA read in 5′ ⟶ 3′ direction

subunits; the subunits only bind together during protein synthesis. The structure of the ribosome dictates its main function, which is to bring the mRNA message together with the charged aminoacyl-tRNA complex to generate the protein. There are three binding sites in the ribosome for tRNA: the A site (aminoacyl), P site (peptidyl), and E site (exit). These are described further in the section on translation below.

Eukaryotic ribosomes contain four strands of rRNA, designated the 28S, 18S, 5.8S, and the 5S rRNAs; the "S" values indicate the size of the strand. The genes for some of the rRNAs (28S, 18S, and 5.8S rRNAs) used to construct the ribosome are found in the nucleolus. RNA polymerase I transcribes the 28S, 18S, and 5.8S rRNAs as a single unit within the nucleolus, which results in a 45S ribosomal precursor RNA. This 45S pre-rRNA is processed to become the 18S rRNA of the 40S (small) ribosomal subunit and to the 28S and 5.8S rRNAs of the 60S (large) ribosomal subunit. RNA polymerase III transcribes the 5S rRNA, which is also found in the 60S ribosomal subunit; this process takes place outside of the nucleolus. The ribosomal subunits created are the 60S and 40S subunits; these subunits join during protein synthesis to form the whole 80S ribosome.

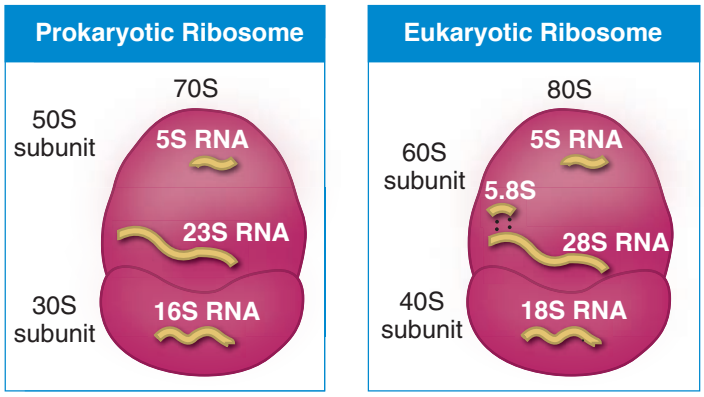

Figure 7.11. The Composition of Prokaryotic and Eukaryotic Ribosomes

In comparison with eukaryotes, prokaryotes have 50S and 30S large and small subunits, which assemble to create the complete 70S ribosome. Note that the "S" value is determined experimentally by studying the behavior of particles in a ultracentrifuge; thus, the numbers of each subunit and each rRNA are not additive because they are based on size and shape, not size alone. The structure of eukaryotic and prokaryotic ribosomes are shown in Figure 7.11.

Real World

The fact that prokaryotic and eukaryotic ribosomes have slightly different structure is no small fact. This difference allows us to target antibiotics, like macrolides (*azithromycin*, *erythromycin*), tetracyclines (*doxycycline*), *vancomycin*, and others to bacterial cells with fewer side effects to humans.

MECHANISM OF TRANSLATION

Translation occurs in the cytoplasm in prokaryotes and eukaryotes. In prokaryotes, the ribosomes start translating before the mRNA is complete; in eukaryotes, however, transcription and translation occur at separate times and in separate locations

within the cell. The process of translation occurs in three stages, as shown in Figure 7.12: **initiation**, **elongation**, and **termination**. Specialized factors for initiation (initiation factors, IF), elongation (elongation factors, EF), and termination (release factors, RF), as well as GTP are required for each step.

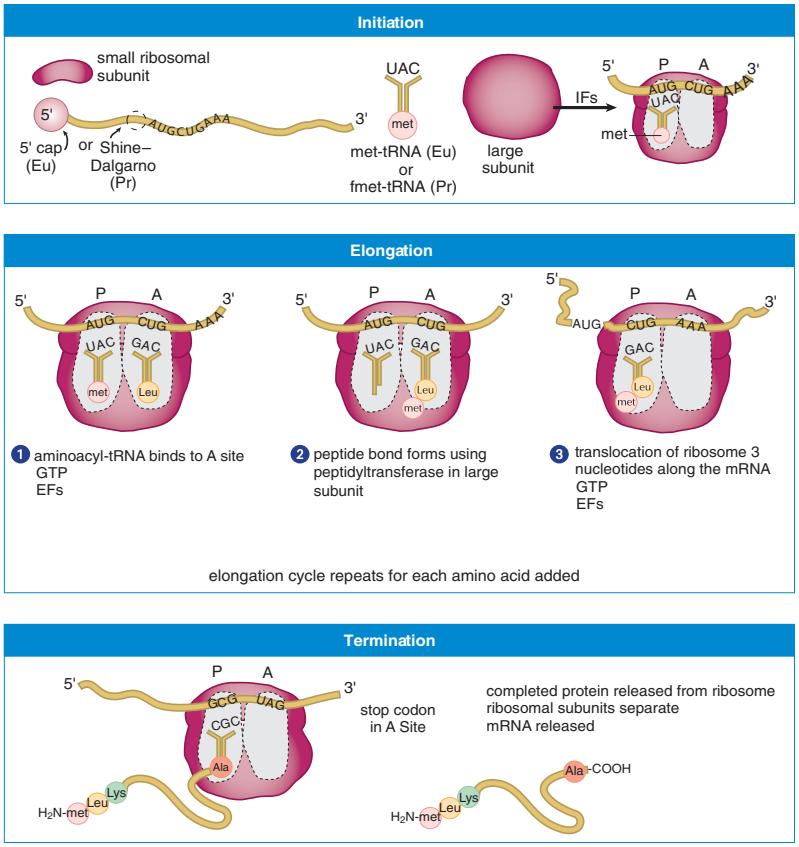

Figure 7.12. Steps in Translation

Initiation

The small ribosomal subunit binds to the mRNA. In prokaryotes, the small subunit binds to the **Shine–Dalgarno sequence** in the 5′ untranslated region of the mRNA. In eukaryotes, the small subunit binds to the 5′ cap structure. The charged **initiator tRNA** binds to the AUG **start codon** through base-pairing with its anticodon within the P site of the ribosome. The initial amino acid in prokaryotes is *N-formylmethionine* (fMet); in eukaryotes, it's methionine.

The large subunit then binds to the small subunit, forming the completed initiation complex. This is assisted by **initiation factors** (**IF**) that are not permanently associated with the ribosome.

Mnemonic

Order of sites in the ribosome during translation: **APE.**

Elongation

Elongation is a three-step cycle that is repeated for each amino acid added to the protein after the initiator methionine. During elongation, the ribosome moves in the 5′ to 3′ direction along the mRNA, synthesizing the protein from its amino (N-) to carboxyl (C-) terminus. The ribosome contains three very important binding sites:

- The **A site** holds the incoming aminoacyl-tRNA complex. This is the next amino acid that is being added to the growing chain, and is determined by the mRNA codon within the A site.
- The **P site** holds the tRNA that carries the growing polypeptide chain. It is also where the first amino acid (methionine) binds because it is starting the polypeptide chain. A **peptide bond** is formed as the polypeptide is passed from the tRNA in the P site to the tRNA in the A site. This requires ***peptidyl transferase***, an enzyme that is part of the large subunit. GTP is used for energy during the formation of this bond.
- The **E site** (not shown in Figure 7.12) is where the now inactivated (uncharged) tRNA pauses transiently before exiting the ribosome. As the now-uncharged tRNA enters the E site, it quickly unbinds from the mRNA and is ready to be recharged.

Elongation factors (**EF**) assist by locating and recruiting aminoacyl-tRNA along with GTP, while helping to remove GDP once the energy has been used.

Some eukaryotic proteins contain signal sequences, which designate a particular destination for the protein, as shown in Figure 7.13. For peptides that will be secreted, such as hormones and digestive enzymes, a signal sequence directs the ribosome to move to the endoplasmic reticulum (ER), so that the protein can be translated directly into the lumen of the rough ER. From there, the protein can be sent to the Golgi apparatus and be secreted from a vesicle via exocytosis. Other signal sequences direct proteins to the nucleus, lysosomes, or cell membrane.

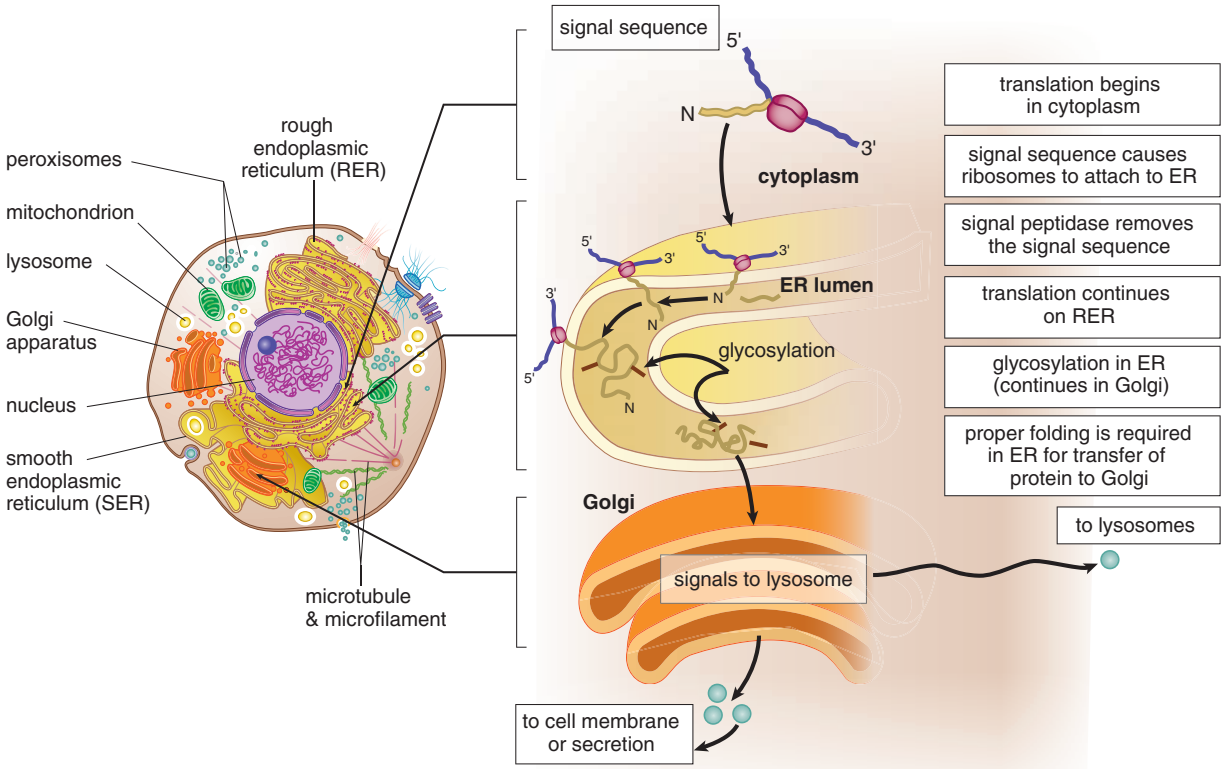

Figure 7.13. Synthesis of Secretory, Membrane, and Lysosomal Proteins

Termination

When any of the three stop codons moves into the A site, a protein called **release factor** (**RF**) binds to the termination codon, causing a water molecule to be added to the polypeptide chain. The addition of this water molecule allows peptidyl transferase and **termination factors** to hydrolyze the completed polypeptide chain from the final tRNA. The polypeptide chain will then be released from the tRNA in the P site, and the two ribosomal subunits will dissociate.

POSTTRANSLATIONAL PROCESSING

The nascent polypeptide chain is subject to posttranslational modifications before it will become a functioning protein, similar to how hnRNA is modified prior to being released from the nucleus. One essential step for the final synthesis of the protein is proper folding. There is a specialized class of proteins called **chaperones**, the main function of which is to assist in the protein-folding process.

Many proteins are also modified by cleavage events. A common example of this is insulin, which needs to be cleaved from a larger, inactive peptide to achieve its active form. In peptides with signal sequences, the signal sequence must be cleaved if the protein is to enter the organelle and accomplish its function.

In peptides with quaternary structure, subunits come together to form the functional protein. A classic example is hemoglobin, which is composed of two alpha chains and two beta chains.

Other biomolecules may be added to the peptide via the following processes:

- **Phosphorylation**—addition of phosphates by protein kinases to activate or deactivate proteins
- **Carboxylation**—addition of carboxylic acid groups, usually to serve as calcium-binding sites
- **Glycosylation**—addition of oligosaccharides as proteins pass through the ER and Golgi apparatus to determine cellular destination
- **Prenylation**—addition of lipid groups to certain membrane-bound enzymes

Real World

Posttranslational modifications are often important for proper protein functioning. For example, several clotting factors, including prothrombin, require posttranslational carboxylation of some of their glutamic acid residues in order to function properly. Vitamin K is required as a cofactor for these reactions; thus, vitamin K deficiency may result in a bleeding disorder.

MCAT Concept Check 7.3:

Before you move on, assess your understanding of the material with these questions.

1. What are the three steps of translation?

   1. _____
   2. _____
   3. _____

2. What are the roles of each site in the ribosome?

   - A site:

     _____

   - P site:

     _____

   - E site:

     _____

3. What are the major posttranslational modifications that occur in proteins?

_____

_____

_____

7.4 Control of Gene Expression in Prokaryotes

An organism's DNA encodes all of the RNA and protein molecules required to construct its cells. Yet organisms are able to differentially express their genes to make cell-specific products necessary for cellular development at specific times. In the next section, we'll look at these processes in eukaryotic cells; for now, we'll focus on the regulatory processes governing gene expression in prokaryotes—rules that are necessary in determining which subset of genes are selectively expressed or silenced in the prokaryotic cell.

OPERON STRUCTURE

The simplest example of an on–off switch that regulates gene expression levels in prokaryotes was discovered in *E. coli*. *E. coli* regulates the expression of many genes according to food sources that are available in the environment. For example, five genes in *E. coli* encode for enzymes that manufacture the amino acid tryptophan, and these are arranged in a cluster on the chromosome. By sharing a single common promoter region on the DNA sequence, these genes are transcribed as a group. This type of structure is called an **operon**—a cluster of genes transcribed as a single mRNA; this particular cluster in *E. coli* is known as the *trp* operon. Operons are incredibly common in the prokaryotic cell.

The **Jacob–Monod Model** is used to describe the structure and function of operons. In this model, operons contain structural genes, an operator site, a promoter site, and a regulator gene, as shown in Figure 7.14. The **structural gene** codes for the protein of interest. Upstream of the structural gene is the **operator site**, a nontranscribable region of DNA that is capable of binding a repressor protein. Further upstream is the **promoter site**, which is similar in function to promoters in eukaryotes: it provides a place for RNA polymerase to bind. Furthest still upstream is the **regulator gene**, which codes for a protein known as the **repressor**. There are two types of operons: inducible systems and repressible systems.

Key Concept

Operons include both inducible and repressible systems, and offer a simple on–off switch for gene control in prokaryotes.

INDUCIBLE SYSTEMS

In **inducible systems**, the repressor is bonded tightly to the operator system and thereby acts as a roadblock. RNA polymerase is unable to get from the promoter to the structural gene because the repressor is in the way. Such systems—in which the binding of a protein reduces transcriptional activity—are called **negative control** mechanisms. To remove that block, an inducer must bind the repressor protein so that RNA

polymerase can move down the gene, as shown in Figure 7.14. Inducible systems operate on a principle analogous to competitive inhibition for enzyme activity: as the concentration of the inducer increases, it will pull more copies of the repressor off of the operator region, freeing up those genes for transcription. This system is useful because it allows gene products to be produced only when they are needed.

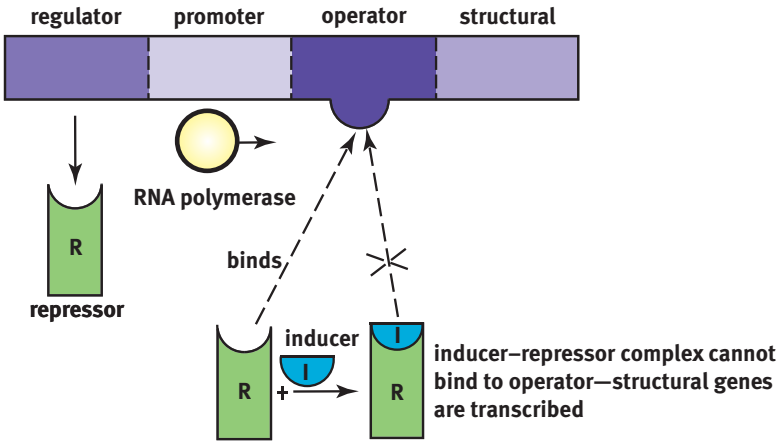

Figure 7.14. Inducible Systems
Allow for gene transcription only when an inducer is present to bind the otherwise present repressor protein.

A classic example of an inducible system is the *lac* operon, which contains the gene for *lactase*, as demonstrated in Figure 7.15. Bacteria can digest lactose, but it is more energetically expensive than digesting glucose. Therefore, bacteria only want to use this option if lactose is high and glucose is low. The *lac* operon is induced by the presence of lactose; thus, these genes are only transcribed when it is useful to the cell.

The *lac* operon is assisted by binding of the **catabolite activator protein** (**CAP**). CAP is a transcriptional activator used by *E. coli* when glucose levels are low to signal that alternative carbon sources should be used. Falling levels of glucose cause an increase in the signaling molecule cyclic AMP (cAMP), which binds to CAP. This induces a conformational change in CAP that allows it to bind the promoter region of the operon, further increasing transcription of the lactase gene. Such systems—in which the binding of a molecule increases transcription of a gene—are called **positive control** mechanisms.

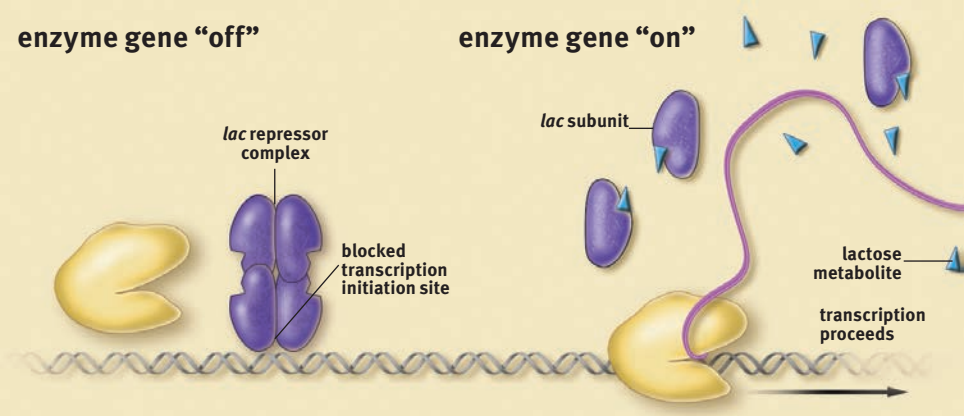

Figure 7.15. The *lac* Operon
An example of an inducible system.

REPRESSIBLE SYSTEMS

Repressible systems allow constant production of a protein product. In contrast to the inducible system, the repressor made by the regulator gene is inactive until it binds to a **corepressor**. This complex then binds the operator site to prevent further transcription, as shown in Figure 7.16. Repressible systems tend to serve as negative feedback; often, the final structural product can serve as a corepressor. Thus, as its levels increase, it can bind the repressor, and the complex will attach to the operator region to prevent further transcription of the same gene.

The *trp* operon, described above, operates in this way as a negative repressible system. When tryptophan is high in the local environment, it acts as a corepressor. The binding of two molecules of tryptophan to the repressor causes the repressor to bind the operator site. Thus, the cell turns off its machinery to synthesize its own tryptophan, which is an energetically expensive process because of its easy availability in the environment.

Key Concept

Negative control—The binding of a protein to DNA stops transcription.
Positive control—The binding of a protein to DNA increases transcription.
Inducible system—The system is normally "off" but can be made to turn "on," given a particular signal.
Repressible system—The system is normally "on" but can be made to turn "off," given a particular signal.

Any combination of control and system are possible; the *lac* operon is a negative inducible system whereas the *trp* operon is a negative repressible system.

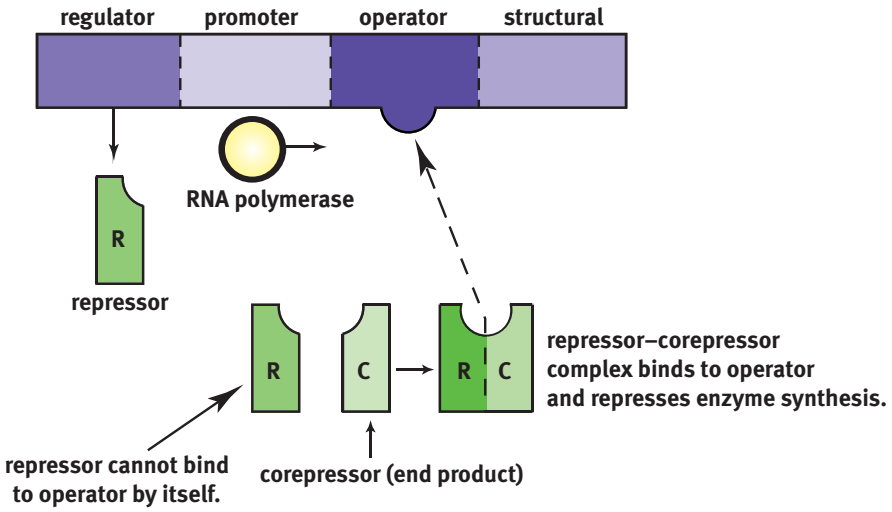

Figure 7.16. Repressible Systems
Continually allow gene transcription unless a corepressor binds to the repressor to stop transcription.

MCAT Concept Check 7.4:

Before you move on, assess your understanding of the material with these questions.

1. What type of operon is the *trp* operon? The *lac* operon?
   - *trp*: _____
   - *lac*: _____

2. From 5′ to 3′, what are the components of the operon, and what are their roles?

Component	Role

3. What is a positive control system? What is a negative control system?
   - Positive control system:

     _____
   - Negative control system:

     _____

7.5 Control of Gene Expression in Eukaryotes

Genomic expression in eukaryotes is considerably more complex than in prokaryotes, and you will need to know those differences for Test Day. Regulation of gene expression is an essential feature that helps in maintaining the overall functionality of cells. In addition to basic transcriptional enzymes, however, there are a host of other regulatory proteins that play a prominent role in controlling gene expression levels in the cell.

TRANSCRIPTION FACTORS

Transcription factors are transcription-activating proteins that search the DNA looking for specific DNA-binding motifs. Transcription factors tend to have two recognizable domains: a DNA-binding domain and an activation domain. The **DNA-binding domain** binds to a specific nucleotide sequence in the promoter region or to a DNA **response element** (a sequence of DNA that binds only to specific transcription factors) to help in the recruitment of transcriptional machinery. The **activation domain** allows for the binding of several transcription factors and other important regulatory proteins, such as RNA polymerase and histone acetylases, which function in the remodeling of the chromatin structure.

GENE AMPLIFICATION

Once the transcription complex is formed, basal (or low-level) transcription can begin and maintain moderate, but adequate, levels of the protein encoded by this gene in the cell. There are times, however, when the expression must be increased, or **amplified**, in response to specific signals such as hormones, growth factors, and other intracellular conditions. Eukaryotic cells accomplish this through enhancers and gene duplication.

Enhancers

Response elements outside the normal promoter regions can be recognized by specific transcription factors to enhance transcription levels. Several response elements may be grouped together to form an **enhancer**, which allows for the control of one gene's expression by multiple signals. Figure 7.17 demonstrates a eukaryotic example of an enhancer. Signal molecules, like cyclic AMP (cAMP), cortisol, and estrogen, bind to specific receptors. For the examples given, these receptors are cyclic AMP response element-binding protein (CREB), the glucocorticoid (cortisol) receptor, and the estrogen receptor, respectively; all are transcription factors that bind to their respective response elements within the

Key Concept

The DNA regulatory base sequences (such as promoters, enhancers, and response elements) are known as *cis* regulators because they are in the same vicinity as the gene they control. Transcription factors, however, have to be produced and translocated back to the nucleus; thus they are called *trans* regulators because they travel through the cell to their point of action.

enhancer. Other proteins are involved in this process, but are outside the scope of the MCAT. Note that the large distance between the enhancer and promoter regions for a given gene means that DNA often must bend into a hairpin loop to bring these elements together spatially.

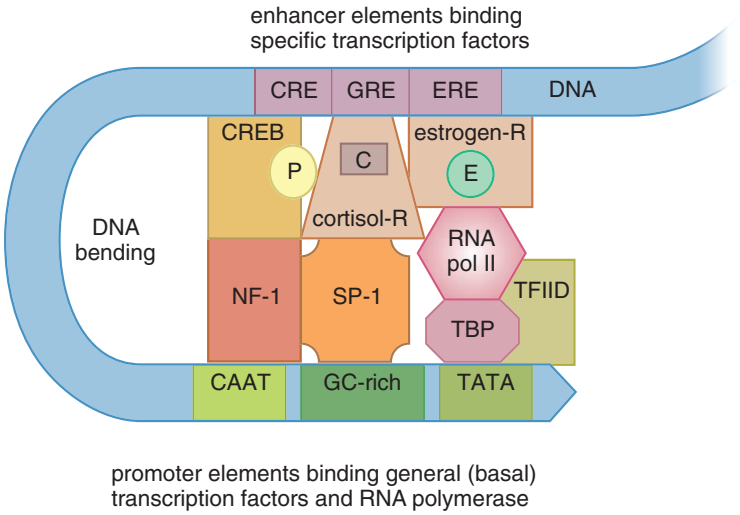

Figure 7.17. Stimulation of Transcription by an Enhancer and Its Associated Transcription Factors

Enhancer regions in the DNA can be up to 1000 base pairs away from the gene they regulate and can even be located within an intron, or noncoding region, of the gene. They differ from upstream promoter elements in their locations because upstream promoter elements must be within 25 bases of the start of a gene. By utilizing enhancer regions, genes have an increased likelihood to be amplified because of the variety of signals that can increase transcription levels.

Gene Duplication

Cells can also increase the expression of a gene product by duplicating the relevant gene. Genes can be duplicated in series on the same chromosome, yielding many copies in a row of the same genetic information. Genes can also be duplicated in parallel by opening the gene with helicases and permitting DNA replication only of that gene; cells can continue replicating the gene until hundreds of copies of the gene exist in parallel on the same chromosome.

REGULATION OF CHROMATIN STRUCTURE

In eukaryotic cells, DNA is packaged in the nucleus as chromatin, which requires chromatin remodeling to allow transcription factors and the transcriptional machinery easier access to the DNA. **Heterochromatin** is tightly coiled DNA that appears dark under the microscope; its tight coiling makes it inaccessible to the transcription

machinery, so these genes are inactive. **Euchromatin**, on the other hand, is looser and appears light under the microscope; the transcription machinery can access the genes of interest, so these genes are active. Remodeling of the chromatin structures regulates gene expression levels in the cell.

Histone Acetylation

Transcription factors that bind to the DNA can recruit other coactivators such as ***histone acetylases***. These proteins are involved in chromatin remodeling, as shown in Figure 7.18, because they acetylate lysine residues found in the amino terminal tail regions of histone proteins. **Acetylation** of histone proteins decreases the positive charge on lysine residues and weakens the interaction of the histone with DNA, resulting in an open chromatin conformation that allows for easier access of the transcriptional machinery to the DNA.

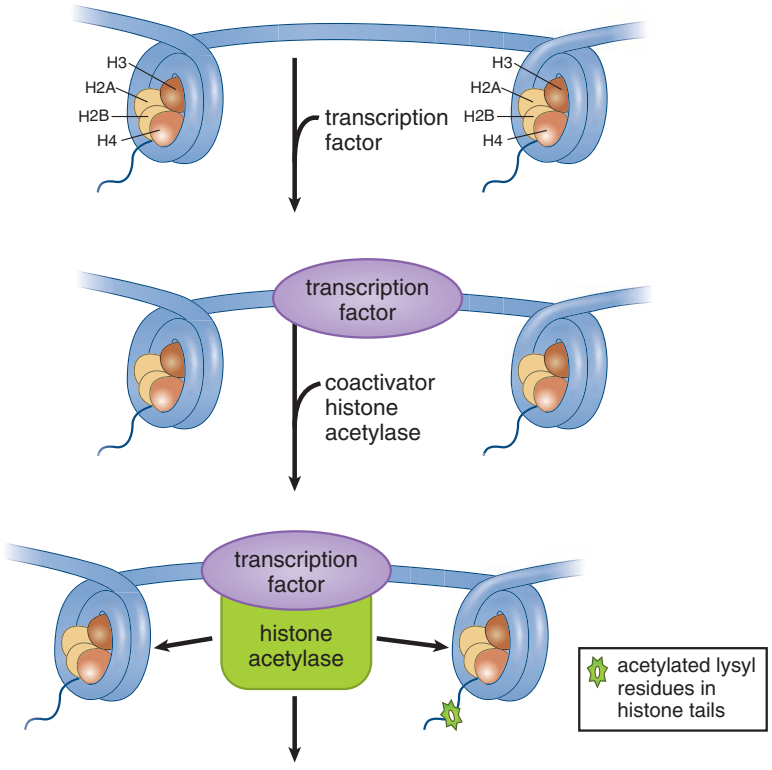

Figure 7.18. Chromatin Remodeling by Acetylation
Increases space between histones, allowing better access to DNA for transcription factors.

Specific patterns of histone acetylation can lead to increased gene expression levels. On the other hand, gene silencing can occur just as easily with chromatin remodeling. ***Histone deacetylases*** are proteins that function to remove acetyl groups from histones, which results in a closed chromatin conformation and overall decrease in gene expression levels in the cell.

DNA Methylation

DNA methylation is also involved in chromatin remodeling and regulation of gene expression levels in the cell. ***DNA methylases*** add methyl groups to cytosine and adenine nucleotides; methylation of genes is often linked with the silencing of gene expression. During development, methylation plays an important role in silencing genes that no longer need to be activated. Heterochromatin regions of the DNA are much more heavily methylated, hindering access of the transcriptional machinery to the DNA.

MCAT Concept Check 7.5:

Before you move on, assess your understanding of the material with these questions.

1. In an enhancer, what are the differences between signal molecules, transcription factors, and response elements?

_____

_____

_____

2. By what histone and DNA modifications can genes be silenced in eukaryotic cells? Would these processes increase the proportion of heterochromatin or euchromatin?

_____

_____

Conclusion

To carry out the functions of life, we must produce around 100,000 different proteins using our 20,000–25,000 available genes. Every protein in the biosphere is produced through the central dogma of molecular biology, as genes in DNA are transcribed into mRNA and then translated into a functional protein. This is a complex, highly regulated process in both prokaryotes and eukaryotes, and questions on transcription and translation, and their regulation, are frequent on the MCAT.

The last two chapters focused on the important roles played by many organelles in the cell, including the nucleus, nucleolus, ribosome, rough endoplasmic reticulum, and Golgi apparatus. After secreted proteins such as hormones and digestive enzymes are produced, they make their way to the plasma membrane for exocytosis. It is this last stop that we'll examine in the next chapter: the structure, function, and biochemistry of biological membranes.

CONCEPT SUMMARY

The Genetic Code

- The **central dogma** states that DNA is transcribed to RNA, which is translated to protein.
- A degenerate code allows multiple codons to encode for the same amino acid.
  - Initiation (start) codon: AUG
  - Termination (stop) codons: UAA, UGA, UAG
- Redundancy and **wobble** (third base in the codon) allows mutations to occur without effects in the protein.
- Point mutations can cause:
  - **Silent** mutations with no effect on protein synthesis.
  - **Nonsense** (**truncation**) mutations that produce a premature stop codon.
  - **Missense** mutations that produce a codon that codes for a different amino acid.
- **Frameshift mutations** result from nucleotide addition or deletion, and change the reading frame of subsequent codons.
- RNA is structurally similar to DNA except:
  - Substitution of a ribose sugar for deoxyribose.
  - Substitution of uracil for thymine.
  - It is single-stranded instead of double-stranded.
- There are three types of RNA with separate jobs in transcription:
  - **Messenger RNA** (**mRNA**) carries the message from DNA in the nucleus via transcription of the gene; it travels into the cytoplasm to be translated.
  - **Transfer RNA** (**tRNA**) brings in amino acids and recognizes the codon on the mRNA using its anticodon.
  - **Ribosomal RNA** (**rRNA**) makes up the ribosome and is enzymatically active.

Transcription

  - **Helicase** unwinds the DNA double helix.
  - **RNA polymerase II** binds to the **TATA box** within the **promoter** region of the gene (25 base pairs upstream from first transcribed base).
  - **hnRNA** is synthesized from the DNA template (antisense) strand.
- Posttranscriptional modifications include:
  - A 7-methylguanylate triphosphate cap is added to the 5′ end.
  - A polyadenosyl (poly-A) tail is added to the 3′ end.

- Splicing is done by snRNA and snRNPs in the **spliceosome**; introns are removed in a **lariat** structure, and exons are ligated together.
- Prokaryotic cells can increase the variability of gene products from one transcript through **polycistronic genes** (in which starting transcription in different sites within the gene leads to different gene products).
- Eukaryotic cells can increase variability of gene products through **alternative splicing** (combining different exons in a modular fashion to acquire different gene products).

Translation

- tRNA translates the codon into the correct amino acid.
- Ribosomes are the factories where translation (protein synthesis) occurs.
- There are three stages of **translation**.
  - **Initiation** in prokaryotes occurs when the 30S ribosome attaches to the **Shine–Dalgarno sequence** and scans for a start codon; it lays down *N*-formylmethionine in the P site of the ribosome.
  - Initiation in eukaryotes occurs when the 40S ribosome attaches to the 5′ cap and scans for a start codon; it lays down methionine in the P site of the ribosome.
  - **Elongation** involves the addition of a new aminoacyl-tRNA into the A site of the ribosome and transfer of the growing polypeptide chain from the tRNA in the P site to the tRNA in the A site. The now uncharged tRNA pauses in the E site before exiting the ribosome.
  - **Termination** occurs when the codon in the A site is a stop codon; **release factor** places a water molecule on the polypeptide chain and thus releases the protein.
  - Initiation, elongation, and release factors help with each step in recruitment and assembly/disassembly of the ribosome.
- Posttranslational modifications include:
  - Folding by **chaperones**
  - Formation of quaternary structure
  - Cleavage of proteins or signal sequences
  - Covalent addition of other biomolecules (phosphorylation, carboxylation, glycosylation, prenylation)

Control of Gene Expression in Prokaryotes

- The **Jacob–Monod model** of repressors and activators explains how operons work.
  - **Operons** are inducible or repressible clusters of genes transcribed as a single mRNA.

- **Inducible systems** (such as the *lac* operon) are bonded to a **repressor** under normal conditions; they can be turned on by an **inducer** pulling the repressor from the **operator site**.
- **Repressible systems** (such as the *trp* operon) are transcribed under normal conditions; they can be turned off by a corepressor coupling with the repressor and the binding of this complex to the operator site.

Control of Gene Expression in Eukaryotes

- **Transcription factors** search for promoter and enhancer regions in the DNA.
  - **Promoters** are within 25 base pairs of the transcription start site.
  - **Enhancers** are more than 25 base pairs away from the transcription start site.
  - Modification of chromatin structure affects the ability of transcriptional enzymes to access the DNA through histone acetylation (increases accessibility) or DNA methylation (decreases accessibility).

ANSWERS TO CONCEPT CHECKS

7.1

1. mRNA carries information from DNA by traveling from the nucleus (where it is transcribed) to the cytoplasm (where it is translated). tRNA translates nucleic acids to amino acids by pairing its anticodon with mRNA codons; it is charged with an amino acid, which can be added to the growing peptide chain. rRNA forms much of the structural and catalytic component of the ribosome, and acts as a ribozyme to create peptide bonds between amino acids.
2.
   - GAT: mRNA codon = AUC; Isoleucine (Ile)
   - ATT: mRNA codon = AAU; Asparagine (Asn)
   - CGC: mRNA codon = GCG; Alanine (Ala)
   - CCA: mRNA codon = UGG; Tryptophan (Trp)
3. The start codon is AUG, which codes for methionine; the stop codons are UAA, UGA, and UAG.
4. Wobble refers to the fact that the third base in a codon often plays no role in determining which amino acid is translated from that codon. For example, any codon starting with "CC" codes for proline, regardless of which base is in the third (wobble) position. This is protective because mutations in the wobble position will not have any effect on the protein translated from that gene.
5.

Type of Mutation	Change in DNA Sequence	Effect on Encoded Protein
Silent (degenerate)	Substitution of bases in the wobble position, introns, or noncoding DNA	No change observed
Missense	Substitution of one base, creating an mRNA codon that matches a different amino acid	One amino acid is changed in the protein; variable effects on function depending on specific change
Nonsense	Substitution of one base, creating a stop codon	Early truncation of protein; variable effects on function, but usually more severe than missense mutations
Frameshift	Insertion or deletion of bases, creating a shift in the reading frame of the mRNA	Change in most amino acids after the site of insertion or deletion; usually the most severe of the types listed here

7.2

1. RNA polymerase I synthesizes most rRNA. RNA polymerase II synthesizes mRNA (hnRNA) and snRNA. RNA polymerase III synthesizes tRNA and some rRNA.
2. RNA polymerase II binds to the TATA box, which is located within the promoter region of a relevant gene, at about –25.
3. The major posttranscriptional modifications are:
   - Splicing: removal of introns, joining of exons. Uses snRNA and snRNPs in the spliceosome to create a lariat, which is then degraded. Exons are ligated together
   - 5′ cap: addition of a 7-methylguanylate triphosphate cap to the 5′ end of the transcript
   - 3′ poly-A tail: addition of adenosine bases to the 3′ end to protect against degradation
4. Alternative splicing is the ability of some genes to use various combinations of exons to create multiple proteins from one hnRNA transcript. This increases protein diversity and allows a species to maximize the number of proteins it can create from a limited number of genes.

7.3

1. Initiation, elongation, and termination
2. - A site: binds incoming aminoacyl-tRNA using codon–anticodon pairing
   - P site: holds growing polypeptide until peptidyl transferase forms peptide bond and polypeptide is handed to A site
   - E site: transiently holds uncharged tRNA as it exits the ribosome
3. Posttranslational modifications include proper folding by chaperones, formation of quaternary structure, cleavage of proteins or signal sequences, and addition of other biomolecules (phosphorylation, carboxylation, glycosylation, prenylation).

7.4

1. The *trp* operon is a negative repressible system; the *lac* operon is a negative inducible system.

2.

Component	Role
Regulator gene	Transcribed to form repressor protein
Promoter site	Site of RNA polymerase binding (similar to promoters in eukaryotes)
Operator site	Binding site for repressor protein
Structural gene	The gene of interest; its transcription is dependent on the repressor being absent from the operator site

3. Positive control systems require the binding of a protein to the operator site to increase transcription. Negative control systems require the binding of a protein to the operator site to decrease transcription.

7.5

1. Signal molecules include steroid hormones and second messengers, which bind to their receptors in the nucleus. These receptors are transcription factors that use their DNA-binding domain to attach to a particular sequence in DNA called a response element. Once bonded to the response element, these transcription factors can then promote increased expression of the relevant gene.
2. Histone deacetylation and DNA methylation will both downregulate the transcription of a gene. These processes allow the relevant DNA to be clumped more tightly, increasing the proportion of heterochromatin.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. What role does peptidyl transferase play in protein synthesis?

A. It transports the initiator aminoacyl-tRNA complex.
B. It helps the ribosome to advance three nucleotides along the mRNA in the 5′ to 3′ direction.
C. It holds the protein in its tertiary structure.
D. It catalyzes the formation of a peptide bond.

2. Which stage of protein synthesis does NOT require energy?

A. Initiation
B. Elongation
C. Termination
D. All stages of protein synthesis require energy.

3. Topoisomerases are enzymes involved in:

A. DNA replication and transcription.
B. posttranscriptional processing.
C. RNA synthesis and translation.
D. posttranslational processing.

4. Val-tRNA^{Val} is the tRNA that carries valine to the ribosome during translation. Which of the following sequences gives an appropriate anticodon for this tRNA? (Note: Refer back to Figure 7.5 for a genetic code table.)

A. CAU
B. AUC
C. UAC
D. GUG

5. Enhancers are transcriptional regulatory sequences that function by enhancing the activity of:

A. RNA polymerase at a single promoter site.
B. RNA polymerase at multiple promoter sites.
C. spliceosomes and lariat formation in the ribosome.
D. transcription factors that bind to the promoter but not to RNA polymerase.

6. In the genetic code of human nuclear DNA, one of the codons specifying the amino acid tyrosine is UAC. If one nucleotide is changed, and the codon is mutated to UAG, what type of mutation will occur?

A. Silent mutation
B. Missense mutation
C. Nonsense mutation
D. Frameshift mutation

7. A double-stranded RNA genome isolated from a virus was found to contain 15% uracil. What percentage of guanine should exist in this virus's genome?

A. 15%
B. 35%
C. 70%
D. 85%

8. When trypsin converts chymotrypsinogen to chymotrypsin, some molecules of chymotrypsin bind to a repressor, which in turn binds to an operator region and prevents further transcription of trypsin. This is most similar to which of the following operons?

A. *trp* operon during lack of tryptophan
B. *trp* operon during abundance of tryptophan
C. *lac* operon during lack of lactose
D. *lac* operon during abundance of lactose

9. Which of the following RNA molecules or proteins is NOT found in the spliceosome during intron excision?

A. snRNA
B. hnRNA
C. shRNA
D. snRNPs

10. A 4-year old toddler with cystic fibrosis (CF) is seen by his physician for an upper respiratory infection. Prior genetic testing has shown that there has been a deletion of three base pairs in exon 10 of the *CFTR* gene that affects codons 507 and 508. The nucleotide sequence in this region for normal and mutant alleles is shown below (*X* denotes the missing nucleotide):

Codon number	506	507	508	509	510	511
Normal gene (coding strand)	ATC	ATC	TTT	GGT	GTT	TCC
Mutant gene (coding strand)	ATC	AT*X*	*XX*T	GGT	GTT	TCC

What effect will this mutation have on the amino acid sequence of the protein encoded by the *CFTR* gene?

A. Deletion of a phenylalanine residue with no change in the C-terminus sequence.
B. Deletion of a leucine residue with no change in the C-terminus sequence.
C. Deletion of a phenylalanine residue with a change in the C-terminus sequence.
D. Deletion of a leucine residue with a change in the C-terminus sequence.

11. A gene encodes a protein with 150 amino acids. There is one intron of 1000 base pairs (bp), a 5′-untranslated region of 100 bp, and a 3′-untranslated region of 200 bp. In the final mRNA, about how many bases lie between the start AUG codon and final termination codon?

A. 150
B. 450
C. 650
D. 1750

12. Peptidyl transferase connects the carboxylate group of one amino acid to the amino group of an incoming amino acid. What type of linkage is created in this peptide bond?

A. Ester
B. Amide
C. Anhydride
D. Ether

13. A eukaryotic cell has been found to exhibit a truncation mutation that creates an inactive RNA polymerase I enzyme. Which type of RNA will be affected by this inactivation?

A. rRNA
B. tRNA
C. snRNA
D. hnRNA

14. You have just sequenced a piece of DNA that reads as follows:

5′—TCTTTGAGACATCC—3′

What would the base sequence of the mRNA transcribed from this DNA be?

A. 5′—AGAAACUCUGUAGG—3′
B. 5′—GGAUGUCUCAAAGA—3′
C. 5′—AGAAACTCTGTAGG—3′
D. 5′—GGATCTCTCAAAGA—3′

15. Double-stranded RNA cannot be translated by the ribosome and is marked for degradation in the cell. Which of the following strands of RNA would prevent mature mRNA in the cytoplasm from being transcribed?

A. Identical mRNA to the one produced
B. Antisense mRNA to the one produced
C. mRNA with thymine substituted for uracil
D. Sense mRNA to the one produced

Explanations to Discrete Practice Questions

1. D

Peptidyl transferase is an enzyme that catalyzes the formation of a peptide bond between the incoming amino acid in the A site and the growing polypeptide chain in the P site. Initiation and elongation factors help transport charged tRNA molecules into the ribosome and advance the ribosome down the mRNA transcript, as in **choices (A)** and **(B)**. Chaperones maintain a protein's three-dimensional shape as it is formed, as in **choice (C)**.

2. D

All three stages of protein synthesis (initiation, elongation, and termination) require large amounts of energy.

3. A

Topoisomerases, such as prokaryotic DNA gyrase, are involved in DNA replication and mRNA synthesis (transcription). DNA gyrase is a type of topoisomerase that enhances the action of helicase enzymes by the introduction of negative supercoils into the DNA molecule. These negative supercoils facilitate DNA replication by keeping the strands separated and untangled.

4. C

There are four different codons for valine: GUU, GUC, GUA, and GUG. Through base-pairing, we can determine that the proper anticodon must end with "AC." Remember that the codon and anticodon are antiparallel to each other, and that nucleic acids are always written $5' \rightarrow 3'$ on the MCAT. Therefore, we are looking for an answer that ends with "AC" (rather than starting with "CA").

5. A

Specific transcription factors bind to a specific DNA sequence, such as an enhancer, and to RNA polymerase at a single promoter sequence. They enable the RNA polymerase to transcribe the specific gene for that enhancer more efficiently.

6. C

UAG is one of the three known stop codons, so changing tyrosine to a stop codon must be a nonsense (or truncation) mutation.

7. B

The percentage of uracil must equal that of adenine due to base-pairing because the genome is double-stranded. This accounts for 30% of the genome. The remaining 70% must be split evenly between guanine and cytosine, so they each account for 35% of the genome.

8. B

The example given is a sample of repression due to the abundance of a corepressor. In other words, this is a repressible system that is currently blocking transcription. For the *trp* operon, an abundance of tryptophan in the environment allows for the repressor to bind tryptophan and then to the operator site. This blocks transcription of the genes required to synthesize tryptophan within the cell. The system described is a repressible system; the *lac* operon is an inducible system, in which an inducer binds to the repressor, thus permitting transcription.

9. C

shRNA (short hairpin RNA) is a useful biotechnology tool used in RNA interference. It is not, however, produced in the nucleus for use in the spliceosome. It targets mRNA to be degraded in the cytoplasm; it is not utilized in splicing of the hnRNA (heterogeneous nuclear RNA). snRNA (small nuclear RNA) and snRNPs (small nuclear ribonucleoproteins), however, do bind to the hnRNA to induce splicing.

10. A

In this table, we are given the sequence of the sense (coding) DNA strand. This will be identical to the mRNA transcript, except all thymine nucleotides will be replaced with uracil. With the deletion of these three bases, codon 507 changes from AUC to AUU in the transcript; these both code for isoleucine due to wobble. However, codon 508 (UUU in the transcript) has been lost. UUU codes for phenylalanine. The C-terminus sequence will remain unchanged because the deletion of three bases (exactly one codon) will not throw off the reading frame. For reference, the mutant reading frames would be:

AUC	AUU	GGU	GUU	UCC

11. B

The intron will not be a part of the final, processed mRNA, and the untranslated regions of the mRNA will not be turned into amino acids. Translation will begin with codon 1 (which would be AUG). Because there are 150 amino acids, we can surmise that there will be 151 codons. Each codon will use 3 nucleotides, so 150 × 3 = 450 because codon 151 will be the stop codon.

12. B

Peptidyl transferase connects the incoming amino terminal to the previous carboxyl terminal; the only functional group listed here with a carbonyl and amino group is the amide. Peptide bonds are thus amide linkages, and the correct answer is **choice (B)**.

13. A

RNA polymerase I in eukaryotes is found in the nucleolus and is in charge of transcribing most of the rRNA for use during ribosomal creation. RNA polymerase II is responsible for hnRNA and snRNA. RNA polymerase III is responsible for tRNA and the 5S rRNA.

14. B

To answer this question correctly, we must remember that mRNA will be antiparallel to DNA. Our answer should be 5′ to 3′ mRNA, with the 5′ end complementary to the 3′ end of the DNA that is being transcribed. Thus, the mRNA transcribed from this strand will be 5′—GGAUGUCUCAAAGA—3′. mRNA contains uracil, rather than thymine.

15. B

The mRNA produced has the same structure as the sense strand of DNA (with uracils instead of thymines). Because bonding of nucleic acids is always complementary but antiparallel, the antisense strand of mRNA would be the one that binds to the produced mRNA, creating double-stranded RNA that is then degraded once found in the cytoplasm.

Concept Summary 276

Introduction

Biological membranes are a stunning combination of opposites and contrasts. They are exceptionally thin, structurally bland, and relatively straightforward to describe. Yet, they define the borders of cells, tissues, and organelles; carry out a significant number of the biological functions within cells; and are an unending source of scientific inquiry and discovery. The most commonly tested biological membrane on the MCAT is the plasma membrane. At first, the plasma membrane seems like it's only a shell—just a barrier that defines the cell. But the plasma membrane plays roles in signaling, entry of nutrients and expulsion of waste, cell recognition, transport of materials between tissues, and even electronic functions.

Cell membranes have both a stretchy, flexible component (phospholipids) and an abundance of stabilizing molecules (cholesterol and protein) to make sure that everything remains intact. In this chapter, we will examine the general function, composition, and transport properties of biological membranes. We will conclude by taking a look at a few specialized cell membranes within the body, in addition to specific membrane properties.

8.1 Fluid Mosaic Model ★★

The **cell** (**plasma**) **membrane** is often described as a semipermeable phospholipid bilayer. This phrase alone describes both the function and structure of the cell membrane: as a semipermeable barrier, it chooses which particles can enter and leave the cell at any

point in time. This selectivity is mediated not only by the various channels and carriers that poke holes in the membrane, but also by the membrane itself. Composed primarily of two layers of phospholipids, the cell membrane permits fat-soluble compounds to cross easily, while larger and water-soluble compounds must seek alternative entry. The cell membrane is illustrated in Figure 8.1; the theory that underlies the structure and function of the cell membrane is referred to as the **fluid mosaic model**.

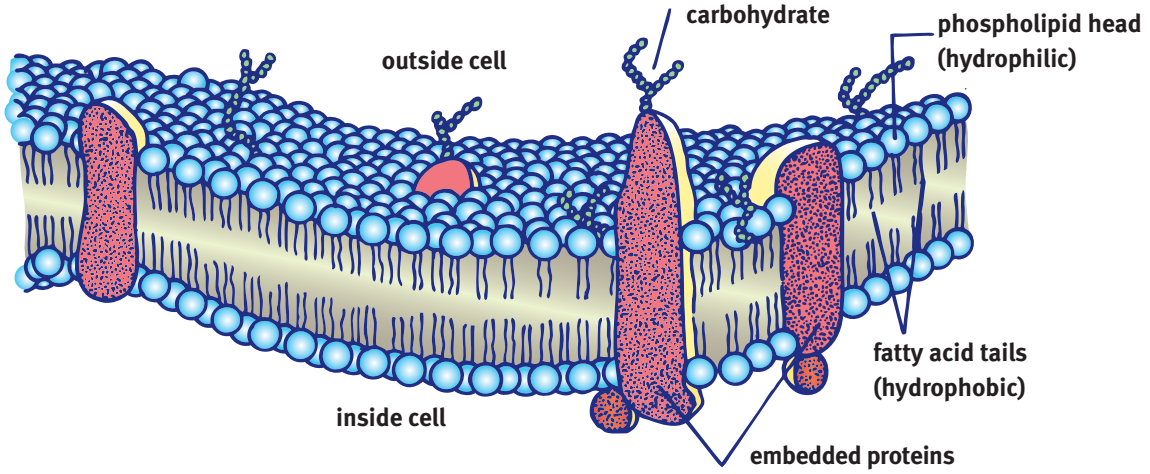

Figure 8.1. Cell Membrane
The cell membrane is a phospholipid bilayer that regulates movement of solutes into and out of the cell.

GENERAL MEMBRANE STRUCTURE AND FUNCTION

The phospholipid bilayer also includes proteins and distinct signaling areas within **lipid rafts**. Carbohydrates associated with membrane-bound proteins create a **glycoprotein coat**. The **cell wall** of plants, bacteria, and fungi contain higher levels of carbohydrates.

The main function of the cell membrane is to protect the interior of the cell from the external environment. Cellular membranes selectively regulate traffic into and out of the cell and are involved in both intracellular and intercellular communication and transport. Cell membranes also contain proteins embedded within the lipid bilayer that act as cellular receptors during signal transduction. These proteins play an important role in regulating and maintaining overall cellular activity.

MEMBRANE DYNAMICS

The cell membrane functions as a stable semisolid barrier between the cytoplasm and the environment, but it is in a constant state of flux on the molecular level. **Phospholipids** move rapidly in the plane of the membrane through simple diffusion.

This can be seen when fusing two membranes that have been tagged with different labels; the tags will migrate with their associated lipids until both types are rapidly intermixed. **Lipid rafts** are collections of similar lipids with or without associated proteins that serve as attachment points for other biomolecules; these rafts often serve roles in signaling. Both lipid rafts and proteins also travel within the plane of the membrane, but more slowly. Lipids can also move between the membrane layers, but this is energetically unfavorable because the polar head group of the phospholipid must be forced through the nonpolar tail region in the interior of the membrane. Specialized enzymes called **flippases** assist in the transition or "flip" between layers.

Dynamic changes in the concentrations of various membrane proteins are mediated by gene regulation, endocytotic activity, and protein insertion. Many cells, particularly those involved in biosignaling processes, can up- or downregulate the number of specific cellular receptors on their surface in order to meet cellular requirements.

Real World

Many antidepressants increase levels of neurotransmitters in the brain, but the effects take longer to appear than the changes in neurochemistry. The reason for this delay is that the nervous system must still upregulate its postsynaptic receptors to respond to the new levels of neurotransmitter.

MCAT Concept Check 8.1:

Before you move on, assess your understanding of the material with these questions.

1. Describe the role of flippases and lipid rafts in biological membranes.
   - Flippases:

     _____
   - Lipid rafts:

     _____
2. List the following membrane components in order from most plentiful to least plentiful: carbohydrates, lipids, proteins, nucleic acids.

_____>_____>_____>_____

8.2 Membrane Components ★★★★

While the fluid mosaic model outlines the general composition of the membrane, the MCAT expects us to have a stronger grasp of the specifics, especially as it pertains to lipids and proteins.

LIPIDS

The cell membrane is composed predominantly of lipids with some associated proteins and carbohydrates. At times, the cell membrane as a whole will be referred to as a phospholipid bilayer, as it is the primary component of this barrier around

the cell. Within the cell membrane, there are a large number of phospholipids with very few free fatty acids. In addition, steroid molecules and cholesterol, which lend fluidity to the membrane, and waxes, which provide membrane stability, help to maintain the structural integrity of the cell. While the structural details of these lipids were discussed in detail in Chapter 5 of *MCAT Biochemistry Review*, we will briefly describe their key points here.

Fatty Acids and Triacylglycerols

Fatty acids are carboxylic acids that contain a hydrocarbon chain and terminal carboxyl group. **Triacylglycerols**, also referred to as **triglycerides**, are storage lipids involved in human metabolic processes. They contain three fatty acid chains esterified to a glycerol molecule. Fatty acid chains can be saturated or unsaturated. **Unsaturated fatty acids** are regarded as "healthier" fats because they tend to have one or more double bonds and exist in liquid form at room temperature; in the plasma membrane, these characteristics impart fluidity to the membrane. Humans can only synthesize a few of the unsaturated fatty acids; the rest come from essential fatty acids in the diet that are transported as triacylglycerols from the intestine inside **chylomicrons**. Two important essential fatty acids for humans are *α-linolenic acid* and *linoleic acid*. **Saturated fatty acids** are the main components of animal fats and tend to exist as solids at room temperature. Saturated fats are found in processed foods and are considered less healthy. When incorporated into phospholipid membranes, saturated fatty acids decrease the overall membrane fluidity.

Real World

Trans fats, which result from the partial hydrogenation of some unsaturated fatty acids, have been banned from certain stores and cities because of their health risks. Part of the health concern is due to their ability to lower membrane fluidity, in addition to the tendency of *trans* fats to accumulate and form plaques in blood vessels.

Phospholipids

By substituting one of the fatty acid chains of triacylglycerol with a phosphate group, a polar head group joins the nonpolar tails, forming a **glycerophospholipid**, commonly called a phospholipid. Phospholipids spontaneously assemble into **micelles** (small monolayer vesicles) or **liposomes** (bilayered vesicles) due to hydrophobic interactions. Glycerophospholipids are used for membrane synthesis and can produce a hydrophilic surface layer on lipoproteins such as *very-low-density lipoprotein* (VLDL), a lipid transporter. In addition, phospholipids are the primary component of cell membranes. Phospholipids serve not only structural roles, but can also serve as second messengers in signal transduction. The phosphate group also provides an attachment point for water-soluble groups, such as *choline* (*phosphatidylcholine*, also known as *lecithin*) or *inositol* (*phosphatidylinositol*). A comparison of triacylglycerols and glycerophospholipids is shown in Figure 8.2.

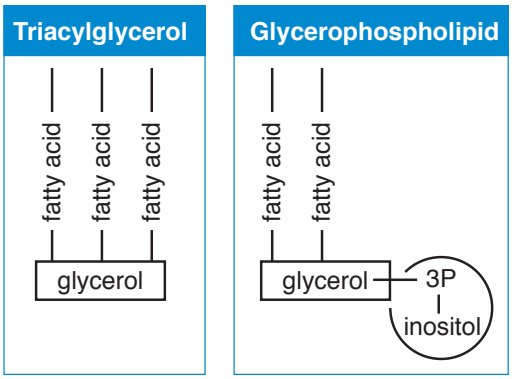

Figure 8.2. Triacylglycerol and Glycerophospholipid (Phosphatidylinositol)

Sphingolipids

Sphingolipids are also important constituents of cell membranes. Although sphingolipids do not contain glycerol, they are similar in structure to glycerophospholipids, in that they contain a hydrophilic region and two fatty acid-derived hydrophobic tails. The various classes of sphingolipids shown in Figure 8.3 differ primarily in the identity of their hydrophilic regions. Classes of sphingolipids and their hydrophilic groups include **ceramide**, **sphingomyelins**, **cerebrosides**, and **gangliosides**.

MCAT Expertise

The ratio of certain sphingolipids to glycerophospholipids can help to identify particular membranes within the cell, but memorizing this information is unnecessary for Test Day. Where small details like this are important, they will be provided in a passage.

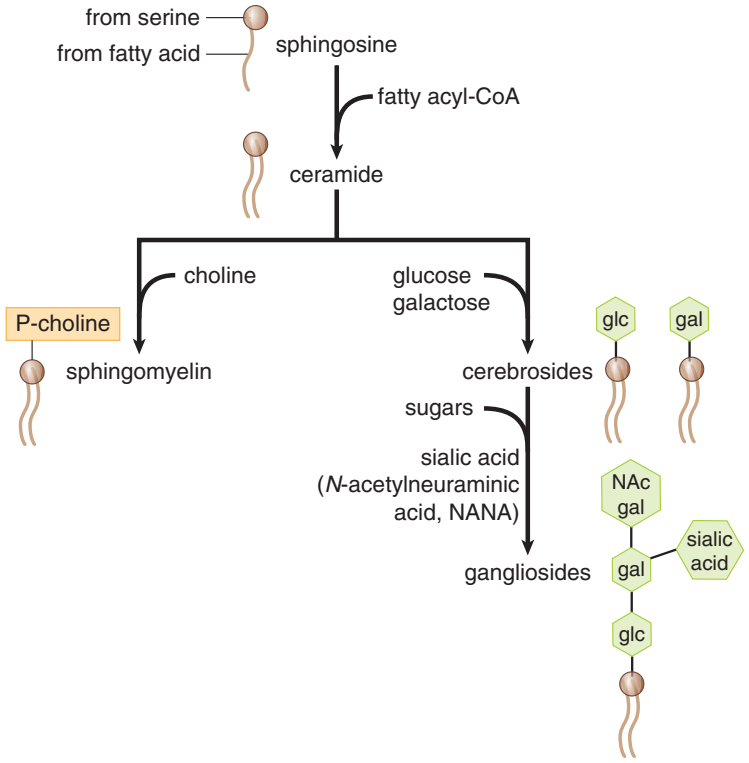

Figure 8.3. Types of Sphingolipids
Sphingolipids are sequentially modified to form each of the biologically necessary molecules in the class.

Cholesterol and Steroids

Cholesterol is associated with a number of negative health effects and receives a lot of negative press; however, it is also a very important molecule in our cells. **Cholesterol** not only regulates membrane fluidity, but it is also necessary in the synthesis of all **steroids**, which are derived from cholesterol.

The structure of cholesterol is similar to that of phospholipids in that cholesterol contains both a hydrophilic and hydrophobic region. Membrane stability is derived from interactions with both the hydrophilic and hydrophobic regions that make up the phospholipid bilayer. While cholesterol stabilizes adjacent phospholipids, it also occupies space between them. This prevents the formation of crystal structures in the membrane, increasing fluidity at lower temperatures. At high temperatures, cholesterol has the opposite effect: by limiting movement of phospholipids within the bilayer, it decreases fluidity and helps hold the membrane intact. By mass, cholesterol composes about 20 percent of the cell membrane; by mole fraction, it makes up about half. This large ratio of cholesterol to phospholipid ensures that the membrane remains fluid.

Waxes

Waxes are a class of lipids that are extremely hydrophobic and are rarely found in the cell membranes of animals, but are sometimes found in the cell membranes of plants. A wax is composed of a long-chain fatty acid and a long-chain alcohol, which contribute to the high melting point of these substances. When present within the cell membrane, waxes can provide both stability and rigidity within the nonpolar tail region only. Most waxes serve an extracellular function in protection or waterproofing.

PROTEINS

The **fluid mosaic model** also accounts for the presence of three types of membrane proteins, as shown in Figure 8.4. **Transmembrane proteins** pass completely through the lipid bilayer. **Embedded proteins**, on the other hand, are associated with only the interior (cytoplasmic) or exterior (extracellular) surface of the cell membrane. Together, transmembrane and embedded proteins are considered **integral proteins** because of their association with the interior of the plasma membrane, which is usually assisted by one or more membrane-associated domains that are partially hydrophobic. **Membrane-associated** (**peripheral**) **proteins** may be bound through electrostatic interactions with the lipid bilayer, especially at lipid rafts, or to other transmembrane or embedded proteins, like the G proteins found in G protein-coupled receptors. Transporters, channels, and receptors are generally transmembrane proteins.

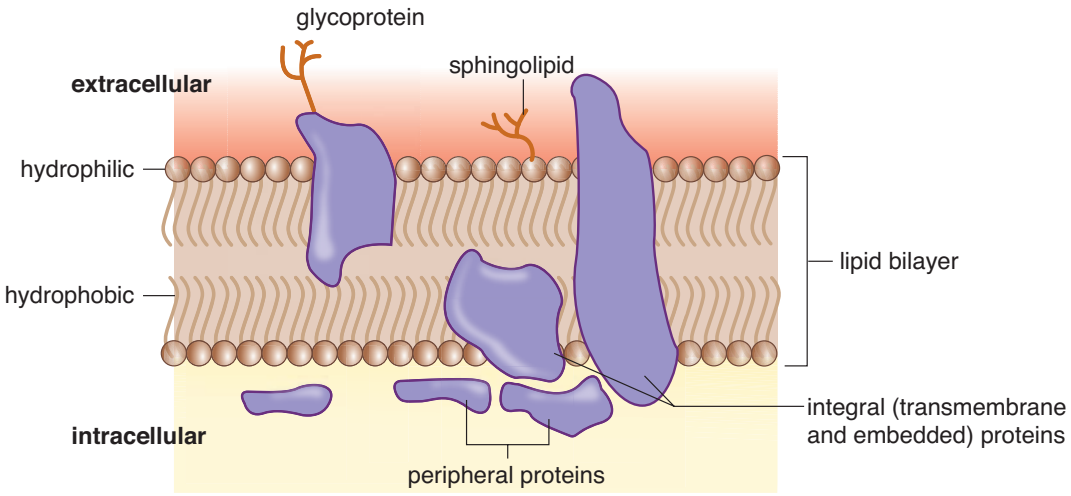

Figure 8.4. Plasma Membrane Proteins

CARBOHYDRATES

Carbohydrates are generally attached to protein molecules on the extracellular surface of cells. Because carbohydrates are generally hydrophilic, interactions between glycoproteins and water can form a coat around the cell, as shown in Figure 8.5. In addition, carbohydrates can act as signaling and recognition molecules. For example, blood group (ABO) antigens on red blood cells are sphingolipids that differ only in their carbohydrate sequence. Our immune systems and some pathogens take advantage of these membrane carbohydrates and membrane proteins to target particular cells.

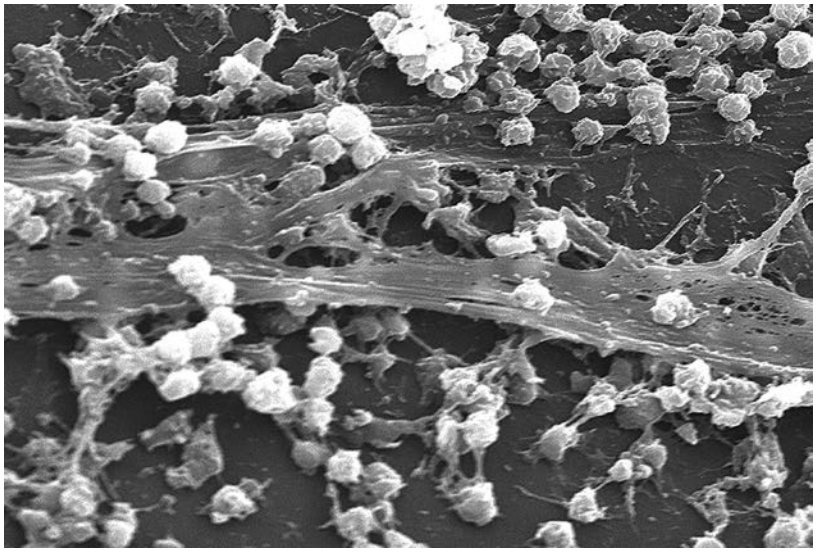

Figure 8.5. Extracellular Membrane-Associated Carbohydrates
Staphylococcus aureus bacteria embedded in bands of extracellular polysaccharides and glycolipids, forming a biofilm.

Bridge

Biosignaling is a major function of the cell membrane. Receptors and signal cascades are covered in more detail in Chapter 3 of *MCAT Biochemistry Review*.

MEMBRANE RECEPTORS

Some of the transporters for facilitated diffusion and active transport can be activated or deactivated by **membrane receptors**, which tend to be transmembrane proteins. For example, ligand-gated ion channels are membrane receptors that open a channel in response to the binding of a specific ligand. Other membrane receptors participate in biosignaling; for example, G protein-coupled receptors are involved in several different signal transduction cascades. Membrane receptors are generally proteins, although there are some carbohydrate and lipid receptors, especially in viruses.

CELL–CELL JUNCTIONS

Cells within tissues can form a cohesive layer via intercellular junctions. These junctions provide direct pathways of communication between neighboring cells or between cells and the extracellular matrix. Cell–cell junctions are generally comprised of **cell adhesion molecules** (**CAM**), which are proteins that allow cells to recognize each other and contribute to proper cell differentiation and development.

Gap Junctions

Gap junctions allow for direct cell–cell communication and are often found in small bunches together. Gap junctions are also called **connexons** and are formed by the alignment and interaction of pores composed of six molecules of **connexin**, as shown in Figure 8.6. They permit movement of water and some solutes directly between cells. Proteins are generally not transferred through gap junctions.

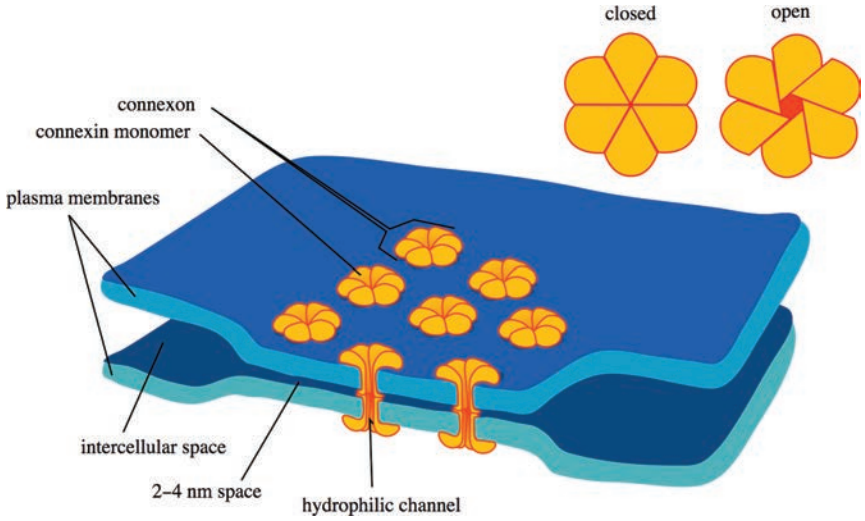

Figure 8.6. Gap Junction
A connexon (gap junction) is composed of six monomers of connexin and permits travel of solutes between cells.

Tight Junctions

Tight junctions prevent solutes from leaking into the space between cells via a **paracellular** route. Tight junctions are found in epithelial cells and function as a physical link between the cells as they form a single layer of tissue. Tight junctions can limit permeability enough to create a transepithelial voltage difference based on differing concentrations of ions on either side of the epithelium. To be effective, tight junctions must form a continuous band around the cell; otherwise, fluid could leak through spaces between tight junctions.

Desmosomes

Desmosomes bind adjacent cells by anchoring to their cytoskeletons. Desmosomes are formed by interactions between transmembrane proteins associated with intermediate filaments inside adjacent cells, as shown in Figure 8.7. Desmosomes are primarily found at the interface between two layers of epithelial tissue. **Hemidesmosomes** have a similar function, but their main function is to attach epithelial cells to underlying structures, especially the basement membrane.

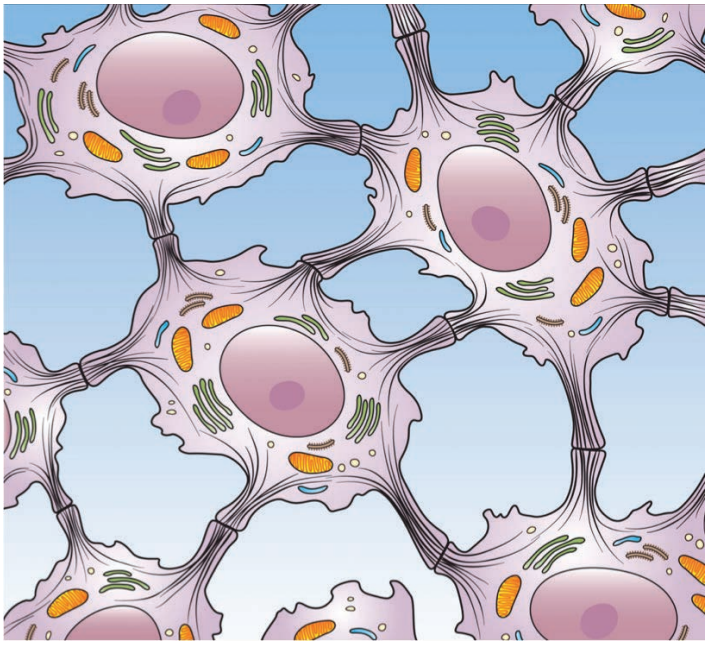

Figure 8.7. Desmosomes between Adjacent Cells

Mnemonic

Tight junctions form a water**tight** seal, preventing paracellular transport of water and solutes.

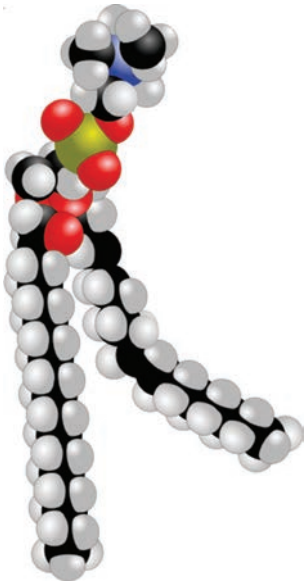
Bridge

Tight junctions are found in the lining of renal tubules, where they restrict passage of solutes and water without cellular control. Nephrons are discussed in Chapter 10 of *MCAT Biology Review*.

MCAT Concept Check 8.2:

Before you move on, assess your understanding of the material with these questions.

1. In the following phospholipid, determine whether the fatty acids are saturated or unsaturated and label their hydrophobic and hydrophilic regions.



2. How does cholesterol play a role in the fluidity and stability of the plasma membrane?

_____

_____

_____

3. What are the three classes of membrane proteins? How are they each most likely to function?

   1. _____
   2. _____
   3. _____

4. Contrast gap junctions and tight junctions.

   - Gap junctions:

     _____

   - Tight junctions:

     _____

8.3 Membrane Transport ★★★★

The cell membrane functions to control movement of substances into and out of the cell; however, it varies in its selectivity for different substances. Transport of small nonpolar molecules occurs rapidly through the cell membrane via diffusion, while ions and larger molecules require more specialized transport processes. The different membrane traffic processes are classified as either active or passive, and are driven by concentration gradients or intracellular energy stores.

CONCENTRATION GRADIENTS

Transport processes can be classified as active or passive depending on their thermodynamics. Spontaneous processes that do not require energy (negative ΔG) proceed through **passive transport**, while those that are nonspontaneous and require energy (positive ΔG) proceed through **active transport**. Diffusion, facilitated diffusion, and osmosis generally increase in rate as temperature increases, while active transport may or may not be affected by temperature, depending on the enthalpy (ΔH) of the process. The primary thermodynamic motivator in most passive transport is an increase in entropy (ΔS).

MCAT Expertise

An important point to keep in mind is that all transmembrane movement is based on concentration gradients, which are an MCAT favorite; understanding concentration gradients will net you points on Test Day. Remember that the gradient will tell us whether this process will be passive or active.

PASSIVE TRANSPORT

Passive transport processes are those that do not require intracellular energy stores but rather utilize the concentration gradient to supply the energy for particles to move.

Simple Diffusion

The most basic of all membrane traffic processes is **simple diffusion**, in which substrates move down their concentration gradient directly across the membrane. Only particles that are freely permeable to the membrane are able to undergo simple diffusion. There is potential energy in a chemical gradient; some of this energy is dissipated as the gradient is utilized during simple diffusion. We can liken this process to a ball rolling down a hill: there is potential energy in the ball when it sits at the top of the hill, and as the ball spontaneously rolls down the hill, some of the energy is dissipated.

Osmosis

Osmosis is a specific kind of simple diffusion that concerns water; water will move from a region of lower solute concentration to one of higher solute concentration. That is, it will move from a region of higher water concentration (more dilute solution) down its gradient to a region of lower water concentration (more concentrated solution). Osmosis is important in several places, most notably when the solute itself is impermeable to the membrane. In such a case, water will move to try to bring solute concentrations to equimolarity, as shown in

Real World

Osmolarity explains why pure water should never be given intravenously for resuscitation. Red blood cells have an osmolarity around 300 $\frac{\text{mOsm}}{\text{L}}$, while pure water has an osmolarity of 0 $\frac{\text{mOsm}}{\text{L}}$. Water would rush into the red blood cells, causing them to burst. To avoid this, saline or dextrose-containing solutions are used.

Mnemonic

To remember that water flows into a cell placed in hyp**O**tonic solution, imagine the cell swelling to form a giant letter **O**.

Figure 8.8. If the concentration of solutes inside the cell is higher than the surrounding solution, the solution is said to be **hypotonic**; such a solution will cause a cell to swell as water rushes in, sometimes to the point of bursting (lysing). A solution that is more concentrated than the cell is termed a **hypertonic** solution, and water will move out of the cell. If the solutions inside and outside are equimolar, they are said to be **isotonic**. A key point here is that isotonicity does not prevent movement; rather, it prevents the *net* movement of particles. Water molecules will continue to move; however, the cell will neither gain nor lose water overall.

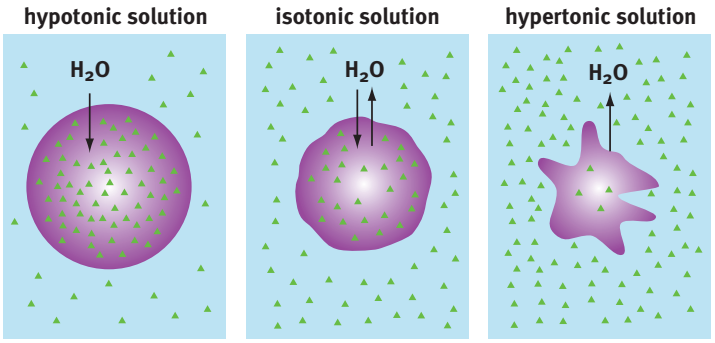


Figure 8.8. Osmosis
Water moves from areas of low solute (high water) concentration to high solute (low water) concentration.

One method of quantifying the driving force behind osmosis is osmotic pressure. **Osmotic pressure** is a **colligative property**: a physical property of solutions that is dependent on the concentration of dissolved particles but not on the chemical identity of those dissolved particles. Other examples of colligative properties include vapor pressure depression (Raoult's Law), boiling point elevation, and freezing point depression.

To illustrate osmotic pressure, consider a container separated into two compartments by a semipermeable membrane, just like the membranes in our cells. One compartment contains pure water, while the other contains water with dissolved solutes. The membrane allows water but not solutes to pass through. Because substances tend to flow, or diffuse, from higher to lower concentration (which results in an increase in entropy), water will diffuse from the compartment containing pure water into the compartment containing the water–solute mixture. This net flow will cause the water level in the compartment containing the solution to rise above the level in the compartment containing pure water, as shown in Figure 8.9.

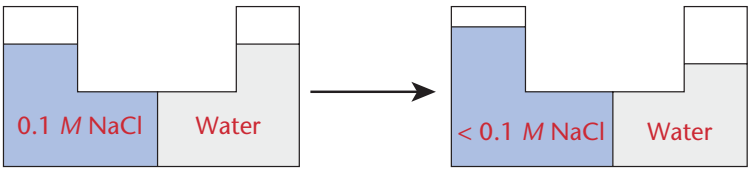

Figure 8.9. Change in Water Level Due to Osmotic Pressure

Because the solute cannot pass through the membrane, the concentrations of solute in the two compartments can never be equal. However, the hydrostatic pressure exerted by the water level in the solute-containing compartment will eventually oppose the influx of water; thus, the water level will only rise to the point at which it exerts a sufficient pressure to counterbalance the tendency of water to flow across the membrane. This pressure, defined as the **osmotic pressure** (**Π**) of the solution, is given by the formula:

$$\Pi = iMRT$$

Equation 8.1

where M is the molarity of the solution, R is the ideal gas constant, T is the absolute temperature (in kelvins), i is the **van 't Hoff factor**, which is simply the number of particles obtained from the molecule when in solution. For example, glucose remains one intact molecule, so $i_{glucose} = 1$; sodium chloride becomes two ions (Na^+ and Cl^-), so $i_{NaCl} = 2$. The equation clearly shows that osmotic pressure is directly proportional to the molarity of the solution. Thus, osmotic pressure, like all colligative properties, depends only on the presence and number of particles in solution, but not their actual identity.

In cells, the osmotic pressure is maintained against the cell membrane, rather than the force of gravity. If the osmotic pressure created by the solutes within a cell exceeds the pressure that the cell membrane can withstand, the cell will lyse. Generally, osmotic pressure is best thought of as a "sucking" pressure, drawing water into the cell in proportion to the concentration of the solution.

Facilitated Diffusion

Facilitated diffusion is simple diffusion for molecules that are impermeable to the membrane (large, polar, or charged); the energy barrier is too high for these molecules to cross freely. Facilitated diffusion requires integral membrane proteins to serve as transporters or channels for these substrates.

The classic examples of facilitated diffusion involve a carrier or channel protein. **Carriers** are only open to one side of the cell membrane at any given point. This model is similar to a revolving door because the substrate binds to the transport protein (walks in), remains in the transporter during a conformational change (spins), and then finally dissociates from the substrate-binding site of the transporter (walks out). Binding of the substrate molecule to the transporter protein induces a conformational change; for a brief time, the carrier is in the **occluded state**, in which the carrier is not open to either side of the phospholipid bilayer. In addition to carriers, **channels** are also viable transporters for facilitated diffusion. Channels may be in an open or closed conformation. In their open conformation, channels are exposed to both sides of the cell membrane and act

Key Concept

Unless otherwise specified, *semipermeable membrane* refers to a membrane governed by the same permeability rules as biological membranes: small, nonpolar, lipid-soluble particles (and water) can pass through freely, while large, polar, or charged particles cannot.

like a tunnel for the particles to diffuse through, thereby permitting much more rapid transport kinetics. The activity of the three main types of ion channels is discussed in Chapter 3 of *MCAT Biochemistry Review*.

ACTIVE TRANSPORT

Active transport results in the net movement of a solute against its concentration gradient, just like rolling a ball uphill. Active transport always requires energy, but the source of this energy can vary. **Primary active transport** uses ATP or another energy molecule to directly power the transport of molecules across a membrane. Generally, primary active transport involves the use of a *transmembrane ATPase*. **Secondary active transport**, also known as **coupled transport**, also uses energy to transport particles across the membrane; however, in contrast to primary active transport, there is no direct coupling to ATP hydrolysis. Instead, secondary active transport harnesses the energy released by one particle going *down* its electrochemical gradient to drive a different particle *up* its gradient. When both particles flow the same direction across the membrane, it is termed **symport**. When the particles flow in opposite directions, it is called **antiport**. Active transport is important in many tissues. For instance, primary active transport maintains the membrane potential of neurons in the nervous system. The kidneys use secondary active transport, usually driven by sodium, to reabsorb and secrete various solutes into and out of the filtrate.

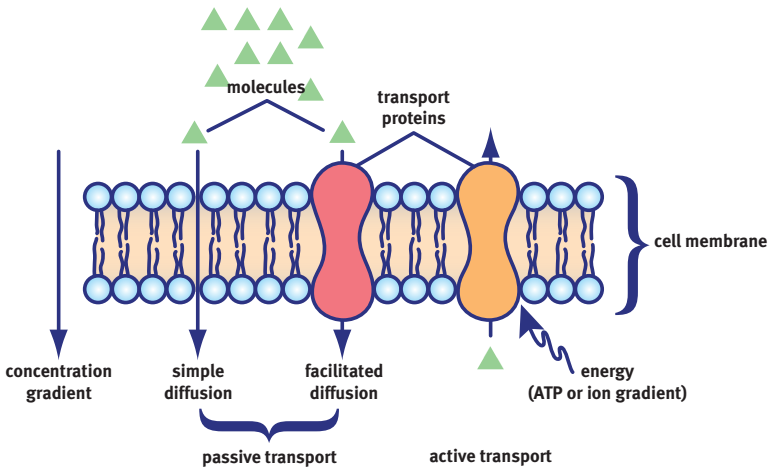

Figure 8.10. Membrane Transport Processes
The movement of solutes across the cell membrane is mediated by concentration gradients.

Figure 8.10 shows simple diffusion, facilitated diffusion, and active transport. Table 8.1 summarizes these types of movement as well as osmosis.

	Simple Diffusion	Osmosis	Facilitated Diffusion	Active Transport
Concentration gradient of solute	High ⟶ Low	Low ⟶ High	High ⟶ Low	Low ⟶ High
Membrane protein required	No	No	Yes	Yes
Energy required	NO—this is a passive process	NO—this is a passive process	NO—this is a passive process	YES—this is an active process; requires energy
Example molecule(s) transported	Small, nonpolar (O_2, CO_2)	H_2O	Polar molecules (glucose) or ions (Na^+, Cl^-)	Polar molecules or ions (Na^+, Cl^-, K^+)

Table 8.1. Membrane Transport Processes

ENDOCYTOSIS AND EXOCYTOSIS

Endocytosis

Endocytosis occurs when the cell membrane invaginates and engulfs material to bring it into the cell. The material is encased in a vesicle, which is important because cells will sometimes ingest toxic substances. **Pinocytosis** is the endocytosis of fluids and dissolved particles, whereas **phagocytosis** is the ingestion of large solids such as bacteria. Substrate binding to specific receptors embedded within the plasma membrane will initiate the process of endocytosis.

Exocytosis

Exocytosis occurs when secretory vesicles fuse with the membrane, releasing material from inside the cell to the extracellular environment. Exocytosis is important in the nervous system and intercellular signaling. For instance, exocytosis of neurotransmitters from synaptic vesicles is a crucial aspect of neuron physiology. Both endo- and exocytosis are illustrated in Figure 8.11.

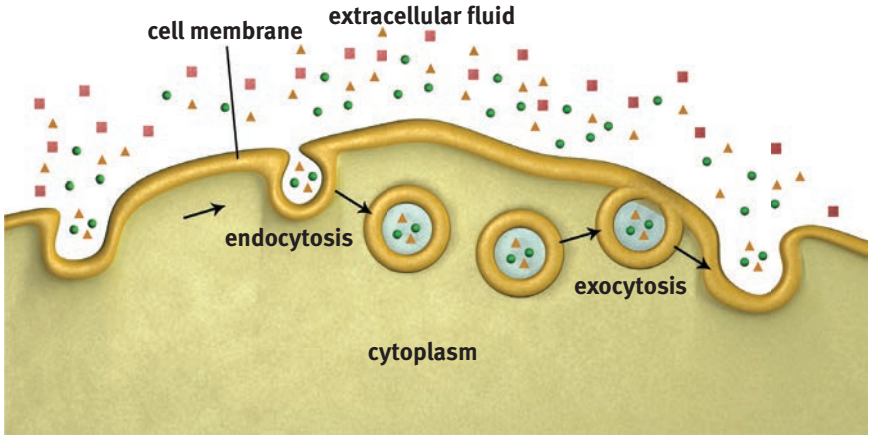

Figure 8.11. Endocytosis and Exocytosis

MCAT Concept Check 8.3:
Before you move on, assess your understanding of the material with these questions.

1. What is the primary thermodynamic factor responsible for passive transport?

_____

2. What is the relationship between osmotic pressure and the direction of osmosis through a semipermeable membrane?

_____

_____

3. Compare the two types of active transport. What is the difference between symport and antiport?

_____

_____

_____

8.4 Specialized Membranes ★★

The membranes of most organelles are similar to the cell membrane in both composition and general characteristics; however, it is important to note that some membranes are specialized to accomplish specific functions. For instance, the **sarcolemma** of muscle cells must maintain a membrane potential for muscle contraction to occur. Membrane composition may also be altered slightly, especially in the case of mitochondria.

MEMBRANE POTENTIAL

The impermeability of the cell membrane to ions and the selectivity of ion channels both lead to an electrochemical gradient between the exterior and interior of cells. The difference in electrical potential across cell membranes is called the **membrane potential**, V_m. The resting potential for most cells is between –40 and –80 mV, although the potential can rise as high as +35 mV during depolarization of the cell. Maintaining membrane potential requires energy because ions may passively diffuse through the cell membrane over time using **leak channels**; therefore, an ion transporter or pump such as the **sodium–potassium pump** (**Na^+/K^+ ATPase**) regulates the concentration of intracellular and extracellular sodium and potassium

ions. Chloride ions also participate in establishing membrane potential. The **Nernst equation** can be used to determine the membrane potential from the intra- and extracellular concentrations of the various ions:

$$E = \frac{RT}{zF} \ln \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}} = \frac{61.5}{z} \log \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}}$$

Equation 8.2

where R is the ideal gas constant, T is the temperature in kelvins, z is the charge of the ion, and F is the Faraday constant (96,485 $\frac{\text{C}}{\text{mol } e^-}$). The simplification to 61.5 in the numerator assumes body temperature, 310 K. The **Goldman–Hodgkin–Katz voltage equation** flows from the Nernst equation, taking into account the relative contribution of each major ion to the membrane potential:

$$V_m = 61.5 \log \left[\frac{P_{Na^+} \times [Na^+]_{\text{outside}} + P_{K^+} \times [K^+]_{\text{outside}} + P_{Cl^-} \times [Cl^-]_{\text{inside}}}{P_{Na^+} \times [Na^+]_{\text{inside}} + P_{K^+} \times [K^+]_{\text{inside}} + P_{Cl^-} \times [Cl^-]_{\text{outside}}} \right]$$

Equation 8.3

where P represents the permeability for the relevant ion. Note that chloride is inverted relative to the other ions because it carries a negative charge.

Sodium–Potassium Pump

There is a steady-state resting relationship between ion diffusion and the **Na^+/K^+ ATPase**. One of the main functions of the Na^+/K^+ ATPase is to maintain a low concentration of sodium ions and high concentration of potassium ions intracellularly by pumping three sodium ions out for every two potassium ions pumped in. This movement of ions removes one positive charge from the intracellular space of the cell, which maintains the negative resting potential of the cell. As mentioned before, the cell membrane also contains leak channels that allow ions, such as Na^+ and K^+, to passively diffuse into or out of the cell down their concentration gradients. Cell membranes are more permeable to K^+ ions than Na^+ ions at rest because there are more K^+ leak channels than Na^+ leak channels. The combination of Na^+/K^+ ATPase activity and leak channels together maintain a stable resting membrane potential.

MITOCHONDRIAL MEMBRANES

Mitochondria are referred to as the "powerhouse" of the cell because of their ability to produce ATP by oxidative respiration. Mitochondria contain two membranes: the inner and outer mitochondrial membranes.

Outer Mitochondrial Membrane

The **outer mitochondrial membrane** is highly permeable due to many large pores that allow for the passage of ions and small proteins. The outer membrane completely

Bridge

The cell membrane is often compared to a capacitor because opposite charges are maintained on either side of the membrane. Capacitance is discussed in Chapter 6 of *MCAT Physics and Math Review*.

surrounds the inner mitochondrial membrane, with the presence of a small **intermembrane space** in between the two layers.

Inner Mitochondrial Membrane

The **inner mitochondrial membrane** has a much more restricted permeability compared to the outer mitochondrial membrane. Structurally, the inner mitochondrial membrane contains numerous infoldings, known as **cristae**, which increase the available surface area for the integral proteins associated with the membrane. These proteins, discussed in Chapter 10 of *MCAT Biochemistry Review*, are involved in the electron transport chain and ATP synthesis. The inner membrane also encloses the **mitochondrial matrix**, where the citric acid cycle produces high-energy electron carriers used in the electron transport chain. The inner mitochondrial membrane contains a very high level of *cardiolipin* and does not contain cholesterol.

MCAT Concept Check 8.4:

Before you move on, assess your understanding of the material with these questions.

1. How is the resting membrane potential maintained?

_____

_____

_____

2. Given the following data, calculate the resting membrane potential of this cell:

Ion	Permeability (Relative)	Intracellular Concentration	Extracellular Concentration
Na^+	0.05	14 m*M*	140 m*M*
K^+	1	120 m*M*	4 m*M*
Cl^-	0	12 m*M*	120 m*M*

_____

_____

_____

3. What distinguishes the inner mitochondrial membrane from other biological membranes? What is the pH gradient between the cytoplasm and the intermembrane space?

_____

_____

_____

Conclusion

Understanding biological membranes becomes increasingly important as you progress in your medical career. At this point, you should have a strong foundation of knowledge about the fluid mosaic model and how membranes exist dynamically. We've also covered the components of cell membranes, with a special emphasis on lipids and the phospholipid bilayer. We reviewed some basic physical properties of the cell, including cell–cell junctions. We also examined membrane transport, such as passive transport (simple diffusion, facilitated diffusion, and osmosis) and active transport, before briefly touching upon endocytosis and exocytosis. Finally, we reviewed specialized membranes within cells. Up to now, you have been exposed to each of the classes of molecules and some of their applications both experimentally and within the cell. This comprehensive review should provide you with a better understanding of what will be expected of you on Test Day and briefly introduce you to topics that you will learn more about in medical school.

The first seven chapters of *MCAT Biochemistry Review* focused on various types of biomolecules, their structures, and their functions. In this chapter, we applied this knowledge of biomolecules to make sense of biological membranes. In the remaining four chapters, we'll turn our attention to the metabolic pathways by which the body builds, stores, and burns these biomolecules.

CONCEPT SUMMARY

Fluid Mosaic Model

- The **fluid mosaic model** accounts for the presence of lipids, proteins, and carbohydrates in a dynamic, semisolid plasma membrane that surrounds cells.
- The plasma membrane contains proteins embedded within the **phospholipid bilayer**.
- The membrane is not static.
  - Lipids move freely in the plane of the membrane and can assemble into **lipid rafts**.
  - **Flippases** are specific membrane proteins that maintain the bidirectional transport of lipids between the layers of the phospholipid bilayer in cells.
  - Proteins and carbohydrates may also move within the membrane, but are slowed by their relatively large size.

Membrane Components

- Lipids are the primary membrane component, both by mass and mole fraction.
  - **Triacylglycerols** and **free fatty acids** act as phospholipid precursors and are found in low levels in the membrane.
  - **Glycerophospholipids** replace one fatty acid with a phosphate group, which is often linked to other hydrophilic groups.
  - **Cholesterol** is present in large amounts and contributes to membrane fluidity and stability.
  - **Waxes** are present in very small amounts, if at all; they are most prevalent in plants and function in waterproofing and defense.
- Proteins located within the cell membrane act as transporters, cell adhesion molecules, and enzymes.
  - **Transmembrane proteins** can have one or more hydrophobic domains and are most likely to function as receptors or channels.
  - **Embedded proteins** are most likely part of a catalytic complex or involved in cellular communication.
  - **Membrane-associated proteins** may act as recognition molecules or enzymes.
- Carbohydrates can form a protective **glycoprotein coat** and also function in cell recognition.

- Extracellular ligands can bind to membrane receptors, which function as channels or enzymes in second messenger pathways.
- Cell–cell junctions regulate transport intracellularly and intercellularly.
  - **Gap junctions** allow for the rapid exchange of ions and other small molecules between adjacent cells.
  - **Tight junctions** prevent **paracellular** transport, but do not provide intercellular transport.
  - **Desmosomes** and **hemidesmosomes** anchor layers of epithelial tissue together.

Membrane Transport

- **Concentration gradients** help to determine appropriate membrane transport mechanisms in cells.
- **Osmotic pressure**, a **colligative property**, is the pressure applied to a pure solvent to prevent osmosis and is used to express the concentration of the solution.
  - It is often better conceptualized as a "sucking" pressure in which a solution is drawing water in, proportional to its concentration.
- **Passive transport** does not require energy because the molecule is moving down its concentration gradient or from an area with higher concentration to an area with lower concentration.
  - **Simple diffusion** does not require a transporter. Small, nonpolar molecules passively move from an area of high concentration to an area of low concentration until equilibrium is achieved.
  - **Osmosis** describes the diffusion of water across a selectively permeable membrane.
  - **Facilitated diffusion** uses transport proteins to move impermeable solutes across the cell membrane.
- **Active transport** requires energy in the form of ATP or an existing favorable ion gradient.
  - Active transport may be **primary** or **secondary** depending on the energy source. Secondary active transport can be further classified as **symport** or **antiport**.
- **Endocytosis** and **exocytosis** are methods of engulfing material into cells or releasing material to the exterior of cells, both via the cell membrane. **Pinocytosis** is the ingestion of liquid into the cell in vesicles formed from the cell membrane and **phagocytosis** is the ingestion of larger, solid molecules.

Specialized Membranes

- The composition of cell membranes is fairly consistent; however, there are some cells that contain specialized membranes.
- **Membrane potential** is maintained by the sodium–potassium pump and leak channels.
  - The electrical potential created by one ion can be calculated using the **Nernst equation**.
  - The resting potential of a membrane at physiological temperature can be calculated using the **Goldman–Hodgkin–Katz voltage equation**, which is derived from the Nernst equation.
- The mitochondrial membrane differs from the cell membrane:
  - The outer mitochondrial membrane is highly permeable to metabolic molecules and small proteins.
  - The inner mitochondrial membrane surrounds the mitochondrial matrix, where the citric acid cycle produces electrons used in the electron transport chain and where many other enzymes important in cellular respiration are located. The inner mitochondrial membrane also does not contain cholesterol.

ANSWERS TO CONCEPT CHECKS

8.1

1. Flippases are responsible for the movement of phospholipids between the layers of the plasma membrane because it is otherwise energetically unfavorable. Lipid rafts are aggregates of specific lipids in the membrane that function as attachment points for other biomolecules and play roles in signaling.
2. Lipids, including phospholipids, cholesterol, and others, are most plentiful; proteins, including transmembrane proteins (channels and receptors), membrane-associated proteins, and embedded proteins, are next most plentiful; carbohydrates, including the glycoprotein coat and signaling molecules, are next; nucleic acids are essentially absent.

8.2

1. The hydrophilic region is at the top of this diagram. While you need not be able to recognize it, the head group is phosphatidylcholine in this example. The hydrophobic region is at the bottom and is composed of two fatty acid tails. The tail on the left is saturated; the tail on the right is unsaturated, as evidenced by the kink in its chain.
2. Cholesterol moderates membrane fluidity by interfering with the crystal structure of the cell membrane and occupying space between phospholipid molecules at low temperatures, and by restricting excessive movement of phospholipids at high temperatures. Cholesterol also provides stability by cross-linking adjacent phospholipids through interactions at the polar head group and hydrophobic interactions at the nearby fatty acid tail.
3. Transmembrane proteins are most likely to serve as channels or receptors. Embedded membrane proteins are most likely to have catalytic activity linked to nearby enzymes. Membrane-associated (peripheral) proteins are most likely to be involved in signaling or are recognition molecules on the extracellular surface.
4. Gap junctions allow for the intercellular transport of materials and do not prevent paracellular transport of materials. Tight junctions are not used for intercellular transport but do prevent paracellular transport. Gap junctions are in discontinuous bunches around the cell, while tight junctions form bands around the cell.

8.3

1. The primary thermodynamic factor responsible for passive transport is entropy.
2. As osmotic pressure increases, more water will tend to flow into the compartment to decrease solute concentration. Osmotic pressure is often considered a "sucking" pressure because water will move toward the compartment with the highest osmotic pressure.

3. Primary active transport uses ATP as an energy source for the movement of molecules against their concentration gradient, while secondary active transport uses an electrochemical gradient to power the transport. Symport moves both particles in secondary active transport across the membrane in the same direction, while antiport moves particles across the cell membrane in opposite directions.

8.4

1. The membrane potential, which results from a difference in the number of positive and negative charges on either side of the membrane, is maintained primarily by the sodium–potassium pump, which moves three sodium ions out of the cell for every two potassium ions pumped in, and to a minor extent by leak channels that allow the passive transport of ions.
2. $$V_m = 61.5 \log\left[\frac{P_{Na^+} \times [Na^+]_{outside} + P_{K^+} \times [K^+]_{outside} + P_{Cl^-} \times [Cl^-]_{inside}}{P_{Na^+} \times [Na^+]_{inside} + P_{K^+} \times [K^+]_{inside} + P_{Cl^-} \times [Cl^-]_{outside}}\right]$$
$$= 61.5 \log\left[\frac{0.05 \times [140] + 1 \times [4] + 0 \times [12]}{0.05 \times [14] + 1 \times [120] + 0 \times [120]}\right] = 61.5 \log\left[\frac{7+4}{0.7+120}\right]$$
$$= 61.5 \log\left[\frac{11}{120.7}\right] \approx 60 \log\frac{1}{10} = -60 \text{ mV}$$

   The exact value is –64.0 mV
3. The inner mitochondrial membrane lacks cholesterol, which differentiates it from most other biological membranes. There is no pH gradient between the cytoplasm and the intermembrane space because the outer mitochondrial membrane has such high permeability to biomolecules (the proton-motive force of the mitochondria is across the inner mitochondrial membrane, not the outer mitochondrial membrane).

EQUATIONS TO REMEMBER

(8.1) **Osmotic pressure:** $\Pi = iMRT$

(8.2) **Nernst equation:** $E = \frac{RT}{z\mathrm{F}} \ln \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}} = \frac{61.5}{z} \log \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}}$

(8.3) **Goldman–Hodgkin–Katz voltage equation:**

$$V_{\text{m}} = 61.5 \log \left[\frac{P_{\text{Na}^+} \times [\text{Na}^+]_{\text{outside}} + P_{K^+} \times [\text{K}^+]_{\text{outside}} + P_{\text{Cl}^-} \times [\text{Cl}^-]_{\text{inside}}}{P_{\text{Na}^+} \times [\text{Na}^+]_{\text{inside}} + P_{K^+} \times [\text{K}^+]_{\text{inside}} + P_{\text{Cl}^-} \times [\text{Cl}^-]_{\text{outside}}} \right]$$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. A student is trying to determine the type of membrane transport occurring in a cell. She finds that the molecule to be transported is very large and polar, and when transported across the membrane, no energy is required. Which of the following is the most likely mechanism of transport?

A. Active transport
B. Simple diffusion
C. Facilitated diffusion
D. Exocytosis

2. A researcher treats a solution containing animal cells with ouabain, a poisonous substance that interferes with the sodium–potassium ATPase embedded in the cell membrane, and the cell lyses as a result. Which of the following statements best describes ouabain's effects?

A. Treatment with ouabain results in high levels of extracellular calcium.
B. Treatment with ouabain results in high levels of extracellular potassium and sodium.
C. Treatment with ouabain increases intracellular concentrations of sodium.
D. Treatment with ouabain decreases intracellular concentrations of sodium.

3. Resting membrane potential depends on:

I. the differential distribution of ions across the membrane.
II. active transport processes.
III. selective permeability of the phospholipid bilayer.

A. I only
B. I and III only
C. II and III only
D. I, II, and III

4. Which of the following is NOT a function of the cell membrane?

A. Cytoskeletal attachment
B. Protein synthesis
C. Transport regulation
D. Second messenger reservoir

5. The dynamic properties of molecules in the cell membrane are most rapid in:

A. phospholipids moving within the plane of the membrane.
B. phospholipids moving between the layers of the membrane.
C. proteins moving within the plane of the membrane.
D. proteins exiting the cell through exocytosis.

6. Which lipid type is LEAST likely to contribute to membrane fluidity?

A. Unsaturated glycerophospholipids
B. *trans* glycerophospholipids
C. Cholesterol
D. Unsaturated sphingolipids

7. A membrane receptor is most likely to be a(n):

A. embedded protein with catalytic activity.
B. transmembrane protein with sequestration activity.
C. membrane-associated protein with sequestration activity.
D. transmembrane protein with catalytic activity.

8. Which of the following is NOT a cell–cell junction in animals?

A. Desmosomes
B. Gap junctions
C. Plasmodesmata
D. Tight junctions

9. Which of the following is true of diffusion and osmosis?

A. Diffusion and osmosis rely on the electrochemical gradient of only the compound of interest.
B. Diffusion and osmosis rely on the electrochemical gradient of all compounds in a cell.
C. Diffusion and osmosis will proceed in the same direction if there is only one solute.
D. Diffusion and osmosis cannot occur simultaneously.

10. The bulk movement of liquid into a cell through vesicular infoldings is known as:

A. phagocytosis.
B. pinocytosis.
C. exocytosis.
D. drinking.

11. Which of the following is LEAST likely to be the resting membrane potential of a cell?

A. –70 mV
B. –55 mV
C. 0 mV
D. +35 mV

12. How does the inner mitochondrial membrane differ from the outer mitochondrial membrane?

A. The inner mitochondrial membrane is more permeable and lacks cholesterol.
B. The inner mitochondrial membrane is less permeable and lacks cholesterol.
C. The inner mitochondrial membrane is more permeable and has cholesterol.
D. The inner mitochondrial membrane is less permeable and has cholesterol.

13. For most cells, the extracellular calcium concentration is around 10,000 times higher than the intracellular calcium concentration. What is the membrane potential established by this electrochemical gradient?

A. –123 mV
B. –61.5 mV
C. +61.5 mV
D. +123 mV

14. Which of the following statements conflicts with the fluid mosaic model?

A. The cell membrane is static in structure.
B. Membrane components can be derived from multiple biomolecules.
C. Hydrophobic interactions stabilize the lipid bilayer.
D. Proteins are asymmetrically distributed within the cell membrane.

15. Which of the following is a sphingolipid?

A. Lecithin
B. Phosphatidylinositol
C. Cholesterol
D. Ganglioside

Explanations to Discrete Practice Questions

1. C

We are asked to identify the type of transport that would allow a large, polar molecule to cross the membrane without any energy expenditure. This scenario describes facilitated diffusion, which uses a transport protein (or channel) to facilitate the movement of large, polar molecules across the nonpolar, hydrophobic membrane. Facilitated diffusion, like simple diffusion, does not require energy.

2. C

This question requires an understanding of osmosis and the action of the sodium–potassium pump. When a cell is placed in a hypertonic solution (a solution having a higher solute concentration than the cell), fluid will diffuse out of the cell and result in cell shrinkage. When a cell is placed in hypotonic solution (a solution having a lower solute concentration than the cell), fluid will diffuse from the solution into the cell, causing the cell to expand and possibly lyse. The sodium–potassium pump moves three sodium ions out of the cell for every two potassium ions it lets into the cell. Therefore, inhibition of the sodium–potassium pump by ouabain will cause a net increase in the sodium concentration inside the cell and water will diffuse in, causing the cell to swell and then lyse.

3. D

The polarization of the membrane at rest is the result of an uneven distribution of ions between the inside and outside of the cell. This difference is achieved through active pumping of ions (predominantly sodium and potassium) into and out of the cell and the selective permeability of the membrane, which allows only certain ions to cross.

4. B

Ribosomes are the site of protein synthesis within a cell and are not coupled to the cell membrane. The cell membrane functions as a site for cytoskeletal attachment, **choice (A)**, through proteins and lipid rafts. Transport regulation, **choice (C)**, is accomplished through channels, transporters, and selective permeability, while the phospholipids act as a reagent for second messenger formation, **choice (D)**.

5. A

Movement of individual molecules in the cell membrane will be affected by size and polarity, just as with diffusion. Lipids are much smaller than proteins in the plasma membrane and will move more quickly. Lipids will move fastest within the plane of the cell membrane because the polar head group does not need to pass through the hydrophobic tail region in the same way that it would if it were moving between the membrane layers.

6. B

Compounds that contribute to membrane fluidity will lower the melting point or disrupt the crystal structure. Cholesterol, **choice (C)**, and unsaturated lipids, **choices (A)** and **(D)**, are known for these functions. *trans* glycerophospholipids tend to increase the melting point of the membrane and therefore decrease membrane fluidity.

7. D

Membrane receptors must have both an extracellular and intracellular domain; therefore, they are considered transmembrane proteins. In order to initiate a second messenger cascade, they typically display enzymatic activity, although some may act strictly as channels.

8. C

Plasmodesmata are cell–cell junctions that are found in plants, not animals. Gap junctions, tight junctions, desmosomes, and hemidesmosomes are all found in animals, particularly in epithelia.

9. A

The movement of any solute or water by diffusion or osmosis is dependent only on the concentration gradient of that molecule and on membrane permeability.

10. B

The endocytosis (bulk uptake through vesicle formation) of fluid is known as pinocytosis. Phagocytosis, **choice (A)**, is the endocytotic intake of solids, while exocytosis, **choice (C)**, is a method of releasing vesicular contents. Drinking, **choice (D)**, does not apply on a cellular level.

11. C

Cell membranes are most likely to have a resting membrane potential that is nonzero because the resting membrane potential creates a state that is capable of responding to stimuli. Signaling molecules and channels would not be as useful with a membrane potential of zero. The values given in the answer choices correspond to different stages of the action potential, but the key information is that a resting potential of 0 mV does not maintain gradients for later activity.

12. B

The outer mitochondrial membrane is very permeable while the inner membrane is highly impermeable. The inner mitochondrial membrane is unique within the cell because it lacks cholesterol.

13. D

The Nernst equation relates the intra- and extracellular concentrations of an ion to the potential created by that gradient. At physiological temperature, it can be simplified to $E = \frac{61.5}{z} \log \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}}$. For calcium, $z = +2$ (Ca^{2+}) and the ratio of $[\text{ion}_{\text{outside}}]$ to $[\text{ion}_{\text{inside}}] = 10^4$. Plugging in, we get:

$$E = \frac{61.5}{+2} \log 10^4 = \frac{61.5}{+2} \times 4 = 123 \text{ mV}.$$

14. A

The fluid mosaic model accounts for a dynamic membrane. In this model, membrane components contain both fatty and carbohydrate-derived components, eliminating **choice (B)**. Further, the membrane is stabilized by the hydrophobic interactions of both fatty acid tails and membrane proteins, which may be found on the cytosolic or extracellular side of the membrane, or may run directly through the membrane; thus, **choices (C)** and **(D)** are also eliminated.

15. D

Gangliosides, along with ceramide, sphingomyelin, and cerebrosides, are sphingolipids.

Concept Summary 314

Introduction

Maintaining a constant blood glucose concentration around 100 $\frac{\text{mg}}{\text{dL}}$ (5.6 m*M*) is of the utmost importance in the body: high blood sugar causes long-term damage to the retina, kidney, blood vessels, and nerves, while low blood sugar can cause autonomic disturbances, seizures, and even coma. Without the ability to take in glucose constantly, the body must find ways to store and release glucose as it is needed. And given the variety of food we eat on a daily basis, the body must find ways to use all of the various carbohydrates it takes in.

There's a complex interplay between the neurological, endocrine, digestive, and excretory systems to maintain this blood glucose concentration, much of which is discussed in Chapter 12 of *MCAT Biochemistry Review*. In this chapter, we'll take a look at the metabolic pathways that involve glucose: the methods by which our bodies digest glucose and other monosaccharides, store and release glucose for energy, generate glucose from other biomolecules, and use glucose to create some of the coenzymes and substrates needed for biosynthesis.

This chapter is the first of four that focus on metabolism in *MCAT Biochemistry Review*. Here, we focus on metabolic processes of glucose that do not require oxygen; in Chapter 10, we'll turn our focus to the processes that only occur under aerobic conditions. In Chapter 11, we'll explore the metabolism of lipids and amino acids. Finally, in Chapter 12, we'll bring all of metabolism together with a focus on bioenergetics and the regulation of metabolism overall.

9.1 Glucose Transport

Glucose entry into most cells is driven by concentration and is independent of sodium, unlike absorption from the digestive tract. Normal glucose concentration in peripheral blood is 5.6 m*M* (normal range: 4–6 m*M*). There are four glucose transporters, called GLUT 1 through GLUT 4. GLUT 2 and GLUT 4 are the most significant of these because they are located only in specific cells and are highly regulated.

Bridge

The K_m is the concentration of substrate when an enzyme is active at half of its maximum velocity (v_{max}). The lower the K_m, the higher the enzyme's affinity for the substrate. See Chapter 2 of *MCAT Biochemistry Review* for more on Michaelis–Menten enzyme kinetics.

GLUT 2 is a low-affinity transporter in hepatocytes and pancreatic cells. After a meal, blood traveling through the hepatic portal vein from the intestine is rich in glucose. GLUT 2 captures the excess glucose primarily for storage. When the glucose concentration drops below the K_m for the transporter, much of the remainder bypasses the liver and enters the peripheral circulation. The K_m of GLUT 2 is quite high (~15 m*M*). This means that the liver will pick up glucose in proportion to its concentration in the blood (first-order kinetics). In other words, the liver will pick up excess glucose and store it preferentially after a meal, when blood glucose levels are high. In the β-islet cells of the pancreas, GLUT 2, along with the glycolytic enzyme *glucokinase*, serves as the glucose sensor for insulin release.

Real World

Diabetes mellitus is caused by a disruption of the insulin/GLUT 4 mechanism. In type 1 diabetes, insulin is absent and cannot stimulate the insulin receptor. In type 2 diabetes, the receptor becomes insensitive to insulin and fails to bring GLUT 4 transporters to the cell surface. In both cases, blood glucose rises, leading to immediate symptoms (increased urination, increased thirst, ketoacidosis) and long-term symptoms (blindness, heart attacks, strokes, nerve damage).

GLUT 4 is in adipose tissue and muscle and responds to the glucose concentration in peripheral blood. The rate of glucose transport in these two tissues is increased by insulin, which stimulates the movement of additional GLUT 4 transporters to the membrane by a mechanism involving exocytosis, as shown in Figure 9.1. The K_m of GLUT 4 is close to the normal glucose levels in blood (~5 m*M*). This means that the transporter is saturated when blood glucose levels are just a bit higher than normal. When a person has high blood sugar concentrations, these transporters will still permit only a constant rate of glucose influx because they will be saturated (zero-order kinetics). Then how can cells with GLUT 4 transporters increase their intake of glucose? By increasing the number of GLUT 4 transporters on their surface.

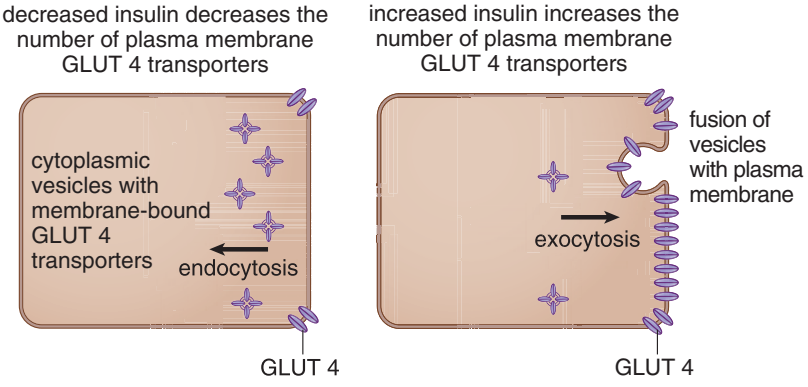

Figure 9.1. Insulin Regulation of Glucose Transport in Muscle and Adipose Cells

Although basal levels of transport occur in all cells independently of insulin, the transport rate increases in adipose tissue and muscle when insulin levels rise. Muscle stores excess glucose as glycogen, and adipose tissue requires glucose to form dihydroxyacetone phosphate (DHAP), which is converted to glycerol phosphate to store incoming fatty acids as *triacylglycerols*.

MCAT Concept Check 9.1:

Before you move on, assess your understanding of the material with these questions.

1. Compare and contrast GLUT 2 and GLUT 4:

	GLUT 2	GLUT 4
Important tissues		
K_m		
Saturated at normal glucose levels?		
Responsive to insulin?		

2. How does insulin promote glucose entry into cells?

_____

_____

9.2 Glycolysis ★★★

All cells can carry out glycolysis. In a few tissues, most importantly red blood cells, glycolysis represents the only energy-yielding pathway available because red blood cells lack mitochondria, which are required for the citric acid cycle, electron transport chain, oxidative phosphorylation, and fatty acid metabolism (β-oxidation). Glucose is the major monosaccharide that enters the pathway, but others such as galactose and fructose can also feed into it.

Glycolysis is a cytoplasmic pathway that converts glucose into two *pyruvate* molecules, releasing a modest amount of energy captured in two substrate-level phosphorylations and one oxidation reaction. If a cell has mitochondria and oxygen, the energy carriers produced in glycolysis (NADH) can feed into the aerobic respiration pathway to generate energy for the cell. If either mitochondria or oxygen is lacking (such as in erythrocytes or exercising skeletal muscle, respectively), glycolysis may occur anaerobically, although some of the available energy is lost.

Glycolysis also provides intermediates for other pathways. In the liver, glycolysis is part of the process by which excess glucose is converted to fatty acids for storage.

Bridge

Red blood cells extrude their mitochondria during development, as discussed in Chapter 7 of *MCAT Biology Review*. This helps them carry out their function (carrying oxygen) in two ways:

- Maximizing volume available for hemoglobin, the primary oxygen-carrying protein
- Stopping the red blood cell from utilizing the oxygen it's supposed to be carrying to oxygen-depleted bodily tissues

Real World

Because glycolysis is necessary in every cell of the body, there are no known diseases caused by the complete absence of any enzyme in glycolysis; in other words, being unable to carry out glycolysis is incompatible with life. Partial enzyme defects are also rare, but include *pyruvate kinase deficiency*.

IMPORTANT ENZYMES OF GLYCOLYSIS

While glycolysis contains many different steps, as illustrated in Figure 9.2, the MCAT predominantly tests on the enzymes that are highly regulated or that serve an important energetic function. Therefore, we'll focus our attention on five of these enzymes.

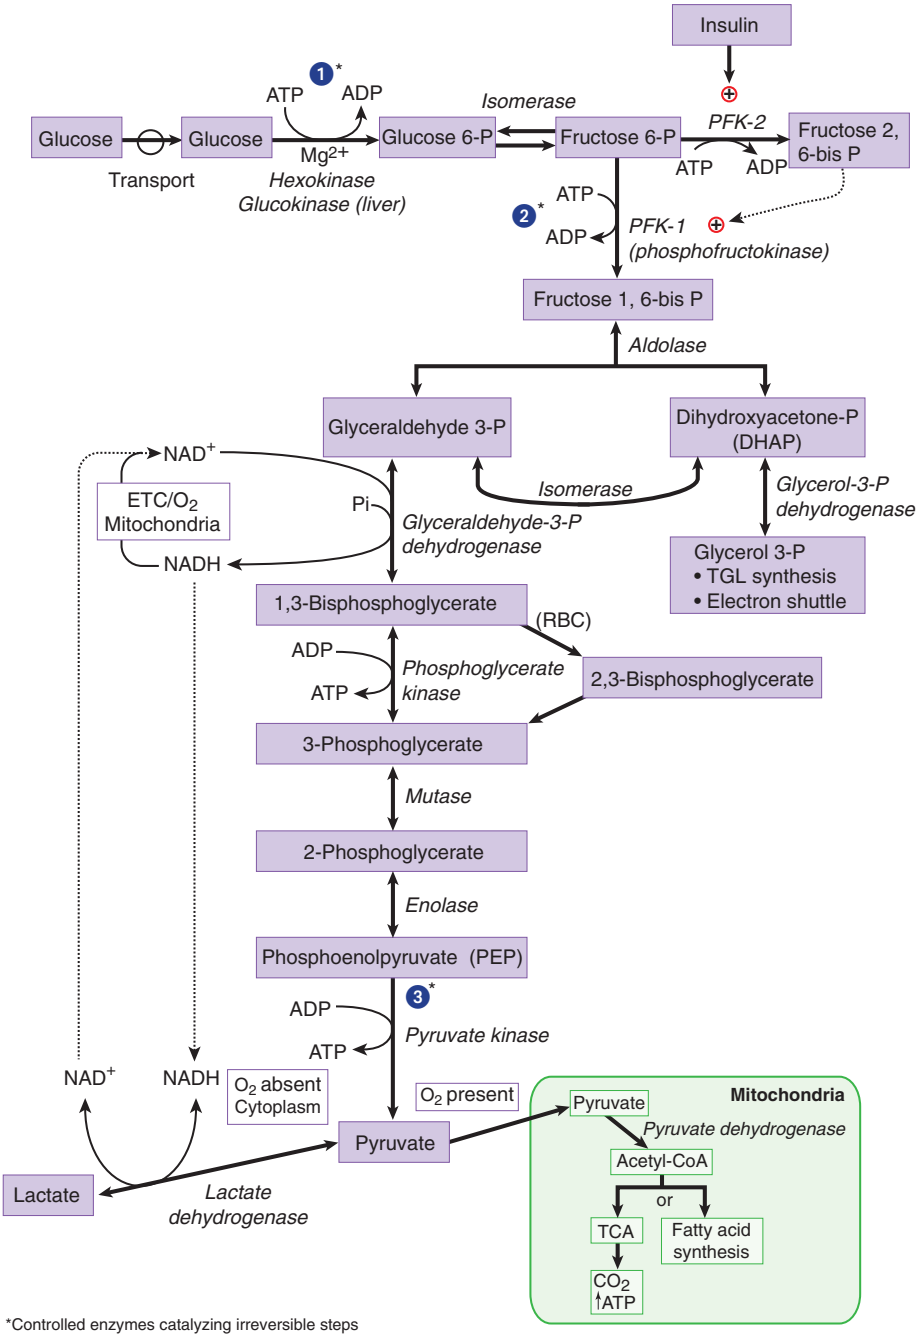

Figure 9.2. Glycolysis

Hexokinase and Glucokinase

The first steps in glucose metabolism in any cell are transport across the membrane and phosphorylation by kinase enzymes inside the cell to prevent glucose from leaving via the transporter. Remember from Chapter 2 of *MCAT Biochemistry Review* that kinases attach a phosphate group from ATP to their substrates. Glucose enters the cell by facilitated diffusion or active transport; in either case, these kinases convert glucose to *glucose 6-phosphate*. Because the GLUT transporters are specific for glucose (not *phosphorylated* glucose), the glucose gets "trapped" inside the cell and cannot leak out. ***Hexokinase*** is widely distributed in tissues and is inhibited by its product, glucose 6-phosphate. ***Glucokinase*** is found only in liver cells and pancreatic β-islet cells; in the liver, glucokinase is induced by insulin. Table 9.1 identifies the differences between these enzymes. These coincide with the differences between the glucose transporters in these tissues.

Hexokinase	Glucokinase
Present in most tissues	Present in hepatocytes and pancreatic β-islet cells (along with GLUT 2, acts as the glucose sensor)
Low K_m (reaches maximum velocity at low [glucose])	High K_m (acts on glucose proportionally to its concentration)
Inhibited by glucose 6-phosphate	Induced by insulin in hepatocytes

Table 9.1. Comparison of Hexokinase and Glucokinase

Phosphofructokinases (PFK-1 and PFK-2)

Phosphofructokinase-1 (**PFK-1**) is the rate-limiting enzyme and main control point in glycolysis. In this reaction, *fructose 6-phosphate* is phosphorylated to *fructose 1,6-bisphosphate* using ATP. PFK-1 is inhibited by ATP and citrate, and activated by AMP. This makes sense because the cell should turn off glycolysis when it has sufficient energy (high ATP) and turn on glycolysis when it needs energy (high AMP). Citrate is an intermediate of the citric acid cycle, so high levels of citrate also imply that the cell is producing sufficient energy.

Insulin stimulates and glucagon inhibits PFK-1 in hepatocytes by an indirect mechanism involving PFK-2 and fructose 2,6-bisphosphate, as shown in Figure 9.2. Insulin activates ***Phosphofructokinase-2*** (**PFK-2**), which converts a tiny amount of *fructose 6-phosphate* to *fructose 2,6-bisphosphate* (F2,6-BP). F2,6-BP activates PFK-1. On the other hand, glucagon inhibits PFK-2, lowering F2,6-BP and thereby inhibiting PFK-1. PFK-2 is found mostly in the liver. By activating PFK-1, it allows these cells to override the inhibition caused by ATP so that glycolysis can continue, even when the cell is energetically satisfied. The metabolites of glycolysis can thus be fed into the production of glycogen, fatty acids, and other storage molecules rather than just being burned to produce ATP.

Key Concept

Of all the enzymes the MCAT is most likely to test you on, the rate-limiting enzymes for each process are at the top of the list:

- Glycolysis: *phosphofructokinase-1*
- Fermentation: *lactate dehydrogenase*
- Glycogenesis: *glycogen synthase*
- Glycogenolysis: *glycogen phosphorylase*
- Gluconeogenesis: *fructose-1,6-bisphosphatase*
- Pentose Phosphate Pathway: *glucose-6-phosphate dehydrogenase*

Bridge

In Chapter 11 of *MCAT General Chemistry Review*, we learn that oxidation is loss of electrons, and reduction is gain of electrons. While this is true with biomolecules, it may be easier to think of oxidation as increasing bonds to oxygen or other heteroatoms (atoms besides C and H) and reduction as increasing bonds to hydrogen, as discussed in Chapter 4 of *MCAT Organic Chemistry Review*. Thus, the conversion of NAD^+ to NADH is a reduction reaction.

Glyceraldehyde-3-Phosphate Dehydrogenase

Glyceraldehyde-3-phosphate dehydrogenase catalyzes an oxidation and addition of inorganic phosphate (P_i) to its substrate, *glyceraldehyde 3-phosphate*. This results in the production of a high-energy intermediate *1,3-bisphosphoglycerate* and the reduction of NAD^+ to NADH. If glycolysis is aerobic, the NADH can be oxidized by the mitochondrial electron transport chain, providing energy for ATP synthesis by oxidative phosphorylation.

3-Phosphoglycerate Kinase

3-Phosphoglycerate kinase transfers the high-energy phosphate from 1,3-bisphosphoglycerate to ADP, forming ATP and *3-phosphoglycerate*. This type of reaction, in which ADP is directly phosphorylated to ATP using a high-energy intermediate, is referred to as **substrate-level phosphorylation**. In contrast to oxidative phosphorylation in mitochondria, substrate-level phosphorylations are not dependent on oxygen, and are the only means of ATP generation in an anaerobic tissue.

Pyruvate Kinase

The last enzyme in aerobic glycolysis, it catalyzes a substrate-level phosphorylation of ADP using the high-energy substrate *phosphoenolpyruvate* (PEP). ***Pyruvate kinase*** is activated by fructose 1,6-bisphosphate from the PFK-1 reaction. This is referred to as **feed-forward activation**, meaning that the product of an earlier reaction of glycolysis (fructose 1,6-bisphosphate) stimulates, or prepares, a later reaction in glycolysis (by activating pyruvate kinase).

FERMENTATION

In the absence of oxygen, **fermentation** will occur. The key fermentation enzyme in mammalian cells is ***lactate dehydrogenase***, which oxidizes NADH to NAD^+, replenishing the oxidized coenzyme for glyceraldehyde-3-phosphate dehydrogenase. Without mitochondria and oxygen, glycolysis would stop when all the available NAD^+ had been reduced to NADH. By reducing pyruvate to *lactate* and oxidizing NADH to NAD^+, lactate dehydrogenase prevents this potential problem from developing. There is no net loss of carbon in this process: pyruvate and lactate are both three-carbon molecules. In aerobic tissues, lactate does not normally form in significant amounts. However, when oxygenation is poor (during strenuous exercise in skeletal muscle, a heart attack, or a stroke), most cellular ATP is generated by anaerobic glycolysis, and lactate production increases.

In yeast cells, fermentation is the conversion of pyruvate (three carbons) to ethanol (two carbons) and carbon dioxide (one carbon). While the end products are different, the result of both mammalian and yeast fermentation is the same: replenishing NAD^+.

IMPORTANT INTERMEDIATES OF GLYCOLYSIS

Glycolysis serves as a crossroads for a number of metabolic processes; the intermediates of glycolysis are often used to link different pathways during both catabolism and anabolism. Three of these intermediates are worth highlighting:

- ***Dihydroxyacetone phosphate*** (**DHAP**) is used in hepatic and adipose tissue for triacylglycerol synthesis. DHAP is formed from fructose 1,6-bisphosphate. It can be isomerized to *glycerol 3-phosphate*, which can then be converted to *glycerol*, the backbone of triacylglycerols.
- 1,3-Bisphosphoglycerate (1,3-BPG) and phosphoenolpyruvate (PEP) are high-energy intermediates used to generate ATP by substrate-level phosphorylation. This is the only ATP gained in anaerobic respiration.

IRREVERSIBLE ENZYMES

Three enzymes in the pathway catalyze reactions that are irreversible. This keeps the pathway moving in only one direction. However, the liver must be able to generate new glucose from other biomolecules through gluconeogenesis, which is essentially the reverse of glycolysis. Because of the irreversible enzymes of glycolysis, different reactions, and therefore different enzymes, must be used at these three points:

- Glucokinase or hexokinase
- PFK-1
- Pyruvate kinase

Mnemonic

Irreversible steps of glycolysis:
How **G**lycolysis **P**ushes **F**orward the **P**rocess: **K**inases.
- **H**exokinase
- **G**lucokinase
- **PF**K-1
- **P**yruvate **K**inase

GLYCOLYSIS IN ERYTHROCYTES

In erythrocytes (red blood cells), anaerobic glycolysis represents the only pathway for ATP production, yielding a net 2 ATP per glucose.

Red blood cells have ***bisphosphoglycerate mutase***, which produces ***2,3-bisphosphoglycerate*** (**2,3-BPG**) from 1,3-BPG in glycolysis. Remember that *mutases* are enzymes that move a functional group from one place in a molecule to another; in this case, the phosphate is moved from the 1-position to the 2-position. 2,3-BPG binds allosterically to the β-chains of hemoglobin A (HbA) and decreases its affinity for oxygen. This effect of 2,3-BPG is seen in the oxygen dissociation curve for HbA, shown in Figure 9.3. The rightward shift in the curve is sufficient to allow unloading of oxygen in tissues, but still allows 100 percent saturation in the lungs. An abnormal increase in erythrocyte 2,3-BPG might shift the curve far enough so that HbA is not fully saturated in the lungs.

Bridge

Adaptation to high altitudes (low pO_2) involves:
- Increased respiration
- Increased oxygen affinity for hemoglobin (initial)
- Increased rate of glycolysis
- Increased [2,3-BPG] in RBC (over a 12–24 hour period)
- Normalized oxygen affinity for hemoglobin restored by the increased level of 2,3-BPG
- Increased hemoglobin (over days to weeks)

Gas exchange is discussed in Chapter 6 of *MCAT Biology Review*, and effects on hemoglobin are discussed in Chapter 7 of *MCAT Biology Review*.

Bridge

Remember the other physiological changes that promote a **right** shift of the oxygen dissociation curve (the Bohr effect), discussed in Chapter 7 of *MCAT Biology Review*:

- High 2,3-BPG
- Low pH
- High $[H^+]$
- High pCO_2

These all occur during exercise, giving the mnemonic: "Exercise is the **right** thing to do."

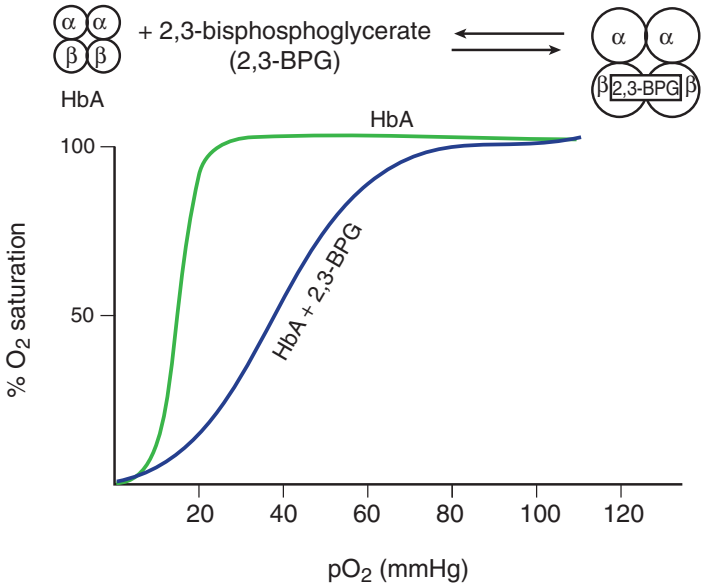

Figure 9.3. Effect of 2,3-Bisphosphoglycerate on Hemoglobin A

Although 2,3-BPG binds to HbA, it does not bind well to fetal hemoglobin (HbF), with the result that HbF has a higher affinity for oxygen than maternal HbA. This allows transplacental passage of oxygen from mother to fetus.

MCAT Concept Check 9.2:

Before you move on, assess your understanding of the material with these questions.

1. What are the function and key regulators of the following enzymes? Which ones are reversible?

Hexokinase

- Function:

_____

- Regulation:

_____

- Reversible? _____

Glucokinase

- Function:

_____

- Regulation:

_____

- Reversible? _____

Phosphofructokinase-1 (PFK-1)

- Function:

_____

- Regulation:

_____

- Reversible? _____

Glyceraldehyde-3-phosphate dehydrogenase

- Function:

_____

- Reversible? _____

3-phosphoglycerate kinase

- Function:

_____

- Reversible? _____

Pyruvate kinase

- Function:

_____

- Regulation:

_____

- Reversible? _____

2. Why must pyruvate undergo fermentation for glycolysis to continue?

_____

_____

3. Why is it necessary that fetal hemoglobin does not bind 2,3-BPG?

_____

_____

9.3 Other Monosaccharides

While glucose represents the primary monosaccharide used by cells, other monosaccharides such as *galactose* and *fructose* can also contribute to ATP production by feeding into glycolysis or other metabolic processes. These monosaccharides are tested far less frequently than glucose on the MCAT, but are included here to compare and contrast their metabolism with glycolysis. In particular, notice the similarities between Figure 9.2 (glycolysis) and Figures 9.4 (galactose metabolism) and 9.5 (fructose metabolism).

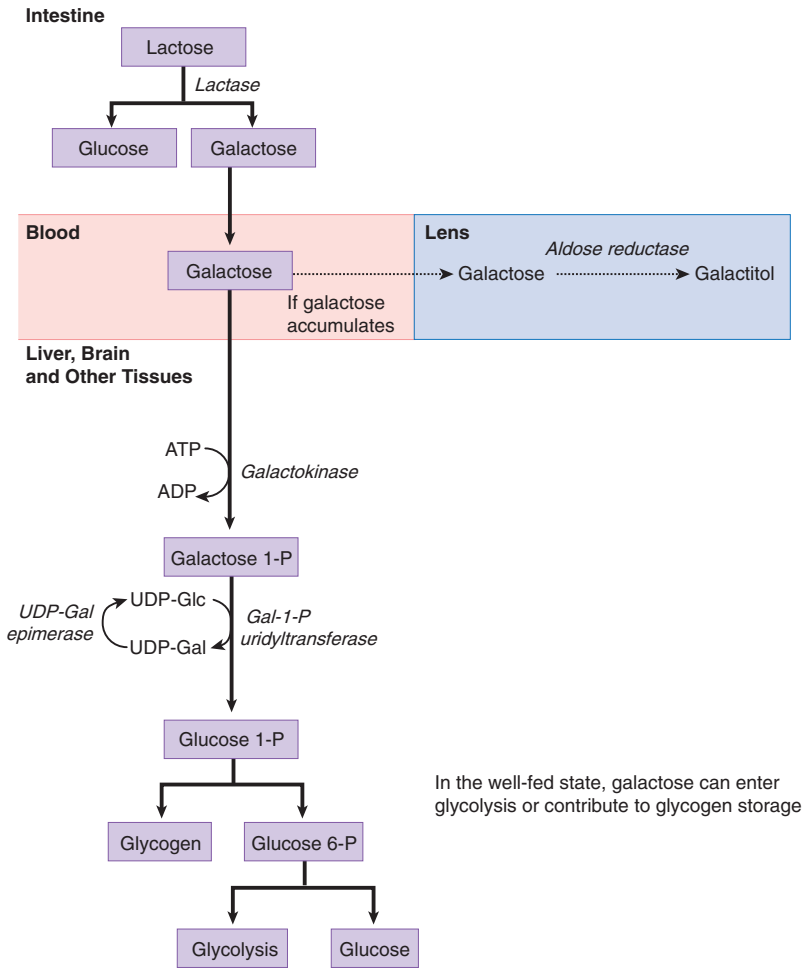

Figure 9.4. Galactose Metabolism

GALACTOSE METABOLISM

An important source of **galactose** in the diet is the disaccharide *lactose* present in milk. Lactose is hydrolyzed to galactose and glucose by *lactase,* which is a brush-border enzyme of the duodenum. Along with other monosaccharides,

Real World

Primary lactose intolerance is caused by a hereditary deficiency of lactase. *Secondary lactose intolerance* can be precipitated at any age by gastrointestinal disturbances that cause damage to the intestinal lining, where lactase is found.

Common symptoms of lactose intolerance include vomiting, bloating, explosive and watery diarrhea, cramps, and dehydration. The symptoms can be attributed to bacterial fermentation of lactose, which produces a mixture of CH_4, H_2, and small organic acids. The acids are osmotically active and result in the movement of water into the intestinal lumen.

galactose reaches the liver through the hepatic portal vein. Once transported into tissues, galactose is phosphorylated by ***galactokinase***, trapping it in the cell. The resulting *galactose 1-phosphate* is converted to *glucose 1-phosphate* by ***galactose-1-phosphate uridyltransferase*** and an *epimerase*. **Epimerases** are enzymes that catalyze the conversion of one sugar epimer to another; remember from Chapter 4 of *MCAT Biochemistry Review* that epimers are diastereomers that differ at exactly one chiral carbon. The pathway is shown in Figure 9.4; important enzymes to remember are:

- Galactokinase
- Galactose-1-phosphate uridyltransferase

FRUCTOSE METABOLISM

Fructose is found in honey and fruit and as part of the disaccharide *sucrose* (common table sugar). Sucrose is hydrolyzed by the duodenal brush-border enzyme *sucrase*, and the resulting monosaccharides, glucose and fructose, are absorbed into the hepatic portal vein. The liver phosphorylates fructose using ***fructokinase*** to trap it in the cell. The resulting *fructose 1-phosphate* is then cleaved into *glyceraldehyde* and DHAP by *aldolase B*. Smaller amounts are metabolized in renal proximal tubules. The pathway is shown in Figure 9.5.

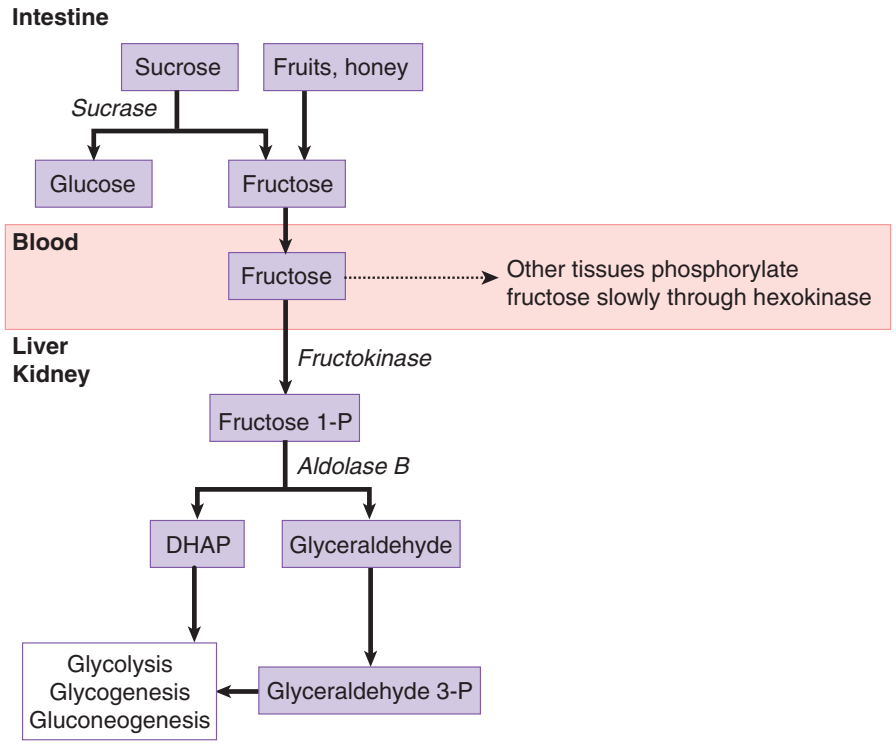

Figure 9.5. Fructose Metabolism

Real World

Genetic deficiencies of galactokinase or galactose-1-phosphate uridyltransferase lead to galactosemia. Cataracts are a characteristic finding, which result from the conversion of excess galactose in the blood to galactitol in the lens of the eye by aldose reductase. Galactitol is a polyol (a carbon chain with many alcohol groups) and, as such, is hydrophilic. Accumulation of galactitol in the lens causes osmotic damage and cataracts.

Deficiency of galactose-1-phosphate uridyltransferase is more severe because, in addition to causing galactosemia, it leads to galactose 1-phosphate getting stuck intracellularly in the liver, brain, and other tissues and not diffusing out.

Key Concept

Because dihydroxyacetone phosphate (DHAP) and glyceraldehyde, the products of fructose metabolism, are downstream from the key regulatory and rate-limiting enzyme of glycolysis (PFK-1), a high-fructose drink supplies a quick source of energy in both aerobic and anaerobic cells.

MCAT Concept Check 9.3:

Before you move on, assess your understanding of the material with these questions.

1. Which enzyme is responsible for trapping galactose in the cell? What enzyme in galactose metabolism results in a product that can feed directly into glycolysis, linking the two pathways?
   - "Trapping" enzyme: _____
   - "Linking" enzyme: _____
2. Which enzyme is responsible for trapping fructose in the cell? What enzyme in fructose metabolism results in a product that can feed directly into glycolysis, linking the two pathways?
   - "Trapping" enzyme: _____
   - "Linking" enzyme: _____

9.4 Pyruvate Dehydrogenase ★

Pyruvate from aerobic glycolysis enters mitochondria, where it may be converted to ***acetyl-CoA*** for entry into the citric acid cycle if ATP is needed, or for fatty acid synthesis if sufficient ATP is present. The ***pyruvate dehydrogenase complex*** (**PDH**) reaction, shown in Figure 9.6, is irreversible and cannot be used to convert acetyl-CoA to pyruvate or to glucose. Pyruvate dehydrogenase in the liver is activated by insulin, whereas in the nervous system, the enzyme is not responsive to hormones. This makes sense because high insulin levels signal to the liver that the individual is in a well-fed state; thus, the liver should not only burn glucose for energy, but shift the fatty acid equilibrium toward production and storage, rather than oxidation (fatty acid synthesis, discussed in Chapter 11 of *MCAT Biochemistry Review*, starts from citrate produced in the citric acid cycle).

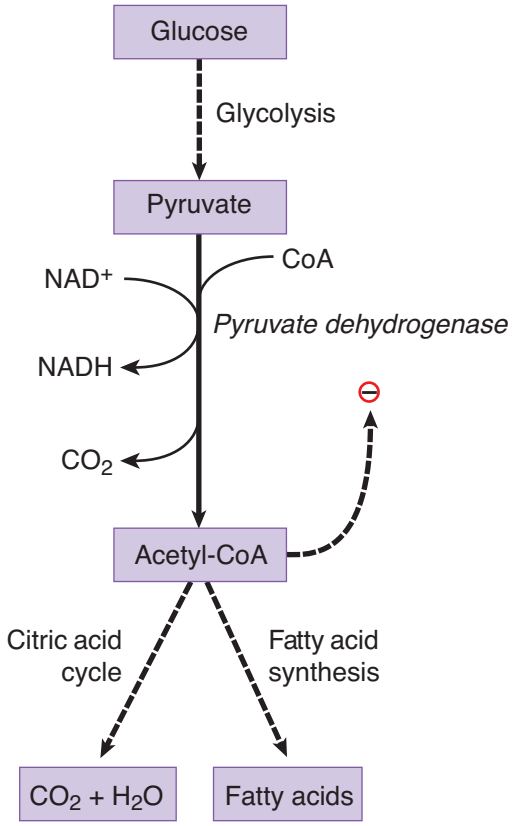

Figure 9.6. Pyruvate Dehydrogenase

Pyruvate dehydrogenase is actually a complex of enzymes carrying out multiple reactions in succession. The details of each of these reactions are covered in Chapter 10 of *MCAT Biochemistry Review*, but an overview of the enzyme is provided here because it represents one of three possible fates of pyruvate: conversion to acetyl-CoA by PDH, conversion to lactate by lactate dehydrogenase, or conversion to *oxaloacetate* by *pyruvate carboxylase*.

This large complex requires multiple cofactors and coenzymes, including *thiamine pyrophosphate*, *lipoic acid*, CoA, FAD, and NAD^+. Insufficient amounts of any of these cofactors or coenzymes can result in metabolic derangements.

Pyruvate dehydrogenase is inhibited by its product acetyl-CoA. This control is important in several contexts and should be considered along with pyruvate carboxylase, the other mitochondrial enzyme that uses pyruvate (introduced in gluconeogenesis, later in this chapter). Essentially, the buildup of acetyl-CoA (which happens during β-oxidation) causes a shift in metabolism: pyruvate is no longer converted into acetyl-CoA (to enter the citric acid cycle), but rather into oxaloacetate (to enter gluconeogenesis).

Real World

A deficiency in thiamine (vitamin B_1) can result in:

- *Beriberi*, which is characterized by congestive heart failure or nerve damage.
- *Wernicke–Korsakoff syndrome*, which is characterized by difficulty walking, uncoordinated eye movements, confusion, and memory disturbances.

Giving glucose to an individual with thiamine deficiency can lead to severe lactic acidosis and other metabolic derangements because pyruvate cannot be converted into acetyl-CoA without the vitamin. This is why thiamine must be given before an infusion of glucose in individuals suspected to have thiamine deficiency (such as alcoholics).

MCAT Concept Check 9.4:

Before you move on, assess your understanding of the material with these questions.

1. What are the reactants of the pyruvate dehydrogenase complex? What are the products?
   - Reactants: _____
   - Products: _____
2. How does acetyl-CoA affect PDH complex activity? Why?

_____

_____

_____

9.5 Glycogenesis and Glycogenolysis

Key Concept

The glycogen in the liver and in skeletal muscle serve two quite different roles. Liver glycogen is broken down to maintain a constant level of glucose in the blood; muscle glycogen is broken down to provide glucose to the muscle during vigorous exercise.

Glycogen, a branched polymer of glucose, represents a storage form of glucose. Glycogen synthesis and degradation occur primarily in liver and skeletal muscle, although other tissues store smaller quantities. Glycogen is stored in the cytoplasm as granules. Each granule has a central protein core with polyglucose chains radiating outward to form a sphere, as shown in Figure 9.7. Glycogen granules composed entirely of linear chains have the highest density of glucose near the core. If the chains are branched, the glucose density is highest at the periphery of the granule, allowing more rapid release of glucose on demand.

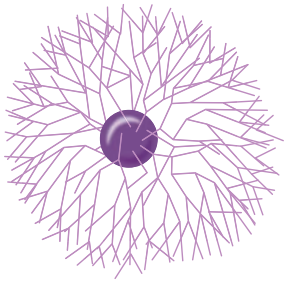

Figure 9.7. A Glycogen Granule

Glycogen stored in the liver is a source of glucose that is mobilized between meals to prevent low blood sugar, whereas muscle glycogen is stored as an energy reserve for muscle contraction.

While our focus is on human metabolism, it is worth mentioning that plants also store excess glucose in long α-linked chains of glucose called **starch**, as seen in Figure 9.8.

Figure 9.8. Potatoes and Potato Starch

GLYCOGENESIS

Glycogenesis is the synthesis of glycogen granules. It begins with a core protein called *glycogenin*. As shown in Figure 9.9, glucose addition to a granule begins with glucose 6-phosphate, which is converted to glucose 1-phosphate. This glucose 1-phosphate is then activated by coupling to a molecule of *uridine diphosphate* (UDP), which permits its integration into the glycogen chain by glycogen synthase. This activation occurs when glucose 1-phosphate interacts with *uridine triphosphate* (UTP), forming UDP-glucose and a *pyrophosphate* (PP_i).

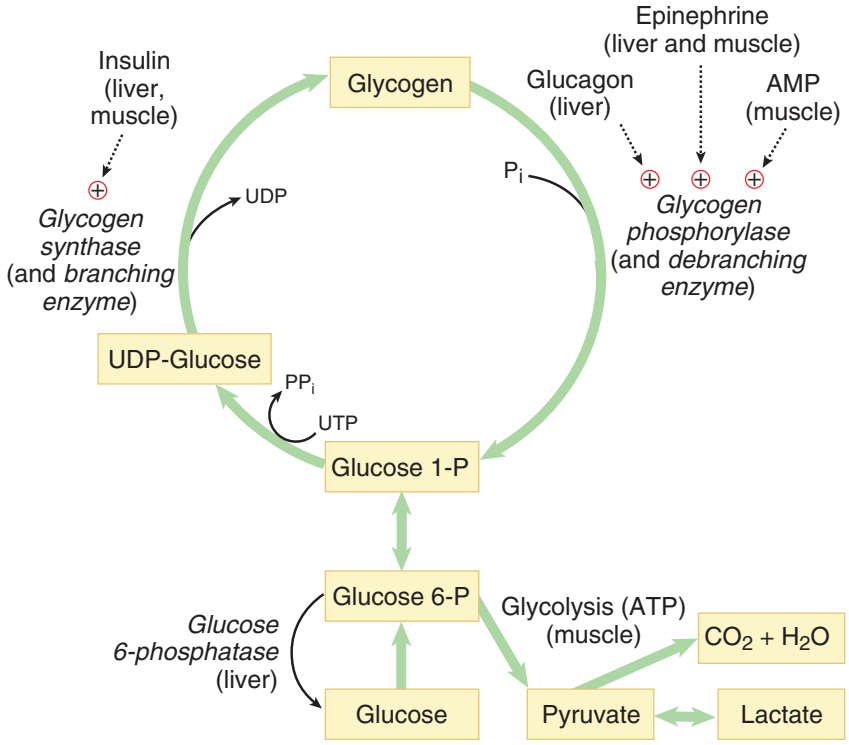

Figure 9.9. Glycogen Metabolism

Glycogen Synthase

Glycogen synthase is the rate-limiting enzyme of glycogen synthesis and forms the α-1,4 glycosidic bond found in the linear glucose chains of the granule. It is stimulated by glucose 6-phosphate and insulin. It is inhibited by epinephrine and glucagon through a protein kinase cascade that phosphorylates and inactivates the enzyme.

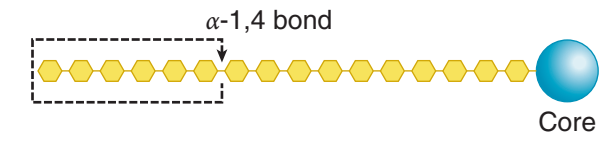
Branching Enzyme (Glycosyl α-1,4:α-1,6 Transferase)

Branching enzyme is responsible for introducing α-1,6-linked branches into the granule as it grows. The process by which the branch is introduced is shown schematically in Figure 9.10. Branching enzyme:

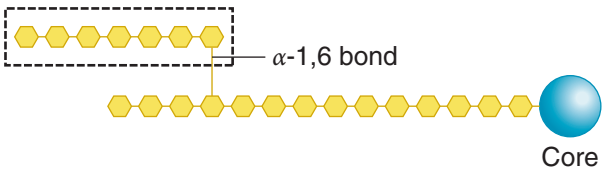
- Hydrolyzes one of the α-1,4 bonds to release a block of oligoglucose (a few glucose molecules bonded together in a chain), which is then moved and added in a slightly different location.
- Forms an α-1,6 bond to create a branch.

Mnemonic

α-1,**4** keeps the same branch moving "**4**ward"; α-1,6 (one-**six**) "puts a branch in the **mix**."



1. Glycogen synthase makes a linear α-1,4-linked polyglucose chain (⬡⬡⬡⬡⬡)
2. Branching enzyme hydrolyzes an α-1,4 bond



3. Branching enzyme transfers the oligoglucose unit and attaches it with an α-1,6 bond to create a branch
4. Glycogen synthase extends both branches

Figure 9.10. Branching Enzyme

GLYCOGENOLYSIS

The rate-limiting enzyme of **glycogenolysis**, the process of breaking down glycogen, is *glycogen phosphorylase*. In contrast to a *hydrolase*, a *phosphorylase* breaks bonds using an inorganic phosphate instead of water. The glucose 1-phosphate formed by glycogen phosphorylase is converted to glucose 6-phosphate by the same mutase used in glycogen synthesis, as shown in Figure 9.9.

Glycogen Phosphorylase

Glycogen phosphorylase breaks α-1,4 glycosidic bonds, releasing glucose 1-phosphate from the periphery of the granule. It cannot break α-1,6 bonds and therefore stops when it nears the outermost branch points. Glycogen phosphorylase is activated by glucagon in the liver, so that glucose can be provided for the rest of the body. In skeletal muscle, it is activated by AMP and epinephrine, which signal that the muscle is active and requires more glucose. It is inhibited by ATP.

Debranching Enzyme (Glucosyl α-1,4:α-1,4 Transferase and α-1,6 Glucosidase)

Debranching enzyme is a two-enzyme complex that deconstructs the branches in glycogen that have been exposed by glycogen phosphorylase. The two-step process by which this occurs is diagrammed in Figure 9.11. Debranching enzyme:

- Breaks an α-1,4 bond adjacent to the branch point and moves the small oligoglucose chain that is released to the exposed end of the other chain.
- Forms a new α-1,4 bond.

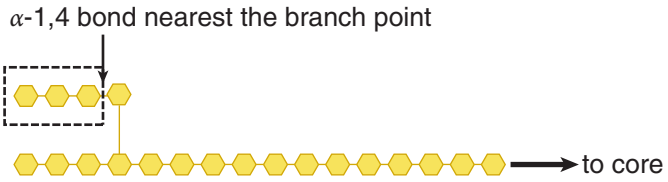
MCAT Expertise

Under the pressure of Test Day, it can be easy to misread words. When given a passage or question about carbohydrate metabolism, be sure you focus so you can distinguish between *glycolysis*, *glycogenesis*, *glycogenolysis*, and *gluconeogenesis*.

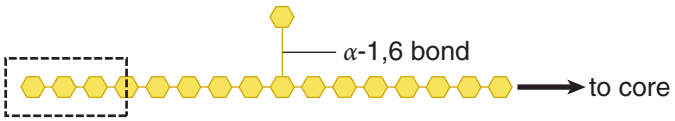
Key Concept

Debranching enzyme is actually made up of two enzymes with different functions: one moves the terminal end of a glycogen chain to the branch point (α-1,4:α-1,4 transferase), and one removes the glucose monomer actually present at the branch point (α-1,6 glucosidase).

- Hydrolyzes the α-1,6 bond, releasing the single residue at the branch point as free glucose. This represents the only free glucose produced directly in glycogenolysis (as opposed to the glucose produced from glucose 1-phosphate, which must be converted by a mutase to glucose 6-phosphate before it can be converted to glucose via the enzyme *glucose 6-phosphatase*).



1. Glycogen phosphorylase releases glucose 1-P from the periphery of the granule until it encounters the first branch point
2. Debranching enzyme hydrolyzes the α-1,4 bond nearest the branch point, as shown



3. Debranching enzyme transfers the oligoglucose unit to the end of another chain, then:
4. Hydrolyzes the α-1,6 bond, releasing the single glucose from the former branch

Figure 9.11. Debranching Enzyme

GLYCOGEN STORAGE DISEASES

There are a number of genetic deficiencies that can impact the metabolism of glycogen. The clinical features of a metabolic glycogen defect depend on a few important factors: which enzyme is affected, the degree to which that enzyme's activity is decreased, and which isoform of the enzyme is affected. **Isoforms** are slightly different versions of the same protein; in the case of glycogen enzymes, there are often different isoforms of the enzymes in the liver and muscle. These deficiencies are termed **glycogen storage diseases** because all are characterized by accumulation or lack of glycogen in one or more tissues.

Real World

The most common glycogen storage disease is *von Gierke's disease*, a defect in glucose-6-phosphatase. Because this enzyme is also the last step of gluconeogenesis, this process is also affected, leading to periods of extremely low blood sugar between meals. These patients therefore need continuous feeding with carbohydrates to maintain blood sugar. With the buildup of glucose 6-phosphate in liver cells, the liver enlarges and is damaged over time.

MCAT Concept Check 9.5:
Before you move on, assess your understanding of the material with these questions.

1. What is the structure of glycogen? What types of glycosidic links exist in a glycogen granule?

_____

_____

_____

2. What are the two main enzymes of glycogenesis, and what does each accomplish?

   1. _____

   2. _____

3. What are the two main enzymes of glycogenolysis, and what does each accomplish?

   1. _____

   2. _____

9.6 Gluconeogenesis ★★

The liver maintains glucose levels in blood during fasting through either glycogenolysis or **gluconeogenesis**. The kidney can also carry out gluconeogenesis, although its contribution is much smaller. These pathways are promoted by glucagon and epinephrine, which act to raise blood sugar levels, and are inhibited by insulin, which acts to lower blood sugar levels. During fasting, glycogen reserves drop dramatically in the first 12 hours, during which time gluconeogenesis increases. After 24 hours, it represents the sole source of glucose. Important substrates for gluconeogenesis are:

- Glycerol 3-phosphate (from stored fats, or triacylglycerols, in adipose tissue)
- Lactate (from anaerobic glycolysis)
- Glucogenic amino acids (from muscle proteins)

The last item of this list merits some explaining. Amino acids can be subclassified as glucogenic, ketogenic, or both. **Glucogenic amino acids** (all except leucine and lysine) can be converted into intermediates that feed into gluconeogenesis, while **ketogenic amino acids** can be converted into ketone bodies, which can be used as an

Key Concept

Insulin acts to lower blood sugar levels; the counterregulatory hormones, which include glucagon, epinephrine, cortisol, and growth hormone, act to raise blood sugar levels by stimulating glycogenolysis and gluconeogenesis. The regulation of metabolism is discussed in Chapter 12 of *MCAT Biochemistry Review*.

Bridge

Amino acids and proteins are extremely important topics for the MCAT. Check out Chapter 1 of *MCAT Biochemistry Review* for more information on amino acids, peptides, and proteins.

alternative fuel, particularly during periods of prolonged starvation. See Chapter 11 of *MCAT Biochemistry Review* for more information on amino acid and protein metabolism.

Dietary fructose and galactose can also be converted to glucose in the liver, as described earlier in this chapter.

In humans, while glucose is converted into acetyl-CoA through glycolysis and pyruvate dehydrogenase, it is not possible to convert acetyl-CoA back to glucose. Because most fatty acids are metabolized solely to acetyl-CoA, they are not a major source of glucose either. One minor exception is fatty acids with an odd number of carbon atoms (for example, fatty acid tails containing 17 carbons), which yield a small amount of *propionyl-CoA*, which is glucogenic.

The pathway of gluconeogenesis is diagrammed in Figure 9.12. Each of the important gluconeogenic intermediates—lactate, alanine, and glycerol 3-phosphate—have enzymes that convert them into glycolytic intermediates. Lactate is converted to pyruvate by *lactate dehydrogenase*. Alanine is converted to pyruvate by *alanine aminotransferase*. Glycerol 3-phosphate is converted to dihydroxyacetone phosphate (DHAP) by *glycerol-3-phosphate dehydrogenase*.

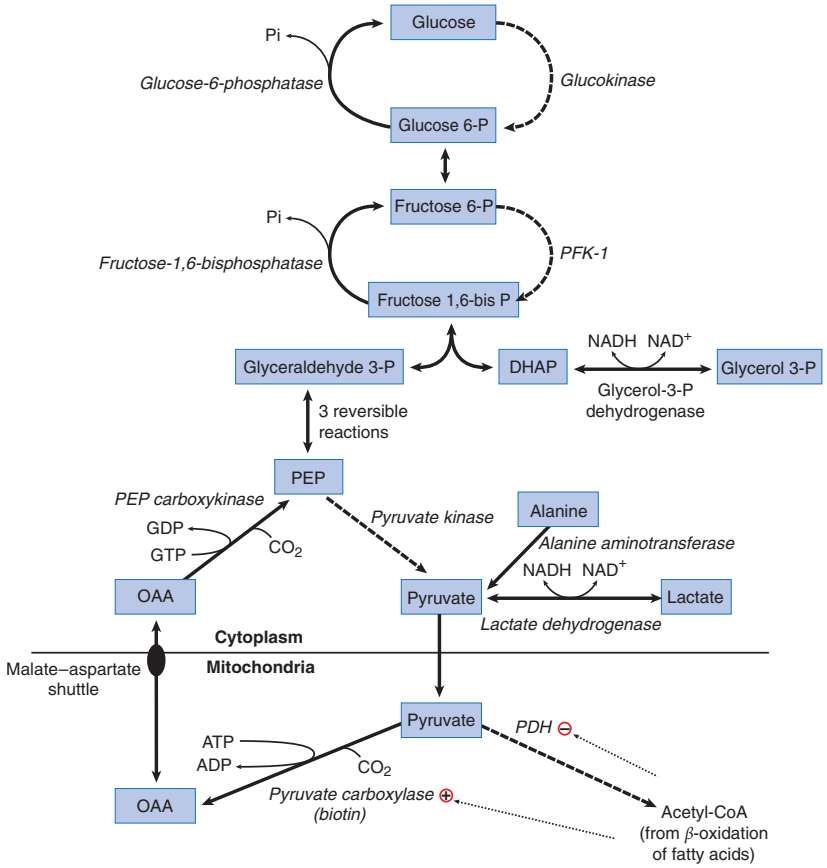


Figure 9.12. Gluconeogenesis

IMPORTANT ENZYMES OF GLUCONEOGENESIS

Most steps in gluconeogenesis represent a reversal of glycolysis and have thus been omitted from the diagram. However, the four important enzymes to know are those required to catalyze reactions that circumvent the irreversible steps of glycolysis in the liver (those catalyzed by glucokinase, phosphofructokinase-1, and pyruvate kinase).

Pyruvate Carboxylase

Pyruvate carboxylase is a mitochondrial enzyme that is activated by acetyl-CoA (from β-oxidation). The product, oxaloacetate (OAA), is a citric acid cycle intermediate and cannot leave the mitochondrion. Rather, it is reduced to *malate*, which can leave the mitochondrion via the malate–aspartate shuttle, which is described in Chapter 10 of *MCAT Biochemistry Review*. Once in the cytoplasm, malate is oxidized to OAA. The fact that acetyl-CoA activates pyruvate carboxylase is an important point. Acetyl-CoA inhibits pyruvate dehydrogenase because a high level of acetyl-CoA implies that the cell is energetically satisfied and need not run the citric acid cycle in the forward direction; in other words, the cell should stop burning glucose. Rather, pyruvate will be shunted through pyruvate carboxylase to help generate additional glucose through gluconeogenesis. Note that the source of acetyl-CoA is not from glycolysis and pyruvate dehydrogenase in this case, but from fatty acids. Thus, to produce glucose in the liver during gluconeogenesis, fatty acids must be burned to provide this energy, stop the forward flow of the citric acid cycle, and produce massive amounts of OAA that can eventually lead to glucose production for the rest of the body.

Phosphoenolpyruvate Carboxykinase (PEPCK)

Phosphoenolpyruvate carboxykinase (**PEPCK**) in the cytoplasm is induced by glucagon and cortisol, which generally act to raise blood sugar levels. It converts OAA to phosphoenolpyruvate (PEP) in a reaction that requires GTP. PEP continues in the pathway to fructose 1,6-bisphosphate. Thus, the combination of pyruvate carboxylase and PEPCK are used to circumvent the action of pyruvate kinase by converting pyruvate back into PEP.

Fructose-1,6-Bisphosphatase

Fructose-1,6-bisphosphatase in the cytoplasm is a key control point of gluconeogenesis and represents the rate-limiting step of the process. It reverses the action of phosphofructokinase-1, the rate-limiting step of glycolysis, by removing phosphate from fructose 1,6-bisphosphate to produce fructose 6-phosphate. A common pattern to note is that *phosphatases* oppose kinases. Fructose-1,6-bisphosphatase is activated by ATP and inhibited by AMP and fructose 2,6-bisphosphate. This should make sense: high levels of ATP imply that a cell is energetically satisfied enough to produce glucose for the rest of

Key Concept

Because glycolysis contains three irreversible steps (those catalyzed by hexokinase, phosphofructokinase-1, and pyruvate kinase), different enzymes must exist in gluconeogenesis to allow the body to revert pyruvate to glucose.

the body, whereas high levels of AMP imply that a cell needs energy and cannot afford to produce energy for the rest of the body before satisfying its own requirements. Fructose 2,6-bisphosphate (F2,6-BP) is sometimes thought of as a marker for satisfactory energy levels in liver cells. It helps these cells override the inhibition of phosphofructokinase-1 that occurs when high levels of acetyl-CoA are formed, signaling to the liver cell that it should shift its function from burning to storing fuel. F2,6-BP, produced by PFK-2, controls both gluconeogenesis and glycolysis (in the liver). Recall from the earlier discussion of this enzyme and Figure 9.2 that PFK-2 is activated by insulin and inhibited by glucagon. Thus, glucagon will lower F2,6-BP and stimulate gluconeogenesis, whereas insulin will increase F2,6-BP and inhibit gluconeogenesis.

Glucose-6-Phosphatase

Glucose-6-phosphatase is found only in the lumen of the endoplasmic reticulum in liver cells. Glucose 6-phosphate is transported into the ER, and free glucose is transported back into the cytoplasm, from where it can diffuse out of the cell using GLUT transporters. The absence of glucose-6-phosphatase in skeletal muscle means that muscle glycogen cannot serve as a source of blood glucose and rather is for use only within the muscle. Glucose-6-phosphatase is used to circumvent glucokinase and hexokinase, which convert glucose to glucose 6-phosphate.

Although alanine is the major glucogenic amino acid, almost all amino acids are also glucogenic. Most of these are converted by individual pathways to citric acid cycle intermediates, then to malate, following the same path from there to glucose.

It is important to note that glucose produced by hepatic (liver-based) gluconeogenesis does not represent an energy source for the liver. Gluconeogenesis requires expenditure of ATP that is provided by β-oxidation of fatty acids. Therefore, as mentioned above, hepatic gluconeogenesis is always dependent on β-oxidation of fatty acids in the liver. During periods of low blood sugar, adipose tissue releases these fatty acids by breaking down triacylglycerols to glycerol (which can also be converted to the gluconeogenic intermediate DHAP) and free fatty acids.

Although the acetyl-CoA from fatty acids cannot be converted into glucose, it can be converted into ketone bodies as an alternative fuel for cells, including the brain. Extended periods of low blood sugar are thus usually accompanied by high levels of ketones in the blood. Ketone bodies can be thought of as a transportable form of acetyl-CoA that is primarily utilized in periods of extended starvation.

Key Concept

Because gluconeogenesis requires acetyl-CoA to occur (to inhibit pyruvate dehydrogenase and stimulate pyruvate carboxylase), gluconeogenesis is inextricably linked to fatty acid oxidation. The source of acetyl-CoA cannot be glycolysis because this would just burn the glucose that is being generated in gluconeogenesis.

Real World

Because red blood cells lack mitochondria, they cannot carry out aerobic metabolism. Rather, pyruvate is converted to lactic acid to regenerate NAD^+. However, lactate is acidic; it must be removed from the bloodstream to avoid acidifying the blood. Red blood cells deliver this lactate to the liver, where it can be converted back into pyruvate and, through gluconeogenesis, become glucose for the red blood cells to use. This is known as the Cori cycle: glucose is converted to lactate in red blood cells, and lactate is converted to glucose in liver cells.

MCAT Concept Check 9.6:

Before you move on, assess your understanding of the material with these questions.

1. Under what physiological conditions should the body carry out gluconeogenesis?

_____

_____

2. What are the four enzymes unique to gluconeogenesis? Which irreversible glycolytic enzymes do they replace?

Gluconeogenic Enzyme	Replaces

3. How does acetyl-CoA shift the metabolism of pyruvate?

_____

_____

_____

9.7 The Pentose Phosphate Pathway ★

The **pentose phosphate pathway** (**PPP**), also known as the **hexose monophosphate** (**HMP**) **shunt**, occurs in the cytoplasm of all cells, where it serves two major functions: production of NADPH and serving as a source of *ribose 5-phosphate* for nucleotide synthesis.

An abbreviated diagram of the pathway is shown in Figure 9.13. The first part of the PPP begins with glucose 6-phosphate, ends with *ribulose 5-phosphate*, and is irreversible. This part produces NADPH and involves the important rate-limiting enzyme ***glucose-6-phosphate dehydrogenase*** (**G6PD**). G6PD is induced by insulin because the abundance of sugar entering the cell under insulin stimulation will be shunted into both fuel utilization pathways (glycolysis and aerobic respiration) as well as fuel storage pathways (fatty acid synthesis, glycogenesis, and the PPP). The shunt is also inhibited by its product, NADPH, and is activated by one of its reactants, $NADP^+$.

Real World

G6PD deficiency is an X-linked disorder and is the most common inherited enzyme defect in the world. Because the PPP is critically important in maintaining levels of glutathione, which helps break down peroxides, these individuals are susceptible to oxidative stress, especially in red blood cells, which carry a large concentration of oxygen. Ingestion of certain oxidizing compounds (especially particular antibiotics and antimalarial medications) or infections can lead to high concentrations of reactive oxygen species, which cause red blood cell lysis. It is hypothesized that the defect evolved because it provides some resistance to malaria infection. G6PD deficiency has also been called *favism* because fava beans are a highly oxidizing food that will also cause hemolysis in these individuals.

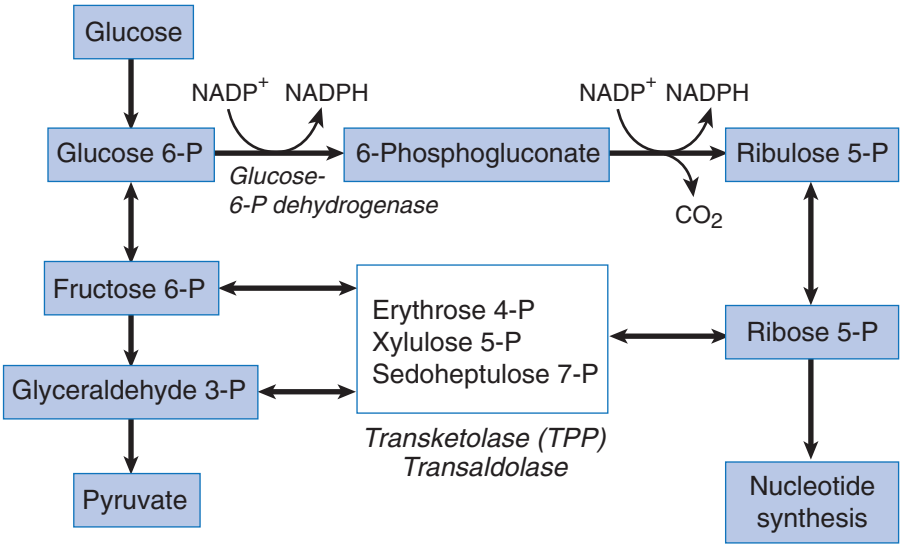

Figure 9.13. The Pentose Phosphate Pathway

Bridge

The ribulose 5-phosphate created in the PPP is isomerized to ribose 5-phosphate, the backbone of nucleic acids. When coupled to a nitrogenous base, it forms a nucleotide that can be integrated into RNA. Make sure to review RNA synthesis (transcription; Chapter 7 of *MCAT Biochemistry Review*), as well as DNA synthesis (Chapter 6 of *MCAT Biochemistry Review*) because these are highly tested topics on the MCAT.

The second part of the pathway, beginning with ribulose 5-phosphate, represents a series of reversible reactions that produce an equilibrated pool of sugars for biosynthesis, including ribose 5-phosphate for nucleotide synthesis. Because fructose 6-phosphate and glyceraldehyde 3-phosphate are among the sugars produced, intermediates can feed back into glycolysis; conversely, pentoses can be made from glycolytic intermediates without going through the G6PD reaction. These interconversions are primarily accomplished by the enzymes *transketolase* and *transaldolase*.

FUNCTIONS OF NADPH

Key Concept

NADPH and NADH are not the same thing. NAD^+ is an energy carrier; NADPH is used in biosynthesis, in the immune system, and to help prevent oxidative damage.

While their names appear similar, NADPH and NADH are not the same thing. In the cell, NAD^+ acts as a high-energy electron acceptor from a number of biochemical reactions. It thus can be thought of as a potent oxidizing agent because it helps another molecule be oxidized (and thus is reduced itself during the process). The NADH produced from this reduction of NAD^+ can then feed into the electron transport chain to indirectly produce ATP.

Conversely, **NADPH** primarily acts as an electron donor in a number of biochemical reactions. It thus can be thought of as a potent reducing agent because it helps other molecules be reduced (and thus is oxidized itself during the process). Cells require NADPH for a variety of functions, including:

- Biosynthesis, mainly of fatty acids and cholesterol
- Assisting in cellular bleach production in certain white blood cells, thereby contributing to bactericidal activity
- Maintenance of a supply of reduced *glutathione* to protect against reactive oxygen species (acting as the body's natural antioxidant)

This last function is important in protecting cells from free radical oxidative damage caused by peroxides. Hydrogen peroxide, H_2O_2, is produced as a byproduct in aerobic metabolism, and can break apart to form hydroxide radicals, $OH^{\bullet}$. Free radicals can attack lipids, including those in the phospholipids of the membrane. When oxidized, these lipids lose their function and can weaken the membrane, causing cell lysis. This is especially true in red blood cells, which contain high levels of oxygen, which, when oxidized by other free radicals, becomes the superoxide radical $O_2^{\bullet -}$. Free radicals can also damage DNA, potentially causing cancer. **Glutathione** is a reducing agent that can help reverse radical formation before damage is done to the cell.

MCAT Concept Check 9.7:

Before you move on, assess your understanding of the material with these questions.

1. What are the two major metabolic products of the pentose phosphate pathway (PPP)?
   1. _____
   2. _____
2. What are three primary functions of NADPH?
   1. _____
   2. _____
   3. _____

Conclusion

This chapter is critically important in your studying for the MCAT. The processes of carbohydrate metabolism that do not require oxygen are heavily tested, as is their integration. The body has evolved in such a way that we can use, store, or create fuel 24 hours a day, depending on the demands of the internal and external environment. We can turn on pathways when we need them and turn them off when we don't. And the regulation of these pathways makes sense: for example, acetyl-CoA—a downstream product of glycolysis—can turn off the process of glycolysis and allow us to either store extra sugar as other biomolecules or generate sugar anew if we need it. Return to this chapter repeatedly during your studies to maximize points on metabolism on Test Day. In the next chapter, we'll turn our attention to the oxygen-requiring carbohydrate metabolism processes, including the citric acid cycle, the electron transport chain (ETC), and oxidative phosphorylation.

CONCEPT SUMMARY

Glucose Transport

- **GLUT 2** is found in the liver (for glucose storage) and pancreatic β-islet cells (as part of the glucose sensor). It has a high K_m.
- **GLUT 4** is found in adipose tissue and muscle and is stimulated by insulin. It has a low K_m.

Glycolysis

- **Glycolysis** occurs in the cytoplasm of all cells, and does not require oxygen. It yields 2 ATP per molecule of glucose.
- Important glycolytic enzymes include:
  - **Glucokinase**, which converts glucose to glucose 6-phosphate. It is present in the pancreatic β-islet cells as part of the glucose sensor and is responsive to insulin in the liver.
  - **Hexokinase**, which converts glucose to glucose 6-phosphate in peripheral tissues.
  - **Phosphofructokinase-1** (**PFK-1**), which phosphorylates fructose 6-phosphate to fructose 1,6-bisphosphate in the rate-limiting step of glycolysis. PFK-1 is activated by AMP and fructose 2,6-bisphosphate (F2,6-BP) and is inhibited by ATP and citrate.
  - **Phosphofructokinase-2** (**PFK-2**), which produces the F2,6-BP that activates PFK-1. It is activated by insulin and inhibited by glucagon.
  - **Glyceraldehyde-3-phosphate dehydrogenase** produces NADH, which can feed into the electron transport chain.
  - **3-phosphoglycerate kinase** and **pyruvate kinase** each perform **substrate-level phosphorylation**, placing an inorganic phosphate (P_i) onto ADP to form ATP.
- The enzymes that catalyze irreversible reactions are glucokinase/hexokinase, PFK-1, and pyruvate kinase.
- The NADH produced in glycolysis is oxidized by the mitochondrial electron transport chain when oxygen is present.
- If oxygen or mitochondria are absent, the NADH produced in glycolysis is oxidized by cytoplasmic **lactate dehydrogenase**. Examples include red blood cells, skeletal muscle (during short, intense bursts of exercise), and any cell deprived of oxygen.

Other Monosaccharides

- **Galactose** comes from lactose in milk. It is trapped in the cell by **galactokinase**, and converted to glucose 1-phosphate via **galactose-1-phosphate uridyltransferase** and an epimerase.

- **Fructose** comes from honey, fruit, and sucrose (common table sugar). It is trapped in the cell by **fructokinase**, and then cleaved by **aldolase B** to form glyceraldehyde and DHAP.

Pyruvate Dehydrogenase

- **Pyruvate dehydrogenase** refers to a complex of enzymes that convert pyruvate to acetyl-CoA.
- It is stimulated by insulin and inhibited by acetyl-CoA.

Glycogenesis and Glycogenolysis

- **Glycogenesis** (glycogen synthesis) is the production of glycogen using two main enzymes:
  - **Glycogen synthase**, which creates α-1,4 glycosidic links between glucose molecules. It is activated by insulin in liver and muscle.
  - **Branching enzyme**, which moves a block of oligoglucose from one chain and adds it to the growing glycogen as a new branch using an α-1,6 glycosidic link.
- **Glycogenolysis** is the breakdown of glycogen using two main enzymes:
  - **Glycogen phosphorylase**, which removes single glucose 1-phosphate molecules by breaking α-1,4 glycosidic links. In the liver, it is activated by glucagon to prevent low blood sugar; in exercising skeletal muscle, it is activated by epinephrine and AMP to provide glucose for the muscle itself.
  - **Debranching enzyme**, which moves a block of oligoglucose from one branch and connects it to the chain using an α-1,4 glycosidic link. It also removes the branchpoint, which is connected via an α-1,6 glycosidic link, releasing a free glucose molecule.

Gluconeogenesis

- **Gluconeogenesis** occurs in both the cytoplasm and mitochondria, predominantly in the liver. There is a small contribution from the kidneys.
- Most of gluconeogenesis is simply the reverse of glycolysis, using the same enzymes. The three irreversible steps of glycolysis must be bypassed by different enzymes:
  - **Pyruvate carboxylase** converts pyruvate into oxaloacetate, which is converted to phosphoenolpyruvate by **phosphoenolpyruvate carboxykinase** (**PEPCK**). Together, these two enzymes bypass pyruvate kinase. Pyruvate carboxylase is activated by acetyl-CoA from β-oxidation; PEPCK is activated by glucagon and cortisol.
  - **Fructose-1,6-bisphosphatase** converts fructose 1,6-bisphosphate to fructose 6-phosphate, bypassing phosphofructokinase-1. This is the rate-limiting step of gluconeogenesis. It is activated by ATP directly and glucagon

indirectly (via decreased levels of fructose 2,6-bisphosphate). It is inhibited by AMP directly and insulin indirectly (via increased levels of fructose 2,6-bisphosphate).

- **Glucose-6-phosphatase** converts glucose 6-phosphate to free glucose, bypassing glucokinase. It is found only in the endoplasmic reticulum of the liver.

The Pentose Phosphate Pathway

- The **pentose phosphate pathway** (**PPP**), also known as the **hexose monophosphate** (**HMP**) **shunt**, occurs in the cytoplasm of most cells, generating **NADPH** and sugars for biosynthesis (derived from ribulose 5-phosphate).
- The rate-limiting enzyme is **glucose-6-phosphate dehydrogenase**, which is activated by $NADP^+$ and insulin and inhibited by NADPH.

ANSWERS TO CONCEPT CHECKS

9.1

1.

	GLUT 2	GLUT 4
Important tissues	Liver, pancreas	Adipose tissue, muscle
K_m	High (~15 m*M*)	Low (~5 m*M*)
Saturated at normal glucose levels?	No—cannot be saturated under normal physiological conditions	Yes—saturated when glucose levels are only slightly above 5 m*M*
Responsive to insulin?	No (but serves as glucose sensor to cause release of insulin in pancreatic β-cells)	Yes

2. GLUT 4 is saturated when glucose levels are only slightly above 5 m*M*, so glucose entry can only be increased by increasing the number of transporters. Insulin promotes the fusion of vesicles containing preformed GLUT 4 with the cell membrane.

9.2

1.
- Hexokinase phosphorylates glucose to form glucose 6-phosphate, "trapping" glucose in the cell. It is inhibited by glucose 6-phosphate. It is irreversible.
- Glucokinase also phosphorylates and "traps" glucose in liver and pancreatic cells, and works with GLUT 2 as part of the glucose sensor in β-islet cells. In liver cells, it is induced by insulin. It is irreversible.
- PFK-1 catalyzes the rate-limiting step of glycolysis, phosphorylating fructose 6-phosphate to fructose 1,6-bisphosphate using ATP. It is inhibited by ATP, citrate, and glucagon. It is activated by AMP, fructose 2,6-bisphosphate, and insulin. It is irreversible.
- Glyceraldehyde-3-phosphate dehydrogenase generates NADH while phosphorylating glyceraldehyde 3-phosphate to 1,3-bisphosphoglycerate. It is reversible.
- 3-phosphoglycerate kinase performs a substrate-level phosphorylation, transferring a phosphate from 1,3-bisphosphoglycerate to ADP, forming ATP and 3-phosphoglycerate. It is reversible.
- Pyruvate kinase performs another substrate-level phosphorylation, transferring a phosphate from phosphoenolpyruvate (PEP) to ADP, forming ATP and pyruvate. It is activated by fructose 1,6-bisphosphate. It is irreversible.

2. Fermentation must occur to regenerate NAD^+, which is in limited supply in cells. Fermentation generates no ATP or energy carriers; it merely regenerates the coenzymes needed in glycolysis.

3. The binding of 2,3-BPG decreases hemoglobin's affinity for oxygen. Fetal hemoglobin must be able to "steal" oxygen from maternal hemoglobin at the placental interface; therefore, it would be disadvantageous to lower its affinity for oxygen.

9.3

1. Galactose is phosphorylated by galactokinase, trapping it in the cell. Galactose-1-phosphate uridyltransferase produces glucose 1-phosphate, a glycolytic intermediate, thus linking the pathways.
2. Fructose is phosphorylated by fructokinase, trapping it in the cell (with a small contribution from hexokinase). Aldolase B produces dihydroxyacetone phosphate (DHAP) and glyceraldehyde (which can be phosphorylated to form glyceraldehyde 3-phosphate), which are glycolytic intermediates, thus linking the pathways.

9.4

1. Pyruvate, NAD^+, and CoA are the reactants of the PDH complex. Acetyl-CoA, NADH, and CO_2 are the products.
2. Acetyl-CoA inhibits the PDH complex. As a product of the enzyme complex, a buildup of acetyl-CoA from either the citric acid cycle or fatty acid oxidation signals that the cell is energetically satisfied and that the production of acetyl-CoA should be slowed or stopped. Pyruvate can then be used to form other products, such as oxaloacetate for use in gluconeogenesis.

9.5

1. Glycogen is made up of a core protein of glycogenin with linear chains of glucose emanating out from the center, connected by α-1,4 glycosidic links. Some of these chains are branched, which requires α-1,6 glycosidic links.
2. Glycogen synthase attaches the glucose molecule from UDP-glucose to the growing glycogen chain, forming an α-1,4 link in the process. Branching enzyme creates a branch by breaking an α-1,4 link in the growing chain and moving a block of oligoglucose to another location in the glycogen granule. The oligoglucose is then attached with an α-1,6 link.
3. Glycogen phosphorylase removes a glucose molecule from glycogen using a phosphate, breaking the α-1,4 link and creating glucose 1-phosphate. Debranching enzyme moves all of the glucose from a branch to a longer glycogen chain by breaking an α-1,4 link and forming a new α-1,4 link to the longer chain. The branchpoint is left behind; this is removed by breaking the α-1,6 link to form a free molecule of glucose.

9.6

1. Gluconeogenesis occurs when an individual has been fasting for >12 hours. To carry out gluconeogenesis, hepatic (and renal) cells must have enough energy to drive the process of glucose creation, which requires sufficient fat stores to undergo β-oxidation.

2.

Gluconeogenic Enzyme	Replaces
Pyruvate carboxylase	Pyruvate kinase
Phosphoenolpyruvate carboxykinase (PEPCK)	Pyruvate kinase
Fructose-1,6-bisphosphatase	Phosphofructokinase-1
Glucose-6-phosphatase	Glucokinase

3. Acetyl-CoA inhibits pyruvate dehydrogenase complex while activating pyruvate carboxylase. The net effect is to shift from burning pyruvate in the citric acid cycle to creating new glucose molecules for the rest of the body. The acetyl-CoA for this regulation comes predominantly from β-oxidation, not glycolysis.

9.7

1. The two major metabolic products of the pentose phosphate pathway are ribulose 5-phosphate and NADPH.
2. NADPH is involved in lipid biosynthesis, bactericidal bleach formation in certain white blood cells, and maintenance of glutathione stores to protect against reactive oxygen species.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. A man collapses while running a marathon and is taken to the emergency room. His blood is found to be somewhat acidic, and further tests show increased lactate dehydrogenase activity. This enzyme is involved in which of the following pathways?

A. Anaerobic glycolysis
B. β-Oxidation of fatty acids
C. Citric acid cycle
D. Pentose phosphate pathway

2. Which of the following organs does NOT require a constant supply of glucose from the blood for energy during a fast?

A. Red blood cells
B. Brain
C. Pancreas
D. Liver

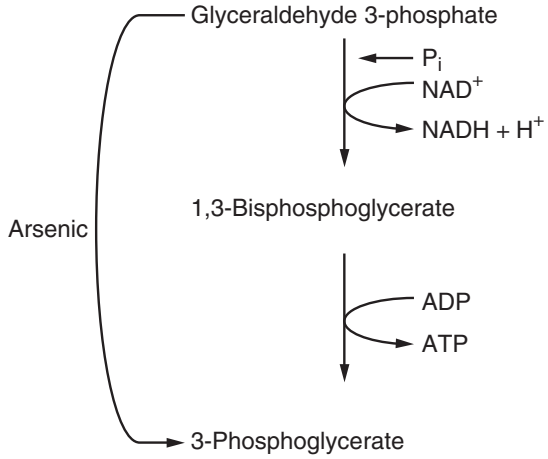
3. When insulin is released, it acts to increase the absorption of glucose into skeletal muscle predominantly through which of the following transporters?

A. GLUT 1
B. GLUT 2
C. GLUT 3
D. GLUT 4

4. After an overnight fast, which of the following enzymes would be expected to have little, if any, physiological activity?

A. Malate dehydrogenase
B. Glucokinase
C. α-Ketoglutarate dehydrogenase
D. Phosphofructokinase-1

5. The diagram below shows the effects of arsenic on the metabolism of glyceraldehyde 3-phosphate. As a result, in the presence of arsenic, how many molecules of ATP would be created directly from the conversion of two glucose molecules to four pyruvate molecules?



A. 0
B. 1
C. 2
D. 4

6. When fatty acid β-oxidation predominates in the liver, mitochondrial pyruvate is most likely to be:

A. carboxylated to phosphoenolpyruvate for entry into gluconeogenesis.
B. oxidatively decarboxylated to acetyl-CoA for oxidation in the citric acid cycle.
C. carboxylated to oxaloacetate for entry into gluconeogenesis.
D. reduced to lactate in the process of fermentation.

7. A biopsy is done on a child with an enlarged liver and shows accumulation of glycogen granules with single glucose residues remaining at the branch points near the periphery of the granule. The most likely genetic defect is in the gene encoding:

A. α-1,4 phosphorylase (glycogen phosphorylase).
B. α-1,4:α-1,6 transferase (branching enzyme).
C. α-1,4:α-1,4 transferase (part of debranching enzyme complex).
D. α-1,6 glucosidase (part of debranching enzyme complex).

8. An investigator is measuring the activity of various enzymes involved in reactions of intermediary metabolism. One of the enzymes has greatly decreased activity compared to reference values. The buffer of the assay contains citrate. Which of the following enzymes will most likely be directly affected by the use of citrate?

A. Fructose-2,6-bisphosphatase
B. Isocitrate dehydrogenase
C. Phosphofructokinase-1
D. Pyruvate carboxylase

9. After a brief period of intense exercise, the activity of muscle pyruvate dehydrogenase is greatly increased. This increased activity is most likely due to:

A. decreased ADP.
B. increased acetyl-CoA.
C. increased NADH/NAD^+ ratio.
D. increased pyruvate concentration.

10. After a large, well-balanced meal, all of the following substances would be expected to be elevated EXCEPT:

A. fatty acids.
B. insulin.
C. glucose.
D. glucagon.

11. A man is given antibiotics to treat a urinary tract infection and develops an episode of red blood cell lysis. Further studies show weakness of the plasma membrane and Heinz bodies (collections of oxidized hemoglobin). Which of the following enzymes is most likely defective in this patient?

A. Fructose-1,6-bisphosphatase
B. Glucose-6-phosphate dehydrogenase
C. Hexokinase
D. Pyruvate kinase

12. The unique enzymes of gluconeogenesis are used to circumvent specific irreversible steps of glycolysis. Which of the following correctly pairs an enzyme from glycolysis with its corresponding enzyme(s) used in gluconeogenesis?

A. Phosphofructokinase-1 / fructose-1,6-bisphosphatase
B. Pyruvate dehydrogenase / pyruvate carboxylase and phosphoenolpyruvate carboxykinase
C. Hexokinase / glucokinase
D. Pyruvate kinase / glucose-6-phosphatase

13. After an overnight fast, which of the following processes would be expected to occur at an elevated rate compared with the well-fed state?

A. Glycolysis
B. Glycogenolysis
C. Glycogenesis
D. Glycerol synthesis

14. Which of the following is/are function(s) of NADPH in the cell?

I. Antimicrobial resistance via bacterial destruction by bleach within lysosomes.

II. Involvement in the production of the precursors to steroid hormones.

III. Functional carriage of energy across organelle membranes for use within the mitochondria

A. I only
B. I and II only
C. II and III only
D. I, II, and III

15. Each of the following catalyzes a rate-limiting step of a carbohydrate metabolism pathway EXCEPT:

A. hexokinase.
B. glycogen synthase.
C. glucose-6-phosphate dehydrogenase.
D. fructose-1,6-bisphosphatase.

Explanations to Discrete Practice Questions

1. A

Under normal conditions, when oxygen is readily available, the pyruvate generated in glycolysis enters the mitochondrion and is converted into acetyl-CoA by the action of pyruvate dehydrogenase. During strenuous exercise, particularly by individuals in poor physical condition, the oxygen demands of the skeletal muscle may exceed the ability of the heart and lungs to provide oxygen. In this setting, the muscles switch to anaerobic glycolysis, and the pyruvate that is produced is fermented to lactate by the action of lactate dehydrogenase.

2. D

The liver, like all cells, needs a constant supply of glucose; however, it is able to produce its own glucose through gluconeogenesis (cells in the kidney can also complete low levels of gluconeogenesis). The other cells listed here are absolutely dependent on a glucose source from the blood for energy, although they may also use other fuels in addition to glucose. For example, the brain can utilize ketone bodies during lengthy periods of starvation; however, it still requires at least some glucose for proper function.

3. D

GLUT is an abbreviation for glucose transporter and describes a family of sugar transporters with varying distributions and activities. GLUT 4 is found in adipose tissue and muscle, and mediates insulin-stimulated glucose uptake; in fact, it is the only insulin-responsive glucose transporter. Insulin acts via its receptor to translocate GLUT 4 to the plasma membrane. GLUT 4 in skeletal muscle is also stimulated by exercise through an insulin-independent pathway.

4. B

After an overnight fast, the liver is producing glucose and glucokinase activity would be insignificant. Glucokinase is used to trap extra glucose in liver cells as part of a storage mechanism; with low blood glucose, liver cells would be generating new glucose, not storing it. It is also in the pancreas, where it serves as a glucose sensor; if glucose levels are low, it has little activity in this tissue as well. Malate dehydrogenase, **choice (A)**, and α-ketoglutarate dehydrogenase, **choice (C)**, are citric acid cycle enzymes. Phosphofructokinase-1, **choice (D)**, is a glycolytic enzyme. Other enzymes used in glycolysis, the citric acid cycle, or gluconeogenesis, such as phosphofructokinase-1, would be expected to maintain normal activity after an overnight fast, using glucose derived from glycogen or gluconeogenesis, rather than orally ingested glucose.

5. A

The net ATP yield from glycolysis is 2 ATP per glucose. According to the question, arsenic bypasses glyceraldehyde-3-phosphate dehydrogenase and 3-phosphoglycerate kinase, directly forming 3-phosphoglycerate. 3-phosphoglycerate kinase is one of the two substrate-level phosphorylation steps and normally produces 2 ATP (one for each of the two molecules of glyceraldehyde 3-phosphate formed from glucose). If these two ATP molecules are lost, the net yield of glycolysis is now 0 ATP.

6. C

Pyruvate is converted primarily into three main intermediates: acetyl-CoA, **choice (B)**, for the citric acid cycle (via pyruvate dehydrogenase complex); lactate, **choice (D)**, during fermentation (via lactate dehydrogenase); or oxaloacetate, **choice (C)**, for gluconeogenesis (via pyruvate carboxylase). High

levels of acetyl-CoA, which is produced during β-oxidation, will inhibit pyruvate dehydrogenase and shift the citric acid cycle to run in the reverse direction, producing oxaloacetate for gluconeogenesis. Acetyl-CoA also stimulates pyruvate carboxylase directly.

7. D

The pattern described for this child's glycogen demonstrates appropriate production: there are long chains of glucose monomers, implying that glycogen synthase works. There are also branch points, implying that branching enzyme, **choice (B)** works. During glycogenolysis, it seems that the child is able to remove individual glucose monomers and process glycogen down to the branch point itself, which requires glycogen phosphorylase, **choice (A)**, and α-1,4:α-1,4 transferase, **choice (C)**. The metabolic problem here is removing the final glucose at the branch point, which is an α-1,6 (not α-1,4) link. This requires **choice (D)**, α-1,6 glucosidase.

8. C

Citrate is produced by citrate synthase from acetyl-CoA and oxaloacetate. This reaction takes place in the mitochondria. When the citric acid cycle slows down, citrate accumulates. In the cytosol, it acts as a negative allosteric regulator of phosphofructokinase-1, the enzyme that catalyzes the rate-limiting step of glycolysis.

9. D

In most biochemical pathways, only a few enzymatic reactions are under regulatory control. These often occur either at the beginning of pathways or at pathway branch points. The pyruvate dehydrogenase (PDH) complex controls the link between glycolysis and the citric acid cycle, and decarboxylates pyruvate (the end product of glycolysis) with production of NADH and acetyl-CoA (the substrate for the citric acid cycle). After intense exercise, one would expect PDH to be highly active to generate ATP. ADP levels, **choice (A)**, should be high because ATP was just burned by the muscle. Acetyl-CoA, **choice (B)**, is an inhibitor of PDH, causing a shift of pyruvate into the gluconeogenic pathway. A high NADH/NAD^+ ratio, **choice (C)**, would imply that the cell is already energetically satisfied and not in need of energy, which would not be expected in intensely exercising muscle.

10. D

After a large meal, one would expect blood to contain high levels of nutrients, such as glucose, **choice (C)**, and fatty acids, **choice (A)**, as well as regulators telling the body to utilize and store this fuel, like insulin, **choice (B)**. Glucagon is a peptide hormone used to raise blood sugar levels by promoting, among other processes, glycogenolysis and gluconeogenesis. Glucagon should be elevated during a fast.

11. B

Based on the question stem, we can infer that the antibiotics must have been an oxidative stress on the patient (indeed, antibiotics, antimalarial medications, infections, certain foods like fava beans, and other common exposures can induce an oxidative stress). The pentose phosphate pathway is responsible for generating NADPH, which is used to reduce glutathione, one of the natural antioxidants present in the body. In individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency, NADPH cannot be produced at sufficient levels, and oxidative stresses lead to cell membrane and protein (hemoglobin) damage. Note that you do not need to actually know the disease to answer this question; merely knowing that the enzyme must be from the pentose phosphate pathway, which is involved in mitigating oxidative stress, is sufficient.

12. A

The irreversible enzymes in glycolysis are hexokinase (or glucokinase in liver and pancreatic β-cells), phosphofructokinase-1, and pyruvate kinase. Pyruvate dehydrogenase is not considered a glycolytic enzyme because it requires the mitochondria to function. The list below shows the correct pairing of glycolytic enzymes with gluconeogenic enzymes:

- Hexokinase or glucokinase / glucose-6-phosphatase
- Phosphofructokinase-1 / fructose-1,6-bisphosphatase
- Pyruvate kinase / pyruvate carboxylase and phosphoenolpyruvate carboxykinase (PEPCK)

13. B

After a fast, the liver must contribute glucose into the bloodstream through two main processes: glycogenolysis (early to intermediate fasting) and gluconeogenesis (intermediate to late fasting). The other processes would continue at normal basal levels or have decreased activity after a fast.

14. B

NADPH has three primary functions: involvement in biosynthesis of lipids and cholesterol (the precursor to steroid hormones), production of bactericidal bleach in the lysosomes of certain white blood cells, and maintenance of a supply of reduced glutathione for protection against free radical damage. Energy carriage is an important function of NADH, not NADPH.

15. A

Hexokinase catalyzes an important irreversible step of glycolysis, but it is not the rate-limiting step. Phosphofructokinase-1 catalyzes the rate-limiting step of glycolysis. Glycogen synthase, **choice (B)**, catalyzes the rate-limiting step of glycogenesis; glucose-6-phosphate dehydrogenase, **choice (C)**, catalyzes the rate-limiting step of the pentose phosphate pathway; and fructose-1,6-bisphosphatase, **choice (D)**, catalyzes the rate-limiting step of gluconeogenesis.

Introduction

Have you ever heard that eating peach pits is deadly? Before you start panicking about the snack you had during your study break, you should know that the accuracy of such a statement is debatable. While it is true that digesting peach pits can result in the formation of trace amounts of cyanide, the concentration is far too low to be clinically worrisome. Cyanide is a poison that binds irreversibly to *cytochrome* a/a_3, a protein located in the electron transport chain of the mitochondria. Why can this be deadly? Blocking the electron transport chain (ETC) inhibits aerobic respiration from yielding the ATP the body requires to function properly. Cyanide poisoning leaves cells unable to utilize oxygen for aerobic respiration because it blocks oxygen from binding to the ETC. Therefore, symptoms resemble those of tissue hypoxia: perceived difficulty breathing, general weakness, and, in higher doses, cardiac arrest followed by death within minutes.

But what about the metabolic pathways described in Chapter 9 of *MCAT Biochemistry Review*—don't they produce energy without oxygen? While glycolysis does not depend on oxygen, it only yields a net 2 ATP per molecule of glucose, which is not nearly enough to maintain the body's energy requirements. This brings us to two of the most tested topics on the MCAT: the citric acid cycle and oxidative phosphorylation.

In this chapter, we'll take a close look at what's gained when the products of glycolysis and other derivatives of metabolic pathways enter the citric acid cycle. We'll also look at how this process is regulated with regard to the substrates, products, and reactions involved. Lastly, we'll observe what happens when this cycle's products undergo oxidative phosphorylation, with particular emphasis on how the electron transport chain facilitates the process and the ATP that is yielded.

10.1 Acetyl-CoA

The **citric acid cycle**, also called the **Krebs cycle** or the **tricarboxylic acid** (**TCA**) **cycle**, occurs in the mitochondria. The main function of this cycle is the oxidation of acetyl-CoA to CO_2 and H_2O. In addition, the cycle produces the high-energy electron-carrying molecules NADH and $FADH_2$. Acetyl-CoA can be obtained from the metabolism of carbohydrates, fatty acids, and amino acids, making it a key molecule in the crossroads of many metabolic pathways and a highly testable compound.

METHODS OF FORMING ACETYL-CoA

Recall from Chapter 9 of *MCAT Biochemistry Review* that after glucose undergoes glycolysis, its product, *pyruvate*, enters the mitochondrion via active transport and is oxidized and decarboxylated. These reactions are catalyzed by a multienzyme complex called the ***pyruvate dehydrogenase complex***, which is located in the mitochondrial matrix. As we take a deeper look at the enzymes that make up this complex, as well as the substrates and products of their reactions, it is helpful to follow the carbons in the molecules. For example, the three-carbon pyruvate is cleaved into a two-carbon acetyl group and carbon dioxide. This reaction is irreversible, which explains why glucose cannot be formed directly from acetyl-CoA. In mammals, pyruvate dehydrogenase complex is made up of five enzymes: *pyruvate dehydrogenase* (PDH), *dihydrolipoyl transacetylase*, *dihydrolipoyl dehydrogenase, pyruvate dehydrogenase kinase,* and *pyruvate dehydrogenase phosphatase*. While the first three work in concert to convert pyruvate to acetyl-CoA, the latter two regulate the actions of PDH. Figure 10.1 shows the overall reaction for the conversion of pyruvate to acetyl-CoA. The reaction is exergonic ($\Delta G^{\circ\prime} = -33.4 \frac{kJ}{mol}$). The complex is inhibited by an accumulation of acetyl-CoA and NADH that can occur if the electron transport chain is not properly functioning or is inhibited.

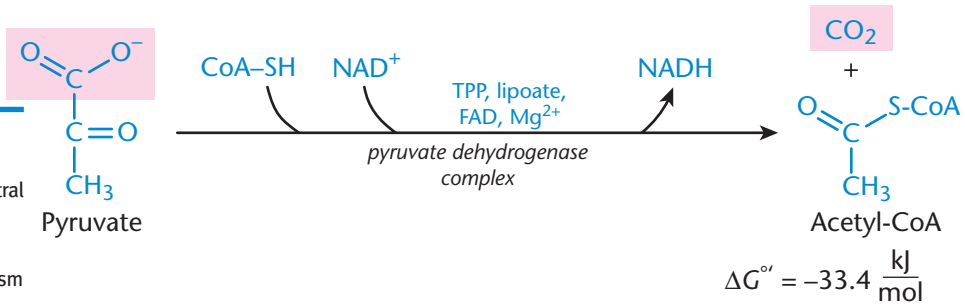

Figure 10.1. Overall Reaction of Pyruvate Dehydrogenase Complex

Note that **coenzyme A** (**CoA**) is written as CoA–SH in the reaction above. This is because CoA is a thiol, containing an –SH group. When acetyl-CoA forms, it does so via covalent attachment of the acetyl group to the –SH group, resulting in the formation of a thioester, which contains sulfur instead of the typical oxygen ester –OR.

MCAT Expertise

Similar to the *gluco–/glyco–* terminology in Chapter 9 of *MCAT Biochemistry Review*, it is critical to keep straight the various enzymes containing *pyruvate*: *pyruvate dehydrogenase* (PDH), its two regulators (*PDH kinase* and *PDH phosphatase*), and *pyruvate carboxylase*, an enzyme in gluconeogenesis.

Real World

In studies of pathologies that affect the central cholinergic system such as Alzheimer's disease, Huntington's disease, and even alcoholism, a decrease in glucose metabolism and oxidative phosphorylation has been observed in the brain. Ongoing research will hopefully determine if the resulting lack of acetyl-CoA could be a cause of the disease or a result of the disease. With decreased amounts of acetyl-CoA, not only is energy production a concern, but also the production of the neurotransmitter acetylcholine.

The formation of a thioester rather than a typical ester is worth noting because of the high-energy properties of thioesters. That is to say, when a thioester undergoes a reaction such as hydrolysis, a significant amount of energy will be released. This can be enough to drive other reactions forward, like the citric acid cycle. The pyruvate dehydrogenase complex enzymes needed to catalyze acetyl-CoA formation are listed below in sequential order, and the mechanism is shown in Figure 10.2.

- **Pyruvate dehydrogenase** (**PDH**): pyruvate is oxidized, yielding CO_2, while the remaining two-carbon molecule binds covalently to *thiamine pyrophosphate* (vitamin B_1, TPP). TPP is a coenzyme held by noncovalent interactions to PDH. Mg^{2+} is also required.
- **Dihydrolipoyl transacetylase**: the two-carbon molecule bonded to TPP is oxidized and transferred to lipoic acid, a coenzyme that is covalently bonded to the enzyme. Lipoic acid's disulfide group acts as an oxidizing agent, creating the acetyl group. The acetyl group is now bonded to lipoic acid via thioester linkage. After this, dihydrolipoyl transacetylase catalyzes the CoA–SH interaction with the newly formed thioester link, causing transfer of an acetyl group to form acetyl-CoA. Lipoic acid is left in its reduced form.
- **Dihydrolipoyl dehydrogenase**: flavin adenine dinucleotide (FAD) is used as a coenzyme in order to reoxidize lipoic acid, allowing lipoic acid to facilitate acetyl-CoA formation in future reactions. As lipoic acid is reoxidized, FAD is reduced to $FADH_2$. In subsequent reactions, this $FADH_2$ is reoxidized to FAD, while NAD^+ is reduced to NADH.

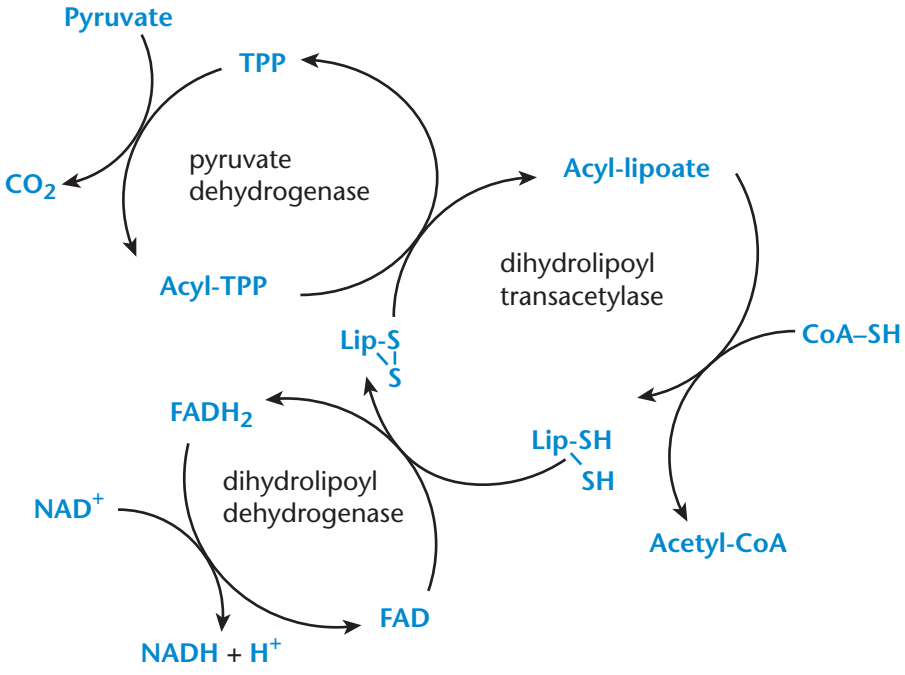

Figure 10.2. Mechanism of Pyruvate Dehydrogenase

While glycolysis is a heavily reviewed and heavily tested contributor to the production of acetyl-CoA, other pathways are capable of forming acetyl-CoA. These pathways act on fatty acids, ketogenic amino acids, ketone bodies, and alcohol. Descriptions of these pathways are provided below. The ultimate production of acetyl-CoA allows all of these pathways to culminate in the final common pathway of the citric acid cycle.

- **Fatty acid oxidation** (***β*-oxidation**): in the cytosol, a process called **activation** causes a thioester bond to form between carboxyl groups of fatty acids and CoA–SH. Activated *fatty acyl-CoA* is then transported to the intermembrane space of the mitochondrion. Because fatty acyl-CoA cannot cross the inner mitochondrial membrane, the fatty acyl group is transferred to *carnitine* via a transesterification reaction, as shown in Figure 10.3. Carnitine is a molecule that can cross the inner membrane with a fatty acyl group in tow. Once acyl-carnitine crosses the inner membrane; it transfers the fatty acyl group to a mitochondrial CoA–SH via another transesterification reaction. In other words, carnitine's function is merely to carry the acyl group from a cytosolic CoA–SH to a mitochondrial CoA–SH. Once acyl-CoA is formed in the matrix, β-oxidation can occur, which removes two-carbon fragments from the carboxyl end.

Bridge

Once formed, mitochondrial acyl-CoA can undergo β-oxidation. This process is discussed in Chapter 11 of *MCAT Biochemistry Review*.

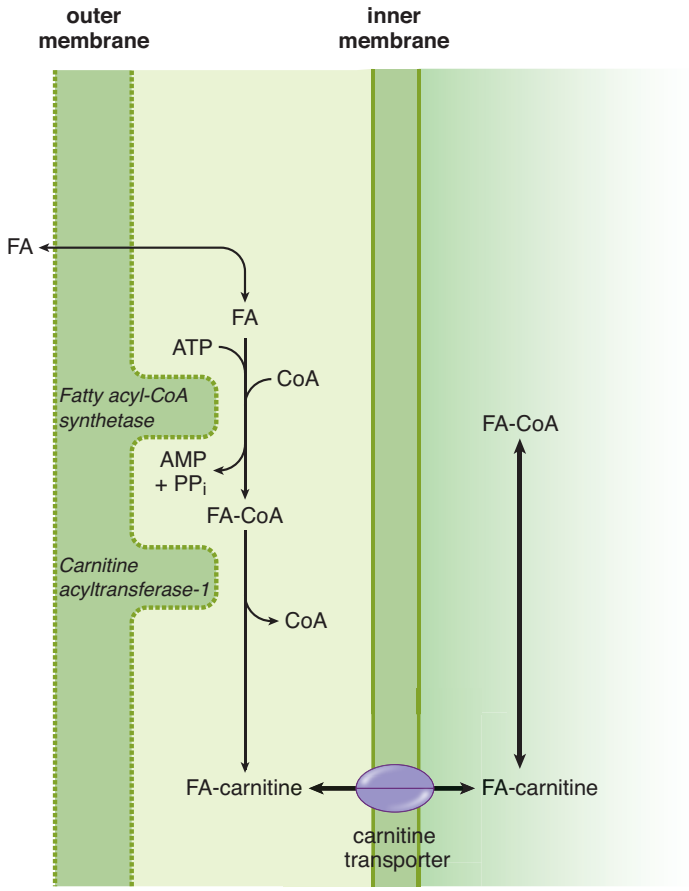

Figure 10.3. Fatty Acid Activation and Transport

- **Amino acid catabolism**: certain amino acids can be used to form acetyl-CoA. These amino acids must lose their amino group via transamination; their carbon skeletons can then form ketone bodies. These amino acids are termed *ketogenic* for that reason. The conversion of ketone bodies to acetyl-CoA is mentioned below.
- **Ketones**: although acetyl-CoA is typically used to produce ketones when the pyruvate dehydrogenase complex is inhibited, the reverse reaction can occur as well.
- **Alcohol**: when alcohol is consumed in moderate amounts, the enzymes ***alcohol dehydrogenase*** and ***acetaldehyde dehydrogenase*** convert it to acetyl-CoA. However, this reaction is accompanied by NADH buildup, which inhibits the Krebs cycle. Therefore, the acetyl-CoA formed through this process is used primarily to synthesize fatty acids.

Real World

While the brain normally uses glucose for energy, under conditions such as starvation, ketone bodies can become the brain's major source of energy.

MCAT Concept Check 10.1:

Before you move on, assess your understanding of the material with these questions.

1. What is the overall reaction of the pyruvate dehydrogenase complex?

_____

2. What other molecules can be used to make acetyl-CoA, and how does the body perform this conversion for each?

Molecule	Mechanism of Conversion to Acetyl-CoA

10.2 Reactions of the Citric Acid Cycle

The citric acid cycle takes place in the mitochondrial matrix and begins with the coupling of a molecule of acetyl-CoA to a molecule of *oxaloacetate*. While parts of this molecule are oxidized to carbon dioxide and both energy (GTP) and energy carriers (NADH and $FADH_2$) are produced, the other substrates and products of the cycle are reused over and over again. Although oxygen is not directly required in the cycle, the pathway will not occur anaerobically. This is because NADH and $FADH_2$ will accumulate if oxygen is not available for the electron transport chain and will inhibit the cycle. As we look at the individual reactions that take place during the citric acid cycle, it cannot be overemphasized that this process is exactly what it's called: a *cycle*, not just a series of reactions. An overview of the cycle is provided in Figure 10.4, and we'll take a deeper look at those steps below.

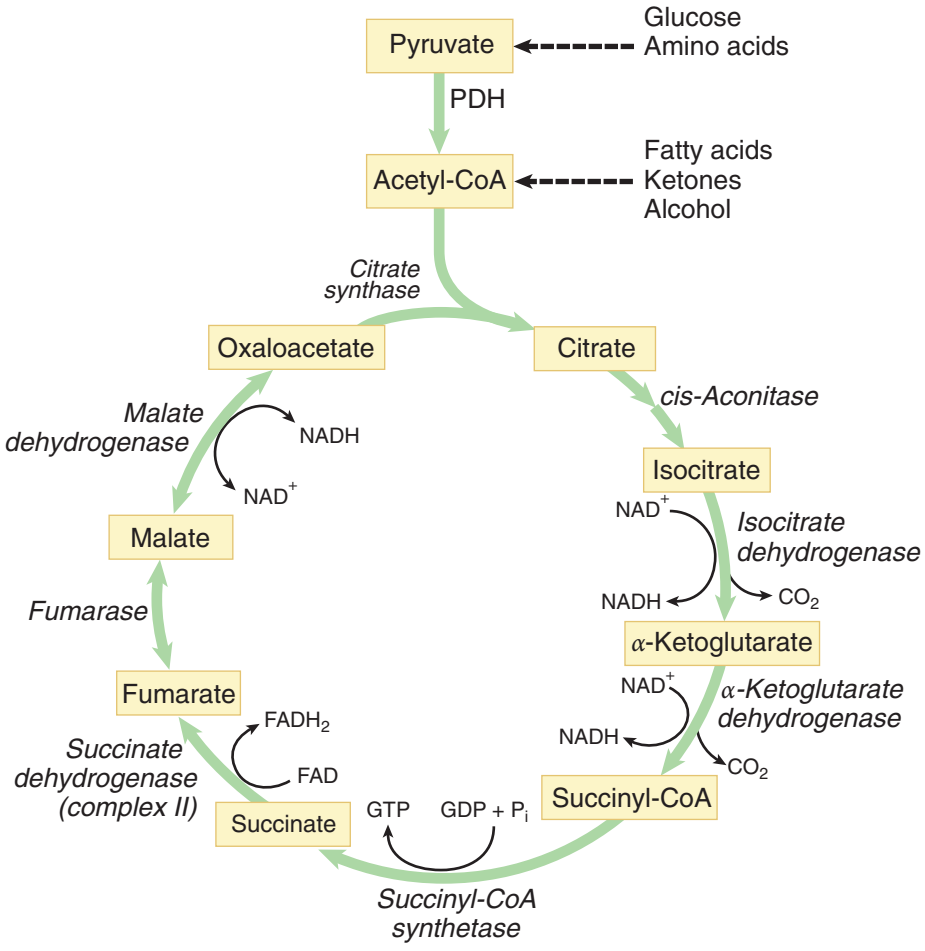

Figure 10.4. The Citric Acid Cycle

KEY REACTIONS

Step 1—Citrate Formation: first, acetyl-CoA and *oxaloacetate* undergo a condensation reaction to form *citryl-CoA*, an intermediate. Then, the hydrolysis of citryl-CoA yields citrate and CoA–SH. This reaction is catalyzed by *citrate synthase.* As discussed in Chapter 2 of *MCAT Biochemistry Review*, *synthases* are enzymes that form new covalent bonds without needing significant energy. This second part of this step energetically favors the formation of citrate and helps the cycle revolve in the forward direction. This reaction can be seen in Figure 10.5.

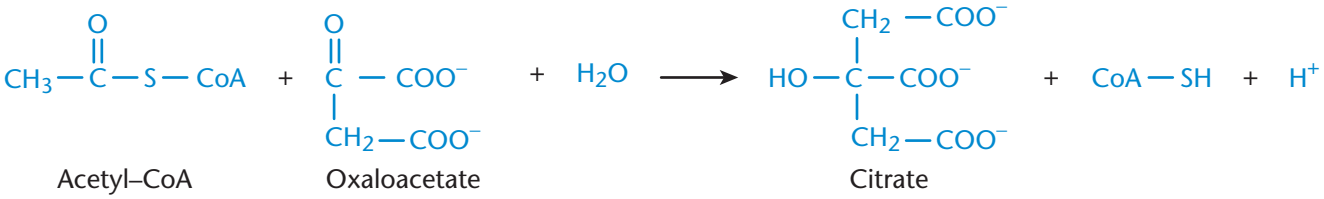

Figure 10.5. Citrate Formation

Step 2—Citrate Isomerized to Isocitrate: achiral citrate is isomerized to one of four possible isomers of *isocitrate*. First, citrate binds at three points to the enzyme *aconitase*. Then water is lost from citrate, yielding cis-*aconitate*. Finally, water is added back to form isocitrate. The enzyme is a metalloprotein that requires Fe^{2+}. In Figure 10.6, you can see that this results in a switching of a hydrogen and a hydroxyl group. Overall, this step is necessary to facilitate the subsequent oxidative decarboxylation.

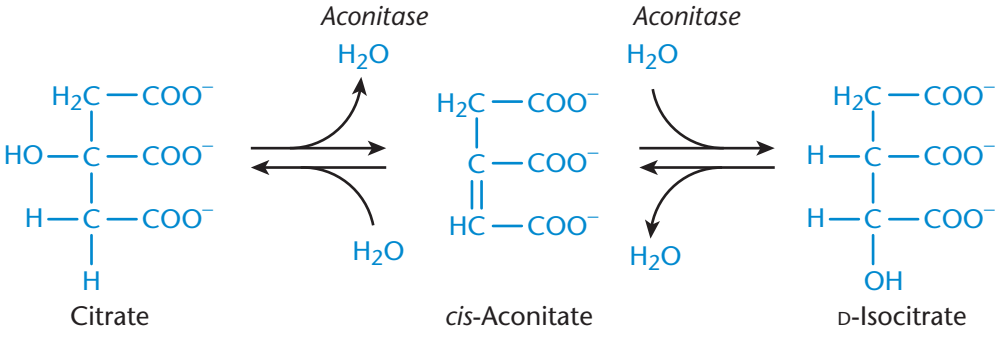

Figure 10.6. Citrate Isomerized to Isocitrate

Step 3—α-Ketoglutarate and CO_2 Formation: isocitrate is first oxidized to *oxalosuccinate* by *isocitrate dehydrogenase*. Then oxalosuccinate is decarboxylated to produce *α-ketoglutarate* and CO_2, as shown in Figure 10.7. This is a very important step to know for Test Day because isocitrate dehydrogenase is the rate-limiting enzyme of the citric acid cycle. The first of the two carbons

from the cycle is lost here. This is also the first NADH produced from intermediates in the cycle.

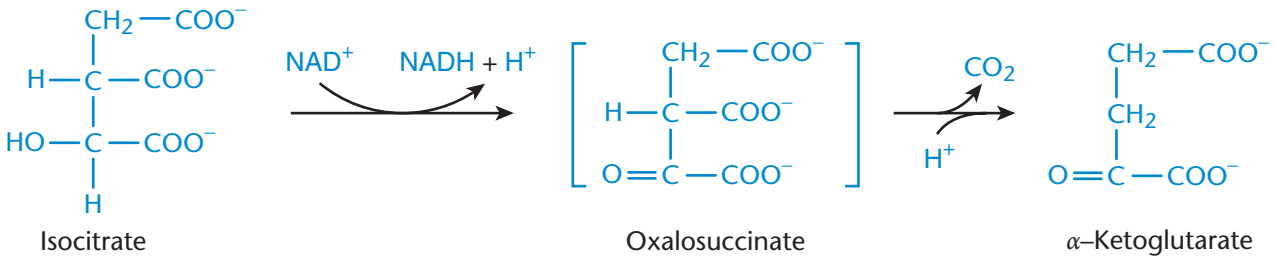

Figure 10.7. α-Ketoglutarate and CO_2 Formation

Key Concept

Dehydrogenases are a subtype of *oxidoreductases* (enzymes that catalyze an oxidation–reduction reaction). Dehydrogenases transfer a hydride ion (H^-) to an electron acceptor, usually NAD^+ or FAD. Therefore, whenever you see *dehydrogenase* in aerobic metabolism, be on the lookout for a high-energy electron carrier being formed!

Step 4—Succinyl-CoA and CO_2 Formation: these reactions are carried out by the *α-ketoglutarate dehydrogenase complex*, which is similar in mechanism, cofactors, and coenzymes to the pyruvate dehydrogenase (PDH) complex. In the formation of succinyl-CoA, α-ketoglutarate and CoA come together and produce a molecule of carbon dioxide, as shown in Figure 10.8. This carbon dioxide represents the second and last carbon lost from the cycle. Reducing NAD^+ produces another NADH.

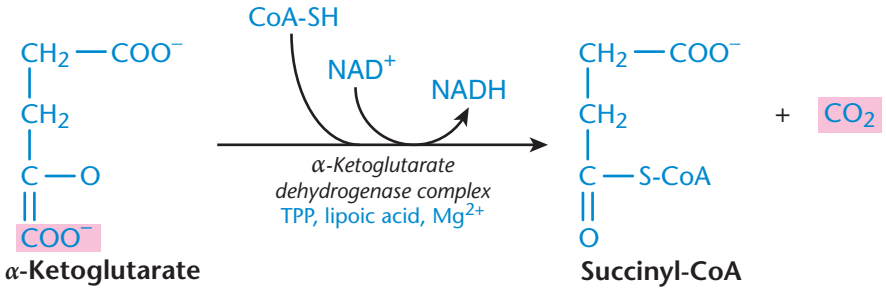

Figure 10.8. Succinyl-CoA and CO_2 Formation

Key Concept

Citrate *synthase* doesn't require energy input in order to form covalent bonds, but succinyl-CoA *synthetase* certainly does. Pay careful attention to enzyme names: little things can add up to careless mistakes on Test Day otherwise!

Step 5—Succinate Formation: hydrolysis of the thioester bond on succinyl-CoA yields *succinate* and CoA–SH, and is coupled to the phosphorylation of GDP to GTP. This reaction is catalyzed by *succinyl-CoA synthetase*, as shown in Figure 10.9. *Synthetases*, unlike *synthases*, create new covalent bonds *with* energy input. Recall the earlier discussion about thioester bonds with regard to acetyl-CoA: they're unique in that their hydrolysis is accompanied by a significant release of energy. Therefore, phosphorylation of GDP to GTP is driven by the energy released by thioester hydrolysis. Once GTP is formed, an enzyme called *nucleosidediphosphate*

kinase catalyzes phosphate transfer from GTP to ADP, thus producing ATP. Note that this is the only time in the entire citric acid cycle that ATP is produced directly; ATP production occurs predominantly within the electron transport chain.

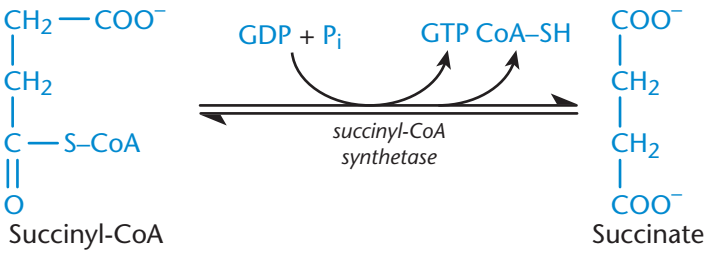

Figure 10.9. Succinate Formation

Step 6—Fumarate Formation: this is the only step of the citric acid cycle that doesn't take place in the mitochondrial matrix; instead, it occurs on the inner membrane. Let's look at why: succinate undergoes oxidation to yield *fumarate*. This reaction is catalyzed by *succinate dehydrogenase*. Succinate dehydrogenase is considered a **flavoprotein** because it is covalently bonded to FAD, the electron acceptor in this reaction. This enzyme is an integral protein on the inner mitochondrial membrane. As succinate is oxidized to fumarate, FAD is reduced to $FADH_2$. Each molecule of $FADH_2$ then passes the electrons it carries to the electron transport chain, which eventually leads to the production of 1.5 ATP (unlike NADH, which will give rise to 2.5 ATP). FAD is the electron acceptor in this reaction because the reducing power of succinate is not great enough to reduce NAD^+.

Step 7—Malate Formation: the enzyme *fumarase* catalyzes the hydrolysis of the alkene bond in fumarate, thereby giving rise to *malate*. Although two enantiomeric forms are possible, only L-malate forms in this reaction.

Step 8—Oxaloacetate Formed Anew: the enzyme *malate dehydrogenase* catalyzes the oxidation of malate to *oxaloacetate*. A third and final molecule of NAD^+ is reduced to NADH. The newly formed oxaloacetate is ready to take part in another turn of the citric acid cycle, and we've gained all of the high-energy electron carriers possible from one turn of the cycle. The last steps of the citric acid cycle—from succinate to oxaloacetate—are shown in Figure 10.10.

Mnemonic

Substrates of Citric Acid Cycle: **P**lease, **C**an **I** **K**eep **S**elling **S**eashells **F**or **M**oney, **O**fficer?

- **P**yruvate
- **C**itrate
- **I**socitrate

- **S**uccinyl-CoA
- **S**uccinate
- **F**umarate
- **M**alate
- **O**xaloacetate

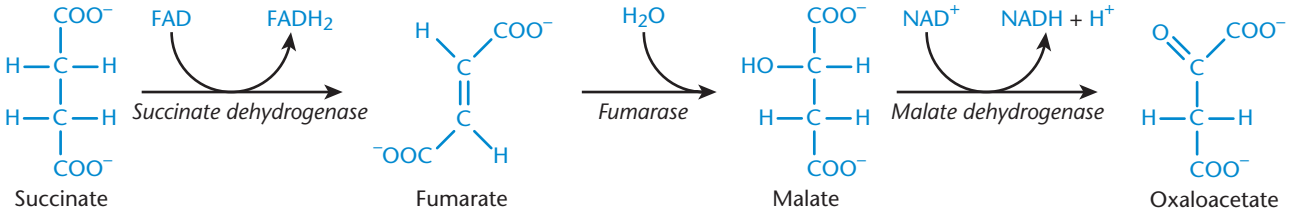

Figure 10.10. The Final Steps of the Citric Acid Cycle

NET RESULTS AND ATP YIELD

Now let's take a step back and see what our net yield is from the steps we just took. Starting with the pyruvate dehydrogenase complex, recall that the products of this reaction include one acetyl-CoA and one NADH. In the citric acid cycle, steps 3, 4, and 8 each produce one NADH, while step 6 forms one $FADH_2$. Step 5 yields one GTP, which can be converted to ATP. Two carbons leave the cycle in the form of CO_2. Each NADH can be converted to approximately 2.5 ATP, while each $FADH_2$ molecule can yield about 1.5 ATP. The total amount of chemical energy harvested per pyruvate is listed below.

Pyruvate Dehydrogenase Complex:

Pyruvate + CoA–SH + NAD^+ → acetyl-CoA + **NADH** + CO_2 + H^+

Citric Acid Cycle:

Acetyl-CoA + 3 NAD^+ + FAD + GDP + P_i + 2 H_2O →
2 CO_2 + CoA–SH + **3 NADH** + 3 H^+ + **$FADH_2$** + **GTP**

ATP Production:

- 4 NADH → 10 ATP (2.5 ATP per NADH)
- 1 $FADH_2$ → 1.5 ATP (1.5 ATP per $FADH_2$)
- 1 GTP → 1 ATP
- Total: 12.5 ATP per pyruvate = 25 ATP per glucose

Glycolysis yields two ATP and two NADH, providing another seven molecules of ATP; thus, the net yield of ATP for one glucose molecule from glycolysis through oxidative phosphorylation is 30–32 ATP. Note that the efficiency of glycolysis varies slightly from cell to cell, so there is a range of ATP yield from one molecule of glucose.

REGULATION

Let's say it's Test Day, and you see the following question: *Which of the following is an inhibitor of isocitrate dehydrogenase?* Before you start to panic, take a step back and use critical thinking. Where have we heard of isocitrate dehydrogenase—or merely isocitrate—before? The Krebs cycle. By knowing this, you can already make a fair attempt at such a question. Because energy (ATP) and energy carriers (NADH and $FADH_2$) are products of this process, it makes sense that these molecules would have a negative feedback effect on the citric acid cycle. Always consider the big picture when faced with questions like these. For now, we'll outline how regulation occurs throughout the citric acid cycle; look for the recurring theme that energy products inhibit energy production processes.

Pyruvate Dehydrogenase Complex Regulation

Even upstream from its actual starting point, the citric acid cycle can be regulated. The mechanism by which this happens is phosphorylation of PDH, which is facilitated by the enzyme ***pyruvate dehydrogenase kinase***. Thus, whenever levels of ATP rise, phosphorylating PDH inhibits acetyl-CoA production. Conversely, the pyruvate dehydrogenase complex is reactivated by the enzyme ***pyruvate dehydrogenase phosphatase*** in response to high levels of ADP. By removing a phosphate from PDH, pyruvate dehydrogenase phosphatase is able to reactivate acetyl-CoA production. Acetyl-CoA also has a negative feedback effect on its own production. When using alternate fuel sources such as fats, the acetyl-CoA production is sufficient to make it redundant to continue producing acetyl-CoA from carbohydrate metabolism—that's part of why eating a high-fat meal fills you up so quickly! ATP and NADH, as markers of the cell being satisfied energetically, also inhibit PDH.

Control Points of the Citric Acid Cycle

There are three essential checkpoints that regulate the citric acid cycle from within, and allosteric activators and inhibitors regulate all of them. The details of these mechanisms are outlined below and in Figure 10.11.

- **Citrate synthase**: ATP and NADH function as allosteric inhibitors of citrate synthase, which makes sense because both are products (indirect and direct, respectively) of the enzyme. Citrate also allosterically inhibits citrate synthase directly, as does succinyl-CoA.
- **Isocitrate dehydrogenase**: as we discussed in the beginning of this section, this enzyme that catalyzes the citric acid cycle is likely to be inhibited by energy products: ATP and NADH. Conversely, ADP and NAD^+ function as allosteric activators for the enzyme and enhance its affinity for substrates.
- **α-Ketoglutarate dehydrogenase complex**: once again, the reaction products of succinyl-CoA and NADH function as inhibitors of this enzyme complex. ATP is also inhibitory and slows the rate of the cycle when the cell has high levels of ATP. The complex is stimulated by ADP and calcium ions.

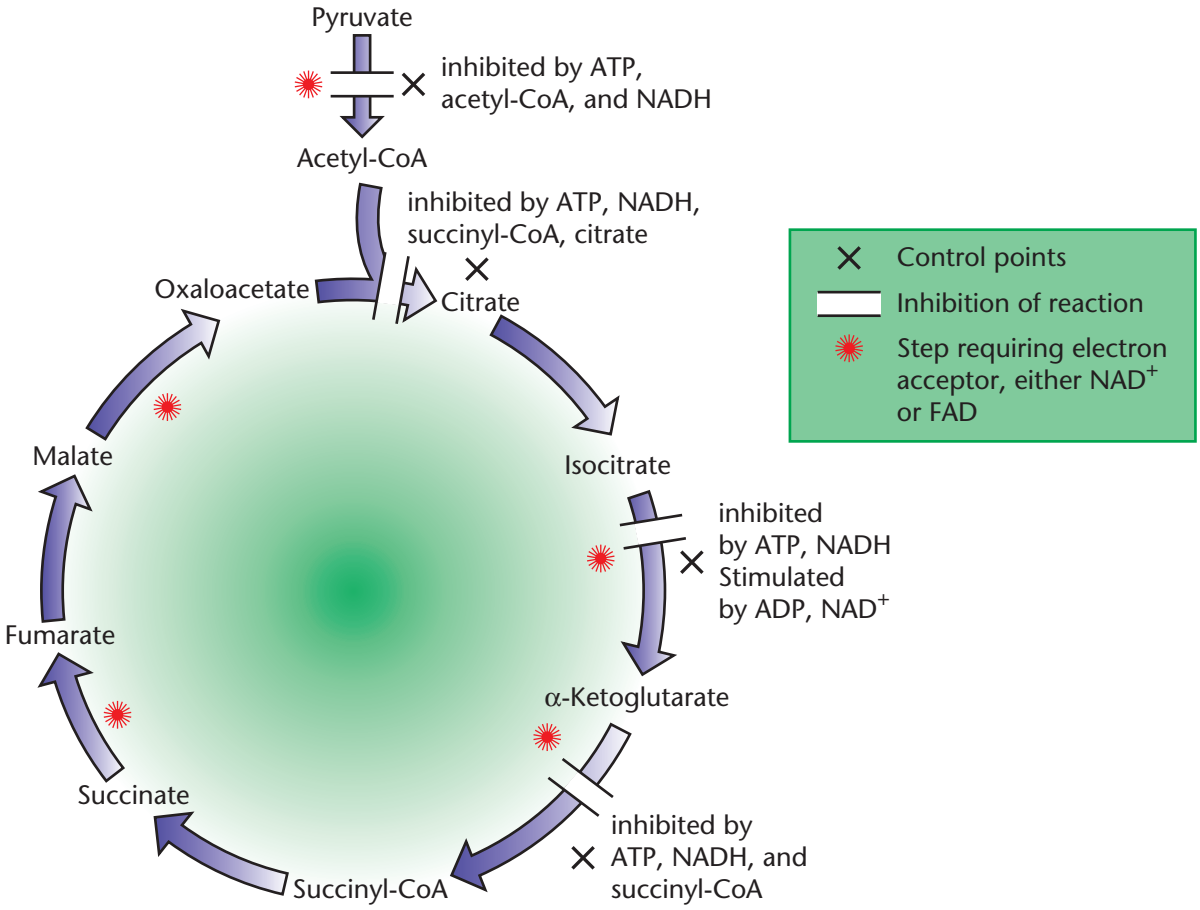

Figure 10.11. Checkpoints and Regulation of the Citric Acid Cycle

Note that high levels of ATP and NADH inhibit the citric acid cycle, while high levels of ADP and NAD^+ promote it. This isn't a coincidence! When energy is being consumed in large amounts, more and more ATP is converted to ADP, and NADH is converted to NAD^+. It is therefore the ATP/ADP ratio and NADH/NAD^+ ratio that help determine whether the citric acid cycle will be inhibited or activated. During a metabolically active state, ADP and NAD^+ levels should rise as ATP and NADH levels decline, thus inducing activation at all the various checkpoints described above, replacing the energy used up by active tissues.

MCAT Concept Check 10.2:
Before you move on, assess your understanding of the material with these questions.

1. What is the purpose of all the reactions that collectively make up the citric acid cycle?

_____

_____

_____

2. What enzyme catalyzes the rate-limiting step of the citric acid cycle?

_____

3. What are the three main sites of regulation within the citric acid cycle? What molecules inhibit and activate the three main checkpoints?

Checkpoints	Inhibitors	Activators

10.3 The Electron Transport Chain ★★★★

The electron transport chain is the final common pathway that utilizes the harvested electrons from different fuels in the body. It is important to make the distinction that it is not the flow of electrons but the proton gradient it generates that ultimately produces

ATP. Aerobic metabolism is the most efficient way of generating energy in living systems, and the mitochondrion is the reason why. In eukaryotes, the aerobic components of respiration are executed in mitochondria, while anaerobic processes such as glycolysis and fermentation occur in the cytosol. Looking at Figure 10.12, notice how the components of the mitochondria are critical in the harvesting of energy. The citric acid cycle takes place in the mitochondrial matrix. The assemblies needed to complete oxidative phosphorylation are housed adjacent to the matrix in the inner membrane of the mitochondria. The inner mitochondrial membrane is assembled into folds called ***cristae***, which maximize surface area. It is the inner mitochondrial membrane that will be essential for generating ATP using the **proton-motive force**, an electrochemical proton gradient generated by the complexes of the electron transport chain.

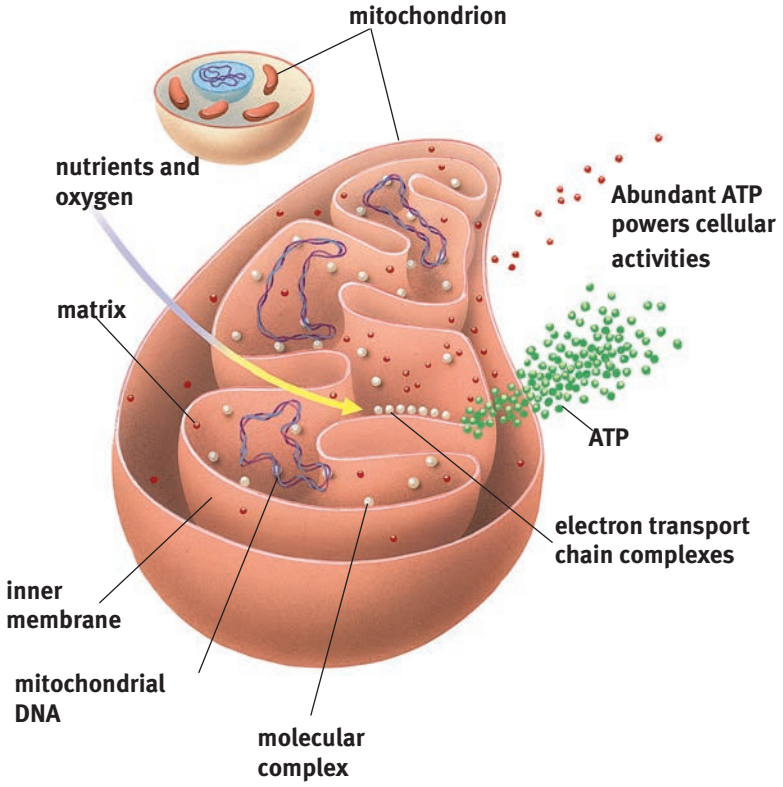

Figure 10.12. Mitochondrial Structure

The final step in aerobic respiration is actually two steps: electron transport along the inner mitochondrial membrane and the generation of ATP via ADP phosphorylation. While these two processes are actually separate entities, they are very much coupled, so explaining these steps together makes a great deal of sense. The electron-rich molecules NADH and $FADH_2$ are formed as byproducts at earlier steps in respiration. They transfer their electrons to carrier proteins located along the inner mitochondrial membrane. Finally, these electrons are given to oxygen in the form of hydride ions (H^-) and water is formed. While this is happening, energy released from transporting electrons facilitates proton transport at three specific

locations in the chain. Protons are moved from the mitochondrial matrix into the intermembrane space of the mitochondria, thereby creating a greater concentration gradient of hydrogen ions that can be used to drive ATP production.

ELECTRON FLOW AND COMPLEXES

The formation of ATP is endergonic and electron transport is an exergonic pathway. By coupling these reactions, the energy yielded by one reaction can fuel the other. In order for energy to be harnessed via electron transport reactions, the proteins along the inner membrane must transfer the electrons donated by NADH and $FADH_2$ in a specific order and direction. The physical property that determines the direction of electron flow is reduction potential. Recall from Chapter 12 of *MCAT General Chemistry Review* that if you pair two molecules with different reduction potentials, the molecule with the higher potential will be reduced, while the other molecule will become oxidized. The electron transport chain is therefore nothing more than a series of oxidations and reductions that occur via the same mechanism. NADH is a good electron donor, and the high reduction potential of oxygen makes it a great final acceptor in the electron transport chain. The organizational structure of the membrane-bound complexes that make up the transport chain is diagrammed in Figure 10.13, and further detailed below.

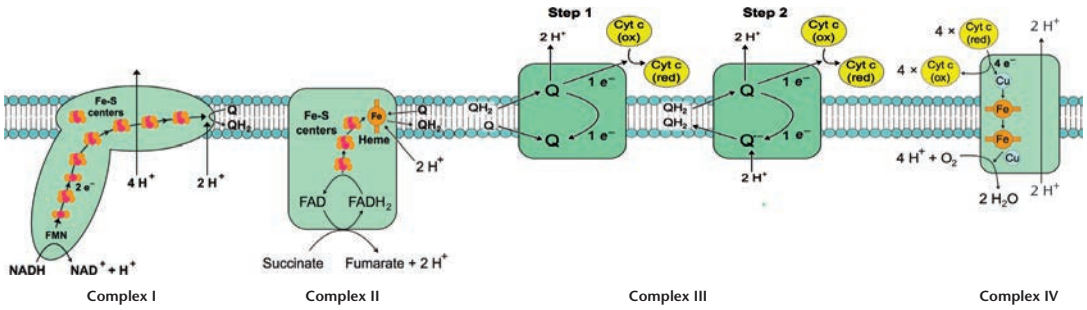

Figure 10.13. Respiratory Complexes on the Inner Mitochondrial Membrane

- **Complex I** (***NADH-CoQ oxidoreductase***): The transfer of electrons from NADH to coenzyme Q (CoQ) is catalyzed in this first complex. This complex has over 20 subunits, but the two highlighted here include a protein that has an iron–sulfur cluster and a flavoprotein that oxidizes NADH. The flavoprotein has a coenzyme called *flavin mononucleotide* (FMN) covalently bonded to it. FMN is quite similar in structure to FAD, flavin adenine dinucleotide. The first step in the reaction involves NADH transferring its electrons over to FMN, thereby becoming oxidized to NAD^+ as FMN is reduced to $FMNH_2$. Next, the flavoprotein becomes reoxidized while the iron–sulfur subunit is reduced. Finally, the reduced iron–sulfur subunit donates the electrons it received from $FMNH_2$ to coenzyme Q (also called *ubiquinone*). Coenzyme Q becomes

$CoQH_2$. This first complex is one of three sites where proton pumping occurs, as four protons are moved to the intermembrane space.

- $NADH + H^+ + FMN \rightarrow NAD^+ + FMNH_2$
- $FMNH_2 + 2\ Fe\text{–}S_{oxidized} \rightarrow FMN + 2\ Fe\text{–}S_{reduced} + 2\ H^+$
- $2\ Fe\text{–}S_{reduced} + CoQ + 2\ H^+ \rightarrow 2\ Fe\text{–}S_{oxidized} + CoQH_2$

The net effect is passing high-energy electrons from NADH to CoQ to form $CoQH_2$:

- $NADH + H^+ + CoQ \rightarrow NAD^+ + CoQH_2$

Bridge

Ubiquinone can be created from its corresponding phenol by oxidation and represents an example of a quinone (2,5-cyclohexadiene-1,4-diones). These fascinating compounds are explored in Chapter 5 of *MCAT Organic Chemistry Review*.

Real World

Unlike iron in cytochromes, iron in the heme group of hemoglobin always remains as Fe^{2+} during the transport of oxygen through the bloodstream under normal conditions.

- **Complex II (*Succinate-CoQ oxidoreductase*)**: Just like complex I, complex II transfers electrons to coenzyme Q. While complex I received electrons from NADH, complex II actually receives electrons from succinate. Remember that succinate is a citric acid cycle intermediate, and that it is oxidized to fumarate upon interacting with FAD. FAD is covalently bonded to complex II, and once succinate is oxidized, it's converted to $FADH_2$. After this, $FADH_2$ gets reoxidized to FAD as it reduces an iron–sulfur protein. The final step reoxidizes the iron–sulfur protein as coenzyme Q is reduced. Because succinate dehydrogenase was responsible for oxidizing succinate to fumarate in the citric acid cycle, it makes sense that succinate dehydrogenase is also a part of complex II. It should be noted that no hydrogen pumping occurs here to contribute to the proton gradient.

  - $succinate + FAD \rightarrow fumarate + FADH_2$
  - $FADH_2 + Fe\text{–}S_{oxidized} \rightarrow FAD + Fe\text{–}S_{reduced}$
  - $Fe\text{–}S_{reduced} + CoQ + 2\ H^+ \rightarrow Fe\text{–}S_{oxidized} + CoQH_2$

  The net effect is passing high-energy electrons from succinate to CoQ to form $CoQH_2$:

  - $succinate + CoQ + 2\ H^+ \rightarrow fumarate + CoQH_2$

- **Complex III (*$CoQH_2$-cytochrome c oxidoreductase*)**: Also called cytochrome reductase, this complex facilitates the transfer of electrons from coenzyme Q to cytochrome *c* in a few steps. The overall reaction is written below. The following steps involve the oxidation and reduction of ***cytochromes***: proteins with heme groups in which iron is reduced to Fe^{2+} and reoxidized to Fe^{3+}.

  - $CoQH_2 + 2$ cytochrome *c* [with Fe^{3+}] $\rightarrow$
    $CoQ + 2$ cytochrome *c* [with Fe^{2+}] $+ 2\ H^+$

  In the transfer of electrons from iron, only one electron is transferred per reaction, but because coenzyme Q has two electrons to transfer, two cytochrome *c* molecules will be needed. Complex III's main contribution to the proton-motive

force is via the **Q cycle**. In the Q cycle, two electrons are shuttled from a molecule of *ubiquinol* ($CoQH_2$) near the intermembrane space to a molecule of *ubiquinone* (CoQ) near the mitochondrial matrix. Another two electrons are attached to heme moieties, reducing two molecules of cytochrome *c*. A carrier containing iron and sulfur assists this process. In shuttling these electrons, four protons are also displaced to the intermembrane space; therefore, the Q cycle continues to increase the gradient of the proton-motive force across the inner mitochondrial membrane.

- **Complex IV (*cytochrome* c *oxidase*)**: This complex facilitates the culminating step of the electron transport chain: transfer of electrons from cytochrome *c* to oxygen, the final electron acceptor. This complex includes subunits of cytochrome *a*, cytochrome a_3, and Cu^{2+} ions. Together, cytochromes *a* and a_3 make up *cytochrome oxidase*. Through a series of redox reactions, cytochrome oxidase gets oxidized as oxygen becomes reduced and forms water. This is the final location on the transport chain where proton pumping occurs, as two protons are moved across the membrane. The role proton pumping plays in ATP synthesis is an essential one that we will describe in detail next. The overall reaction is:

  - 4 cytochrome *c* [with Fe^{2+}] + 4 H^+ + O_2 → 4 cytochrome *c* [with Fe^{3+}] + 2 H_2O

Key Concept

Both coenzyme Q and cytochrome *c* aren't technically part of the complexes we're describing. However, because both are able to move freely in the inner mitochondrial membrane, this degree of mobility allows these carriers to transfer electrons by physically interacting with the next component of the transport chain.

Key Concept

Cyanide, mentioned in the introduction to this chapter, is an inhibitor of cytochrome subunits *a* and a_3. The cyanide anion is able to attach to the iron group and prevents the transfer of electrons. Tissues that rely heavily on aerobic respiration such as the heart and the central nervous system can be greatly impacted.

THE PROTON-MOTIVE FORCE

Let's take a step back and look at the proton gradient that formed as electrons were passed along the ETC. As [H^+] increases in the intermembrane space, two things happen simultaneously: pH drops in the intermembrane space, and the voltage difference between the intermembrane space and matrix increases due to proton pumping. Together, these two changes contribute to what is referred to as an **electrochemical gradient**: a gradient that has both chemical and electrostatic properties. Because it is based on protons, we often refer to the electrochemical gradient across the inner mitochondrial membrane as the proton-motive force. Any electrochemical gradient stores energy, and it will be the responsibility of ***ATP synthase*** to harness this energy to form ATP from ADP and an inorganic phosphate.

NADH SHUTTLES

As we look at the net ATP yield per glucose, note that a range exists between 30–32. This is because efficiency of aerobic respiration varies between cells. This variable efficiency is caused by the fact that cytosolic NADH formed through glycolysis cannot directly cross into the mitochondrial matrix. Because it cannot contribute its electrons to the transport chain directly, it must find alternate means of transportation

referred to as **shuttle mechanisms**. A shuttle mechanism transfers the high-energy electrons of NADH to a carrier that can cross the inner mitochondrial membrane. Depending on which of the two shuttle mechanisms NADH participates in, either 1.5 or 2.5 ATP will end up being produced. Let's take a look at the two mechanisms:

Bridge

Glycerol 3-phosphate is an important link between lipid metabolism, discussed in Chapter 11 of *MCAT Biochemistry Review*, and glycolysis, discussed in Chapter 9. Its ability to be converted to DHAP, an intermediate of glycolysis, means that the glycerol of triacylglycerols can be shunted into glycolysis for energy.

- **Glycerol 3-phosphate shuttle**: The cytosol contains one isoform of *glycerol-3-phosphate dehydrogenase*, which oxidizes cytosolic NADH to NAD^+ while forming glycerol 3-phosphate from dihydroxyacetone phosphate (DHAP). On the outer face of the inner mitochondrial membrane, there exists another isoform of glycerol-3-phosphate dehydrogenase that is FAD-dependent. This mitochondrial FAD is the oxidizing agent, and ends up being reduced to $FADH_2$. Once reduced, $FADH_2$ proceeds to transfer its electrons to the ETC via Complex II, thus generating 1.5 ATP for every molecule of cytosolic NADH that participates in this pathway, which is shown in Figure 10.14.

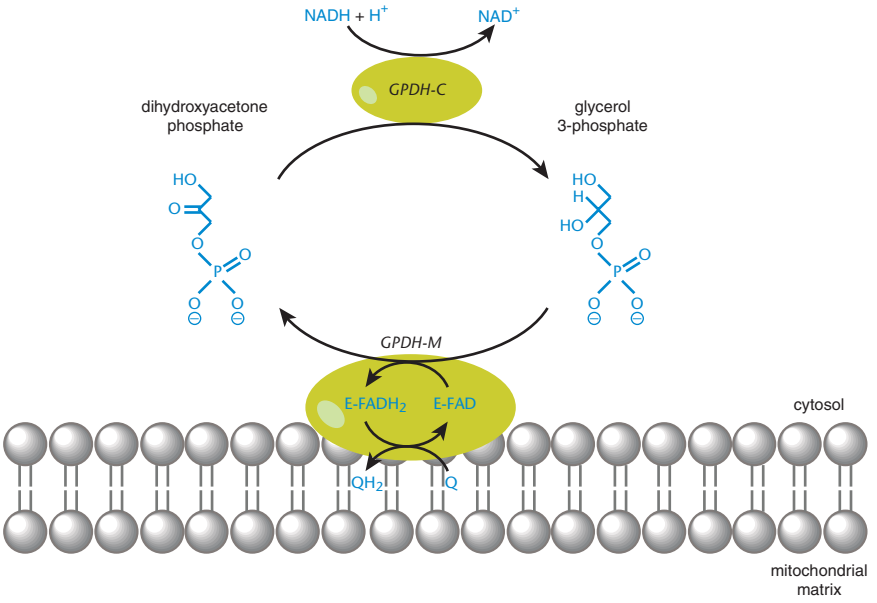

Figure 10.14. Glycerol-3-Phosphate Shuttle

- **Malate–aspartate shuttle**: Cytosolic oxaloacetate, which cannot pass through the inner mitochondrial membrane, is reduced to malate, which can. This is accomplished by cytosolic *malate dehydrogenase*. Accompanying this reduction is the oxidation of cytosolic NADH to NAD^+. Once malate crosses into the matrix, mitochondrial malate dehydrogenase reverses the reaction to form mitochondrial NADH. Now that NADH is in the matrix, it can pass along its electrons to the ETC via Complex I and generate 2.5 ATP per molecule of NADH. Recycling the malate requires oxidation to oxaloacetate, which can be transaminated to form aspartate. Aspartate crosses into the cytosol, and can be reconverted to oxaloacetate to restart the cycle, as shown in Figure 10.15.

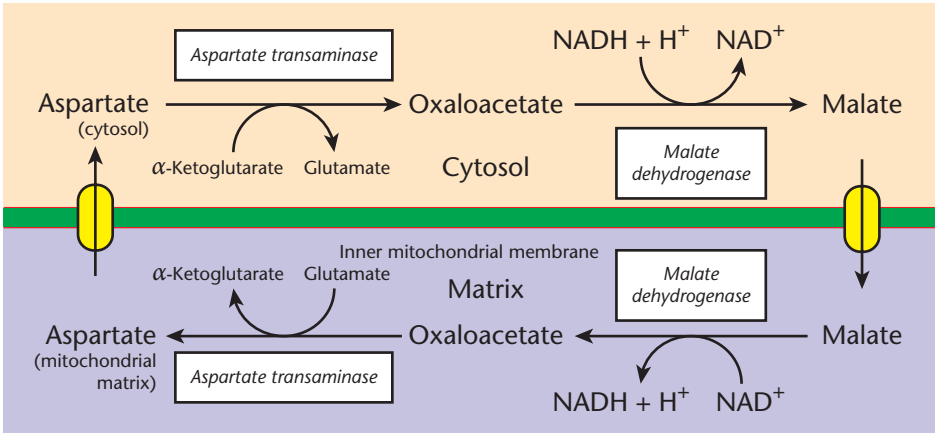

Figure 10.15. Malate–Aspartate Shuttle

MCAT Concept Check 10.3:

Before you move on, assess your understanding of the material with these questions.

1. Which complex(es) are associated with each of the following? (circle all that apply)
   - Pumping a proton into the intermembrane space I II III IV
   - Acquiring electrons from NADH I II III IV
   - Acquiring electrons from $FADH_2$ I II III IV
   - Having the highest reduction potential I II III IV
2. What role does the electron transport chain play in the generation of ATP?

   _____

   _____
3. Based on its needs, which of the two shuttle mechanisms is cardiac muscle most likely to utilize? Why?

   _____

   _____

10.4 Oxidative Phosphorylation ★★★★

We have arrived at the payout site of aerobic respiration: ATP synthesis. Knowing the nuances of ATP synthesis is an absolute must by Test Day. The link between electron transport and ATP synthesis starts with a protein complex called ATP synthase, which spans the entire inner mitochondrial membrane and protrudes into the matrix.

Real World

A small fraction—only 13 of the approximately 100 polypeptides necessary for oxidative phosphorylation—are encoded by mitochondrial DNA. The significance of this fact is that mitochondrial DNA has a mutation rate nearly ten times higher than that of nuclear DNA.

CHEMIOSMOTIC COUPLING

The proton-motive force interacts with the portion of ATP synthase that spans the membrane, which is called the F_0 portion. **F_0** functions as an ion channel, so protons travel through F_0 along their gradient back into the matrix. As this happens, a process called **chemiosmotic coupling** allows the chemical energy of the gradient to be harnessed as a means of phosphorylating ADP, thus forming ATP. In other words, the ETC generates a high concentration of protons in the intermembrane space, which then flow through the F_0 ion channel of ATP synthase back into the matrix. As this happens, the other portion of ATP synthase, which is called the **F_1 portion**, utilizes the energy released from this electrochemical gradient to phosphorylate ADP to ATP, as demonstrated in Figure 10.16. The specific mechanism by which ADP is actually phosphorylated is still a matter of debate.

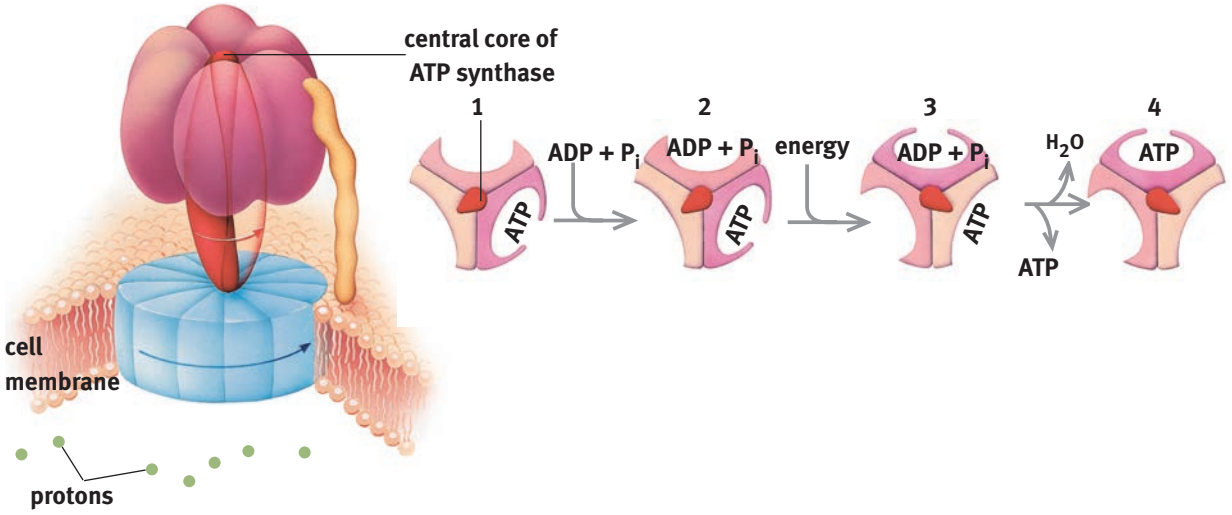

Figure 10.16. ATP Synthase Reaction
ATP synthase generates ATP from ADP and inorganic phosphate by allowing high-energy protons to move down the concentration gradient created by the electron transport chain.

MCAT Expertise

When tackling complex mechanisms such as chemiosmotic coupling on Test Day, it's easy to make mistakes such as interpreting *a pH drop* to be *a $[H^+]$ drop* instead of a rise in proton concentration. Always read actively in order to avoid such mistakes.

Chemiosmotic coupling describes a direct relationship between the proton gradient and ATP synthesis. It is the predominant mechanism accepted in the scientific community when describing oxidative phosphorylation. However, another mechanism called **conformational coupling** suggests that the relationship between the proton gradient and ATP synthesis is indirect. Instead, ATP is released by the synthase as a result of conformational change caused by the gradient. In this mechanism, the F_1 portion of ATP synthase is reminiscent of a turbine, spinning within a stationary compartment to facilitate the harnessing of gradient energy for chemical bonding.

So we now know how we generate ATP, but how much energy was required to do so? When the proton-motive force is dissipated through the F_0 portion of ATP synthase, the free energy change of the reaction, $\Delta G^{\circ\prime}$, is –220 $\frac{kJ}{mol}$, a highly exergonic reaction. This makes sense because phosphorylating ADP to form ATP is an endergonic process. So, by coupling these reactions, the energy harnessed from one reaction can drive another.

REGULATION

Because the citric acid cycle provides the electron-rich molecules that feed into the ETC, it should come as no surprise that the rates of oxidative phosphorylation and the citric acid cycle are closely coordinated. Always think of O_2 and ADP as the key regulators of oxidative phosphorylation. If O_2 is limited, the rate of oxidative phosphorylation decreases, and the concentrations of NADH and $FADH_2$ increase. The accumulation of NADH, in turn, inhibits the citric acid cycle. The coordinated regulation of these pathways is known as **respiratory control**. In the presence of adequate O_2, the rate of oxidative phosphorylation is dependent on the availability of ADP. The concentrations of ADP and ATP are reciprocally related; an accumulation of ADP is accompanied by a decrease in ATP and the amount of energy available to the cell. Therefore, ADP accumulation signals the need for ATP synthesis. ADP allosterically activates isocitrate dehydrogenase, thereby increasing the rate of the citric acid cycle and the production of NADH and $FADH_2$. The elevated levels of these reduced coenzymes, in turn, increase the rate of electron transport and ATP synthesis.

MCAT Concept Check 10.4:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between the ETC and oxidative phosphorylation? What links the two?

_____

_____

_____

_____

_____

Real World

Uncouplers are compounds that prevent ATP synthesis without affecting the ETC, thus greatly decreasing the efficiency of the ETC/oxidative phosphorylation pathway. Because ADP builds up and ATP synthesis decreases, the body responds to this perceived lack of energy by increasing O_2 consumption and NADH oxidation. The energy produced from the transport of electrons is released as heat. An example would be the fever experienced with toxic levels of salicylates, including aspirin.

2. The $\Delta G°$ of NADH reducing oxygen directly is significantly greater than any individual step along the electron transport chain. If this is the case, why does transferring electrons along the ETC generate more ATP than direct reduction of oxygen by NADH?

_____

_____

_____

_____

Conclusion

Both topics discussed in this chapter—the citric acid cycle and oxidative phosphorylation—take place in the mitochondria. In the mitochondrial matrix, the citric acid cycle completely oxidizes acetyl-CoA to carbon dioxide. While this happens, energy is conserved via reduction reactions, forming high-energy electron carriers such as $FADH_2$ and NADH. ATP is also indirectly formed via GTP synthesis. These electron-rich carriers then transfer their electrons to the electron transport chain, which is located along the inner mitochondrial membrane. A series of oxidation–reduction reactions occur in specific complexes until oxygen, the final electron acceptor, gets reduced and forms H_2O. This electrical pathway generates an electrochemical proton gradient that is harnessed by ATP synthase to generate ATP. The link between these two processes is highlighted by the fact that control of the citric acid cycle is NADH-dependent. When NADH accumulates, isocitrate dehydrogenase inhibition occurs, thus stopping both the citric acid cycle and electron transport chain.

It is worth noting that, while glycolysis is a major source of acetyl-CoA for the citric acid cycle, fatty acids also serve as an important source. In the next chapter, we turn our attention to the metabolism of two other types of biomolecules: lipids and amino acids.

CONCEPT SUMMARY

Acetyl-CoA

- **Acetyl-CoA** contains a high-energy thioester bond that can be used to drive other reactions when hydrolysis occurs.
- It can be formed from pyruvate via **pyruvate dehydrogenase complex**, a five-enzyme complex in the mitochondrial matrix that forms—and is also inhibited by—acetyl-CoA and NADH.
  - **Pyruvate dehydrogenase** (PDH) oxidizes pyruvate, creating CO_2; it requires thiamine pyrophosphate (vitamin B_1, TPP) and Mg^{2+}.
  - **Dihydrolipoyl transacetylase** oxidizes the remaining two-carbon molecule using lipoic acid, and transfers the resulting acetyl group to CoA, forming acetyl-CoA.
  - **Dihydrolipoyl dehydrogenase** uses FAD to reoxidize lipoic acid, forming $FADH_2$. This $FADH_2$ can later transfer electrons to NAD^+, forming NADH that can feed into the electron transport chain.
  - **Pyruvate dehydrogenase kinase** phosphorylates PDH when ATP or acetyl-CoA levels are high, turning it off.
  - **Pyruvate dehydrogenase phosphatase** dephosphorylates PDH when ADP levels are high, turning it on.
- Acetyl-CoA can be formed from fatty acids, which enter the mitochondria using carriers.
  - The fatty acid couples with CoA in the cytosol to form fatty acyl-CoA, which moves to the intermembrane space.
  - The acyl (fatty acid) group is transferred to carnitine to form acyl-carnitine, which crosses the inner membrane.
  - The acyl group is transferred to a mitochondrial CoA to re-form fatty acyl-CoA, which can undergo β-oxidation to form acetyl-CoA.
- Acetyl-CoA can be formed from the carbon skeletons of ketogenic amino acids, ketone bodies, and alcohol.

Reactions of the Citric Acid Cycle

- The **citric acid cycle** takes place in the mitochondrial matrix.
- Its main purpose is to oxidize carbons in intermediates to CO_2 and generate high-energy electron carriers (NADH and $FADH_2$) and GTP.
- Key enzymes and reactions:
  - **Citrate synthase** couples acetyl-CoA to oxaloacetate and then hydrolyzes the resulting product, forming **citrate** and CoA–SH. This enzyme is regulated by negative feedback from ATP, NADH, succinyl-CoA, and citrate.

- **Aconitase** isomerizes citrate to **isocitrate**.
- **Isocitrate dehydrogenase** oxidizes and decarboxylates isocitrate to form **α-ketoglutarate**. This enzyme generates the first CO_2 and first NADH of the cycle. As the rate-limiting step of the citric acid cycle, it is heavily regulated: ATP and NADH are inhibitors; ADP and NAD^+ are activators.
- **α-Ketoglutarate dehydrogenase complex** acts similarly to PDH complex, metabolizing **α-ketoglutarate** to form **succinyl-CoA**. This enzyme generates the second CO_2 and second NADH of the cycle. It is inhibited by ATP, NADH, and succinyl-CoA; it is activated by ADP and Ca^{2+}.
- **Succinyl-CoA synthetase** hydrolyzes the thioester bond in succinyl-CoA to form **succinate** and CoA–SH. This enzyme generates the one GTP generated in the cycle.
- **Succinate dehydrogenase** oxidizes succinate to form **fumarate**. This **flavoprotein** is anchored to the inner mitochondrial membrane because it requires FAD, which is reduced to form the one $FADH_2$ generated in the cycle.
- **Fumarase** hydrolyzes the alkene bond of fumarate, forming **malate**.
- **Malate dehydrogenase** oxidizes malate to **oxaloacetate**. This enzyme generates the third and final NADH of the cycle.

The Electron Transport Chain

- The **electron transport chain** takes place on the matrix-facing surface of the inner mitochondrial membrane.
- NADH donates electrons to the chain, which are passed from one complex to the next. As the ETC progresses, reduction potentials increase until oxygen, which has the highest reduction potential, receives the electrons.
  - **Complex I** (**NADH-CoQ oxidoreductase**) uses an iron–sulfur cluster to transfer electrons from NADH to flavin mononucleotide (FMN), and then to **coenzyme Q** (**CoQ**), forming $CoQH_2$. Four protons are translocated by Complex I.
  - **Complex II** (**Succinate-CoQ oxidoreductase**) uses an iron–sulfur cluster to transfer electrons from succinate to FAD, and then to CoQ, forming $CoQH_2$. No proton pumping occurs at Complex II.
  - **Complex III** (**$CoQH_2$-cytochrome *c* oxidoreductase**) uses an iron–sulfur cluster to transfer electrons from $CoQH_2$ to heme, forming cytochrome *c* as part of the **Q cycle**. Four protons are translocated by Complex III.
  - **Complex IV** (**cytochrome *c* oxidase**) uses cytochromes and Cu^{2+} to transfer electrons in the form of hydride ions (H^-) from cytochrome *c* to oxygen, forming water. Two protons are translocated by Complex IV.

- NADH cannot cross the inner mitochondrial membrane. Therefore, one of two available shuttle mechanisms to transfer electrons in the mitochondrial matrix must be used.
  - In the **glycerol 3-phosphate shuttle**, electrons are transferred from NADH to dihydroxyacetone phosphate (DHAP), forming glycerol 3-phosphate. These electrons can then be transferred to mitochondrial FAD, forming $FADH_2$.
  - In the **malate–aspartate shuttle**, electrons are transferred from NADH to oxaloacetate, forming malate. Malate can then cross the inner mitochondrial membrane and transfer the electrons to mitochondrial NAD^+, forming NADH.

Oxidative Phosphorylation

- The **proton-motive force** is the electrochemical gradient generated by the electron transport chain across the inner mitochondrial membrane. The intermembrane space has a higher concentration of protons than the matrix; this gradient stores energy, which can be used to form ATP via **chemiosmotic coupling**.
- **ATP synthase** is the enzyme responsible for generating ATP from ADP and an inorganic phosphate (P_i).
  - The **F_0 portion** is an ion channel, allowing protons to flow down the gradient from the intermembrane space to the matrix.
  - The **F_1 portion** uses the energy released by the gradient to phosphorylate ADP into ATP.
- The following is a summary of the energy yield of the various carbohydrate metabolism processes:
  - Glycolysis generates 2 NADH and 2 ATP.
  - Pyruvate dehydrogenase generates 1 NADH per molecule of pyruvate. Because each glucose forms two molecules of pyruvate, this complex produces a net of 2 NADH.
  - The citric acid cycle generates 3 NADH, 1 $FADH_2$, and 1 GTP (6 NADH, 2 $FADH_2$, and 2 GTP per molecule of glucose).
  - Each NADH yields 2.5 ATP; 10 NADH form 25 ATP.
  - Each $FADH_2$ yields 1.5 ATP; 2 $FADH_2$ form 3 ATP.
  - GTP are converted to ATP.
  - 2 ATP from glycolysis + 2 ATP (GTP) from the citric acid cycle + 25 ATP from NADH + 3 ATP from $FADH_2$ = 32 ATP per molecule of glucose (optimal). Inefficiencies of the system and variability between cells make 30-32 ATP/glucose the commonly accepted range for energy yield.

ANSWERS TO CONCEPT CHECKS

10.1

1. Pyruvate + CoA–SH + NAD^+ → acetyl-CoA + CO_2 + NADH + H^+

2.

Molecule	Mechanism of Conversion to Acetyl-CoA
Fatty acids	Shuttle acyl group from cytosolic CoA–SH to mitochondrial CoA–SH via carnitine; then undergo β-oxidation
Ketogenic amino acids	Transaminate to lose nitrogen; convert carbon skeleton into ketone body, which can be converted into acetyl-CoA
Ketones	Reverse of ketone body formation
Alcohol	Alcohol dehydrogenase and acetaldehyde dehydrogenase convert alcohol into acetyl-CoA

10.2

1. Complete oxidation of carbons in intermediates to CO_2 so that reduction reactions can be coupled with CO_2 formation, thus forming energy carriers such as NADH and $FADH_2$ for the electron transport chain.
2. Isocitrate dehydrogenase

3.

Checkpoints	Inhibitors	Activators
Citrate synthase	ATP, NADH, succinyl-CoA, citrate	None
Isocitrate dehydrogenase	ATP, NADH	ADP, NAD^+
α-Ketoglutarate complex	ATP, NADH, succinyl-CoA	ADP, Ca^{2+}

10.3

1.
   - Pumping a proton into the intermembrane space: I, III, and IV
   - Acquiring electrons from NADH: I
   - Acquiring electrons from $FADH_2$: II
   - Having the highest reduction potential: IV (reduction potentials increase along the ETC)
2. The electron transport chain generates the proton-motive force, an electrochemical gradient across the inner mitochondrial membrane, which provides the energy for ATP synthase to function.
3. The malate–aspartate shuttle. Because this mechanism is the more efficient one, it makes sense for a highly aerobic organ such as the heart to utilize it in order to maximize its ATP yield.

10.4

1. The ETC is made up of the physical set of intermembrane proteins located on the inner mitochondrial matrix, and they undergo oxidation–reduction reactions as they transfer electrons to oxygen, the final electron acceptor. As electrons are transferred, a proton-motive force is generated in the intermembrane space. Oxidative phosphorylation is the process by which ATP is generated via harnessing the proton gradient, and it utilizes ATP synthase to do so.
2. By splitting up electron transfer into several complexes, enough energy is released to facilitate the creation of a proton gradient at many locations, rather than just one. The greater the proton gradient is, the greater the ATP generation will be. Direct reduction of oxygen by NADH would release a significant amount of energy to the environment, resulting in inefficient electron transport.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. During a myocardial infarction, the oxygen supply to an area of the heart is dramatically reduced, forcing the cardiac myocytes to switch to anaerobic metabolism. Under these conditions, which of the following enzymes would be activated by increased levels of intracellular AMP?

A. Succinate dehydrogenase
B. Phosphofructokinase-1
C. Isocitrate dehydrogenase
D. Pyruvate dehydrogenase

2. A patient has been exposed to a toxic compound that increases the permeability of mitochondrial membranes to protons. Which of the following metabolic changes would be expected in this patient?

A. Increased ATP levels
B. Increased oxygen utilization
C. Increased ATP synthase activity
D. Decreased pyruvate dehydrogenase activity

3. Which of the following INCORRECTLY pairs a metabolic process with its site of occurrence?

A. Glycolysis—cytosol
B. Citric acid cycle—outer mitochondrial membrane
C. ATP phosphorylation—cytosol and mitochondria
D. Electron transport chain—inner mitochondrial membrane

4. Which of the following processes has the following net reaction?

2 acetyl-CoA $+ 6\ NAD^+ + 2\ FAD + 2\ GDP + 2\ P_i + 6\ H_2O \rightarrow 4\ CO_2 + 6\ NADH + 2\ FADH_2 + 2\ GTP + 6\ H^+ + 2$ CoA–SH

A. Pyruvate decarboxylation
B. Fermentation
C. Tricarboxylic acid cycle
D. Electron transport chain

5. In glucose degradation under aerobic conditions:

A. oxygen is the final electron acceptor.
B. oxygen is necessary for all ATP synthesis.
C. net water is consumed.
D. the proton-motive force is necessary for all ATP synthesis.

6. Fatty acids enter the catabolic pathway in the form of:

A. glycerol.
B. adipose tissue.
C. acetyl-CoA.
D. ketone bodies.

7. In which of the following reactions is the reactant oxidized?

A. $FAD \rightarrow FADH_2$
B. $NAD^+ \rightarrow NADH$
C. $NADPH \rightarrow NADP^+$
D. $ADP \rightarrow ATP$

8. In which part of the cell is cytochrome *c* located?

A. Mitochondrial matrix
B. Outer mitochondrial membrane
C. Inner mitochondrial membrane
D. Cytosol

9. Which of the following correctly shows the amount of ATP produced from the given high-energy carriers?

A. $FADH_2 \rightarrow 1$ ATP
B. $FADH_2 \rightarrow 1.5$ ATP
C. NADH → 3 ATP
D. NADH → 3.5 ATP

10. Why is it preferable to cleave thioester links rather than typical ester links in aerobic metabolism?

A. Oxygen must be conserved for the electron transport chain.
B. Thioester hydrolysis has a higher energy yield.
C. Typical ester hydrolysis cannot occur *in vivo*.
D. Thioester cleavage requires more energy.

11. Which enzyme converts GDP to GTP?

A. Nucleosidediphosphate phosphatase
B. Nucleosidediphosphate kinase
C. Isocitrate dehydrogenase
D. Pyruvate dehydrogenase

12. Which of the following best explains why cytosolic NADH can yield potentially less ATP than mitochondrial NADH?

A. Cytosolic NADH always loses energy when transferring electrons.
B. Once NADH enters the matrix from the cytosol, it becomes $FADH_2$.
C. Electron transfer from cytosol to matrix can take more than one pathway.
D. There is an energy cost for bringing cytosolic NADH into the matrix.

13. In high doses, aspirin functions as a mitochondrial uncoupler. How would this affect glycogen stores?

A. It causes depletion of glycogen stores.
B. It has no effect on glycogen stores.
C. It promotes additional storage of glucose as glycogen.
D. Its effect on glycogen stores varies from cell to cell.

14. Which complex does NOT contribute to the proton-motive force?

A. Complex I
B. Complex II
C. Complex III
D. Complex IV

15. Which of the following directly provides the energy needed to form ATP in the mitochondrion?

A. Electron transfer in the electron transport chain
B. An electrochemical proton gradient
C. Oxidation of acetyl-CoA
D. β-Oxidation of fatty acids

Explanations to Discrete Practice Questions

1. B

Phosphofructokinase-1 (PFK-1), which catalyzes the rate-limiting step of glycolysis, is the only enzyme listed here that functions under anaerobic conditions. The other enzymes are all involved in the oxygen-requiring processes discussed in this chapter. Succinate dehydrogenase, **choice (A)**, appears in both the citric acid cycle and as part of Complex II of the electron transport chain. Isocitrate dehydrogenase, **choice (C)**, catalyzes the rate-limiting step of the citric acid cycle. Pyruvate dehydrogenase, **choice (D)**, is one of the five enzymes that make up the pyruvate dehydrogenase complex.

2. B

The increased permeability of the inner mitochondrial membrane allows the proton-motive force to be dissipated through locations besides the F_0 portion of ATP synthase. Therefore, ATP synthase is less active and is forming less ATP, invalidating **choices (A)** and **(C)**. The body will attempt to regenerate the proton-motive force by increasing fuel catabolism, eliminating **choice (D)**. This increase in fuel use requires more oxygen utilization in the electron transport chain.

3. B

The citric acid cycle takes place in the mitochondrial matrix, not the outer mitochondrial membrane. While most citric acid cycle enzymes are located within the matrix, succinate dehydrogenase is located on the inner mitochondrial membrane.

4. C

It is not necessary to have all the net reactions memorized for each metabolic process to answer this question; all we need is to identify a few key reactants and products. In this case, we start with acetyl-CoA and end with CoA–SH. We also notice that in this reaction, NAD^+ and FAD are reduced to NADH and $FADH_2$, and that CO_2 is formed. The only metabolic process in which all of the above reactions would occur is the citric acid cycle, also called the tricarboxylic acid (TCA) or Krebs cycle.

5. A

This question is testing our general knowledge of cellular respiration. Notice that all types of cellular respiration (aerobic and anaerobic) start with the degradation of glucose by glycolysis. In aerobic respiration, oxygen is the final electron acceptor, and water is therefore produced at the end of the electron transport chain. While oxygen is needed for aerobic respiration in order to produce the optimal 32 molecules of ATP per glucose, it is not the only method by which ATP is produced. Glycolysis still provides 2 ATP per glucose without the need for oxygen, thus making **choices (B)** and **(D)** incorrect. Water, mentioned in **choice (C)**, is produced in aerobic metabolism, not consumed.

6. C

Fat molecules stored in adipose tissue can be hydrolyzed by lipases to fatty acids and glycerol. While glycerol can be converted into glyceraldehyde 3-phosphate, a glycolytic intermediate, a fatty acid must first be activated in the cytoplasm by coupling the fatty acid to CoA–SH, forming fatty acyl-CoA. The fatty acid is then transferred to a molecule of carnitine, which can carry it across the inner mitochondrial membrane. Once inside, the fatty acid is transferred to a mitochondrial CoA–SH, reforming fatty acyl-CoA. Through fatty acid oxidation, this fatty acyl-CoA can become acetyl-CoA, which enters the citric acid cycle.

7. C

To answer this question, we must remember that reduction is a gain of electrons, while oxidation is a loss of electrons. In the case of the energy-storing molecules of cellular respiration, the high-potential electrons generally come from hydride ions (H^-). Because the question is asking us to determine in which reaction the reactant gets oxidized, our task is to select the equation in which the reactant loses hydride ions. From the given choices, the only one that matches our prediction is **choice (C)**. Another way to look at this question is to notice that $NADP^+$ has a +1 charge, which represents an increase from the zero charge of NADPH, implying than an electron was lost in the conversion from NADPH to $NADP^+$.

8. C

Cytochrome *c* carries electrons from $CoQH_2$-cytochrome *c* oxidoreductase (Complex III) to cytochrome *c* oxidase (Complex IV) as part of the electron transport chain. The ETC takes place on the inner mitochondrial membrane.

9. B

During oxidative phosphorylation, energy is harvested from the energy carriers $FADH_2$ and NADH in order to form ATP. One molecule of mitochondrial $FADH_2$ is oxidized to produce 1.5 molecules of ATP. Similarly, one molecule of mitochondrial NADH is oxidized to produce 2.5 molecules of ATP in the electron transport chain.

10. B

Thioester links release a great deal of energy when hydrolyzed, making them well-suited as respiration reaction drivers. They are particularly useful because they release more energy than typical ester cleavage. It is thioester formation, not hydrolysis, that requires a great deal of energy, making **choice (D)** incorrect.

11. B

The conversion of GDP to GTP is a phosphorylation reaction, in which a phosphate group is added to a molecule. Such reactions are catalyzed by kinases. Nomenclature is helpful here, as nucleosidediphosphate kinase is the only enzyme that contains *kinase* in its name.

12. C

The wording of these answer choices is critical. The electrons from cytosolic NADH can enter the mitochondrion through one of two shuttle mechanisms: the glycerol 3-phosphate shuttle, which ultimately moves these electrons to mitochondrial FAD, and the malate–aspartate shuttle, which ultimately moves these electrons to mitochondrial NAD^+. If the electrons are transferred using the malate –aspartate shuttle, then no energy is lost, making **choices (A)** and **(D)** incorrect. NADH cannot enter the matrix directly, making **choice (B)** incorrect. It is the fact that electrons can use more than one pathway—one of which loses energy that could be used for ATP synthesis—that accounts for the potentially decreased yield of ATP from cytosolic NADH.

13. A

Uncouplers inhibit ATP synthesis without affecting the electron transport chain. Because the body must burn more fuel to maintain the proton-motive force, glycogen stores will be mobilized to feed into glycolysis, then the TCA, and finally oxidative phosphorylation.

14. B

Complex II is the only complex of the ETC that does not contribute to the proton gradient. Complexes I and III each add four protons to the gradient; Complex IV adds two protons to the gradient.

15. B

While all of the other answers contribute to energy production, it is the electrochemical gradient (proton-motive force) that directly drives the phosphorylation of ATP by the F_1 portion of ATP synthase.

Concept Summary 386

Introduction

For weeks before the winter season begins, bears and certain mammals increase their food intake to prepare for hibernation. During this time, they increase their weight by storing energy. Different organisms store fuel and supplies in different ways. Hamsters store extra food in pouches in their cheeks. Cacti absorb and conserve water in preparation for dry seasons. But hibernating animals store extra calories as fat. Over the course of the winter, fat stores are mobilized and metabolized for basic bodily functions, which are minimal during hibernation. Come spring and summer, these reserves will be replenished in preparation for the next winter season. Humans also store extra energy as fat. While we may not hibernate through the winter, fat stores allow us to store energy to use during prolonged periods without food.

As discussed in Chapter 8 of *MCAT Biochemistry Review*, lipids play a major role in maintaining the structure and function of cells; however, they also have important roles as storage molecules for energy and in biological signaling. In this chapter, we'll examine the metabolism of lipids, starting with ingestion of food particles and continuing through absorption, transport, and energy catabolism. We will also cover energy storage via lipid synthesis, as well as the metabolism of cholesterol and ketone bodies. In addition, we will learn about how protein degradation feeds into lipid and carbohydrate pathways, and the urea cycle.

11.1 Lipid Digestion and Absorption ★★

In addition to being a major source of energy in the body, lipids serve a variety of other functions in the body. For instance, some fat-soluble vitamins play roles as coenzymes; prostaglandins and steroid hormones are necessary in the control and maintenance of homeostasis. Aberrant lipid metabolism may also be associated with clinical manifestations such as atherosclerosis and obesity.

DIGESTION

Dietary fat consists mainly of **triacylglycerols**, with the remainder comprised of **cholesterol**, **cholesteryl esters**, **phospholipids**, and free **fatty acids**. Lipid digestion is minimal in the mouth and stomach; lipids are transported to the small intestine essentially intact. Upon entry into the duodenum, **emulsification** occurs, which is the mixing of two normally immiscible liquids (in this case, fat and water). Formation of an emulsion increases the surface area of the lipid, which permits greater enzymatic interaction and processing. Emulsification is aided by bile, which contains **bile salts**, **pigments**, and **cholesterol**; bile is secreted by the liver and stored in the gallbladder. Finally, the pancreas secretes ***pancreatic lipase***, ***colipase***, and ***cholesterol esterase*** into the small intestine; together, these enzymes hydrolyze the lipid components to *2-monoacylglycerol*, free fatty acids, and cholesterol. Figure 11.1 summarizes the digestion and absorption of dietary lipid components.

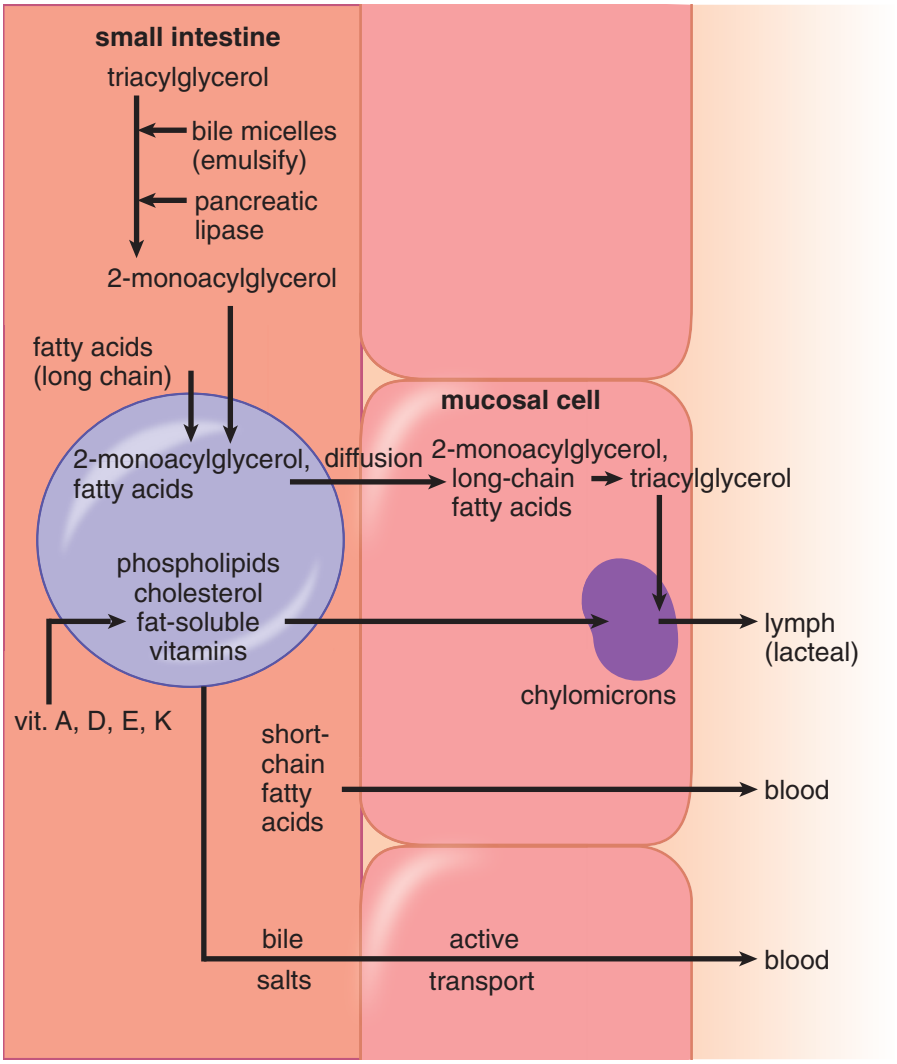

Figure 11.1. Absorption of Lipids

MICELLE FORMATION

Emulsification is followed by absorption of fats by intestinal cells. Free fatty acids, cholesterol, 2-monoacylglycerol, and bile salts contribute to the formation of **micelles**, which are clusters of amphipathic lipids that are soluble in the aqueous environment of the intestinal lumen. Essentially, micelles are water-soluble spheres with a lipid-soluble interior. Micelles are vital in digestion, transport, and absorption of lipid-soluble substances starting from the duodenum all the way to the end of the ileum. At the end of the ileum, bile salts are actively reabsorbed and recycled; any fat that remains in the intestine will pass into the colon, and ultimately ends up in the stool.

Bridge

Absorption in the small intestine and colon follows a characteristic pattern. This is a good time to review digestion, discussed in Chapter 9 of *MCAT Biology Review*, to create a complete schema for the absorption and metabolism of all the macronutrients.

ABSORPTION

Micelles diffuse to the brush border of the intestinal mucosal cells where they are absorbed. The digested lipids pass through the brush border, where they are absorbed into the mucosa and re-esterified to form triacylglycerols and cholesteryl esters and packaged, along with certain apoproteins, fat-soluble vitamins, and other lipids, into **chylomicrons**. Chylomicrons leave the intestine via **lacteals**, the vessels of the lymphatic system, and re-enter the bloodstream via the **thoracic duct**, a long lymphatic vessel that empties into the left subclavian vein at the base of the neck. The more water-soluble short-chain fatty acids can be absorbed by simple diffusion directly into the bloodstream.

MCAT Concept Check 11.1:

Before you move on, assess your understanding of the material with these questions.

1. When lipids leave the stomach, what stages of digestion have been accomplished? What enzymes are added to accomplish the next phase?

_____

_____

_____

2. True or False: All lipids enter the circulation through the lymphatic system.

3. Describe the structure of a micelle.

_____

_____

_____

11.2 Lipid Mobilization

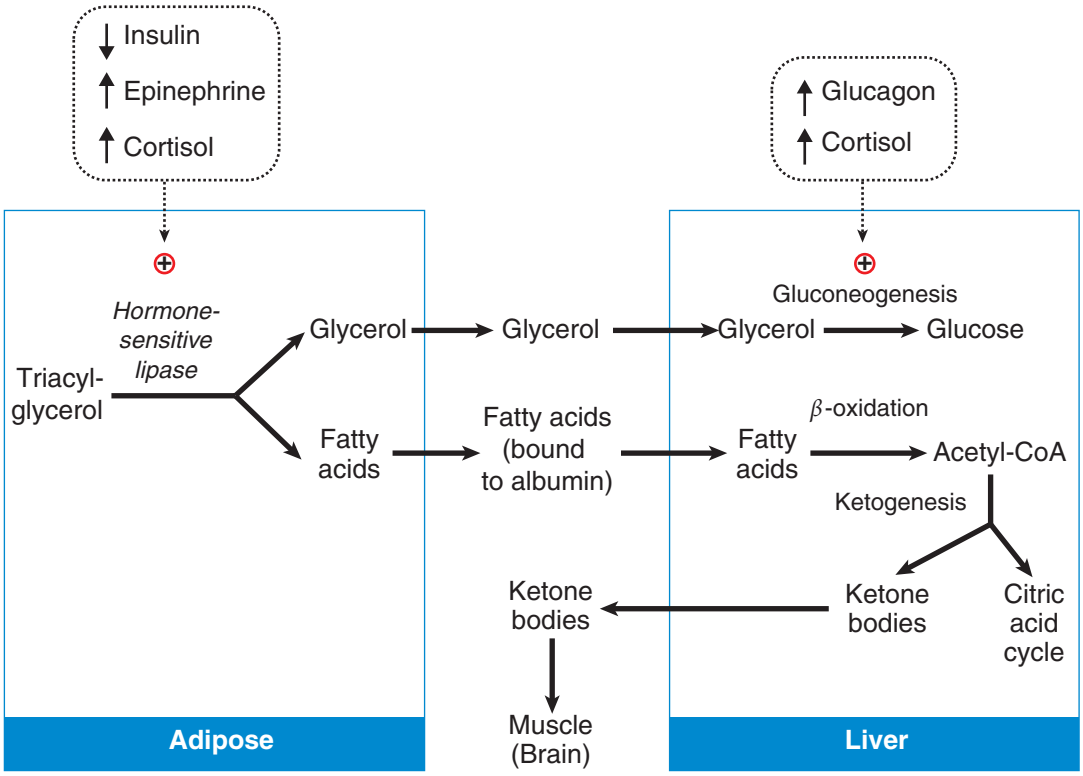

Figure 11.2. Mobilization of Triacylglycerols and Metabolism by the Liver

At night, the body is in the postabsorptive state, utilizing energy stores instead of food for fuel. In the postabsorptive state, fatty acids are released from adipose tissue and used for energy. Although human adipose tissue does not respond directly to glucagon, a fall in insulin levels activates a ***hormone-sensitive lipase*** (**HSL**) that hydrolyzes triacylglycerols, yielding fatty acids and glycerol. Epinephrine and cortisol can also activate HSL, as shown in Figure 11.2; we will discuss the effects of these hormones on metabolism in more detail in the next chapter. Released glycerol from fat may be transported to the liver for glycolysis or gluconeogenesis. HSL is effective within adipose cells, but ***lipoprotein lipase*** (**LPL**) is necessary for the metabolism of chylomicrons and very-low-density lipoproteins (VLDL). LPL is an enzyme that can release free fatty acids from triacylglycerols in these lipoproteins.

MCAT Concept Check 11.2:
Before you move on, assess your understanding of the material with these questions.

1. What conditions and hormones promote lipid mobilization from fat stores?

_____

_____

2. What is the ratio of free fatty acids to glycerol produced through lipid mobilization?

_____

11.3 Lipid Transport ★

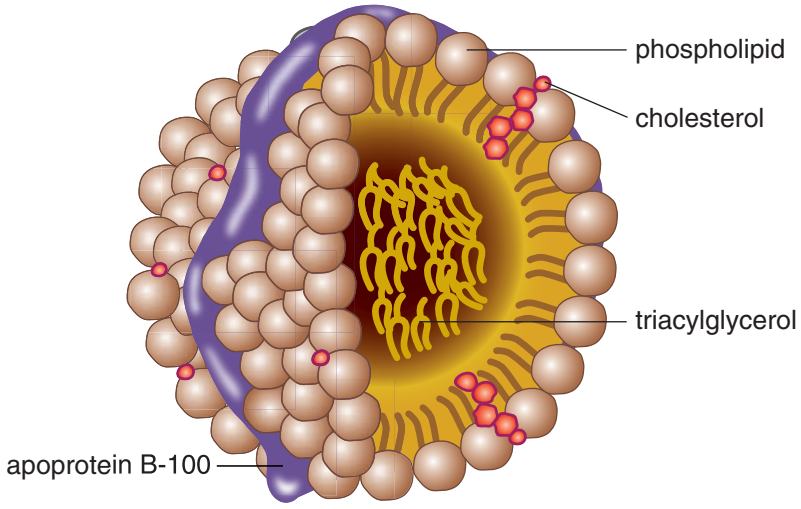

Figure 11.3. Lipoprotein Structure

While free fatty acids are transported through the blood in association with albumin, a carrier protein, triacylglycerol and cholesterol are transported in the blood as **lipoproteins**: aggregates of **apolipoproteins** and lipids, as shown in Figure 11.3. Lipoproteins are named according to their density, which increases in direct proportion to the percentage of protein in the particle. Chylomicrons are the least dense, with the highest fat-to-protein ratio. VLDL (very-low-density lipoprotein) is slightly more dense, followed by IDL (intermediate-density), LDL (low-density), and HDL (high-density). The main functions of each lipoprotein are shown in Table 11.1. Note

that chylomicrons and VLDL primarily carry triacylglycerols, but also contain small quantities of cholesteryl esters. LDL and HDL are primarily cholesterol transport molecules.

Lipoprotein	Functions
Chylomicrons	Transport dietary triacylglycerols, cholesterol, and cholesteryl esters from intestine to tissues
VLDL	Transports triacylglycerols and fatty acids from liver to tissues
IDL (VLDL remnants)	Picks up cholesteryl esters from HDL to become LDL Picked up by the liver
LDL	Delivers cholesterol into cells
HDL	Picks up cholesterol accumulating in blood vessels Delivers cholesterol to liver and steroidogenic tissues Transfers apolipoproteins to other lipoproteins

Table 11.1. Classes of Lipoproteins

CHYLOMICRONS

Chylomicrons are highly soluble in both lymphatic fluid and blood and function in the transport of dietary triacylglycerols, cholesterol, and cholesteryl esters to other tissues. Assembly of chylomicrons occurs in the intestinal lining and results in a nascent chylomicron that contains lipids and apolipoproteins.

VLDL (VERY-LOW-DENSITY LIPOPROTEIN)

VLDL metabolism is similar to that of chylomicrons; however, VLDL is produced and assembled in liver cells. Like chylomicrons, the main function of VLDL is the transport of triacylglycerols to other tissues. VLDLs also contain fatty acids that are synthesized from excess glucose or retrieved from chylomicron remnants.

IDL (INTERMEDIATE-DENSITY LIPOPROTEIN)

Once triacylglycerol is removed from VLDL, the resulting particle is referred to as either a **VLDL remnant** or **IDL**. Some IDL is reabsorbed by the liver by apolipoproteins on its exterior, and some is further processed in the bloodstream. For example, some IDL picks up cholesteryl esters from HDL to become LDL. IDL thus exists as a transition particle between triacylglycerol transport (associated with chylomicrons and VLDL) and cholesterol transport (associated with LDL and HDL). This process is shown in Figure 11.4.

Key Concept

Chylomicrons and VLDL primarily carry triacylglycerols. LDL and HDL primarily carry cholesterol. IDL is intermediate; it is a transition state between VLDL and LDL, occurring as the primary lipid within the lipoprotein changes from triacylglycerol to cholesterol.

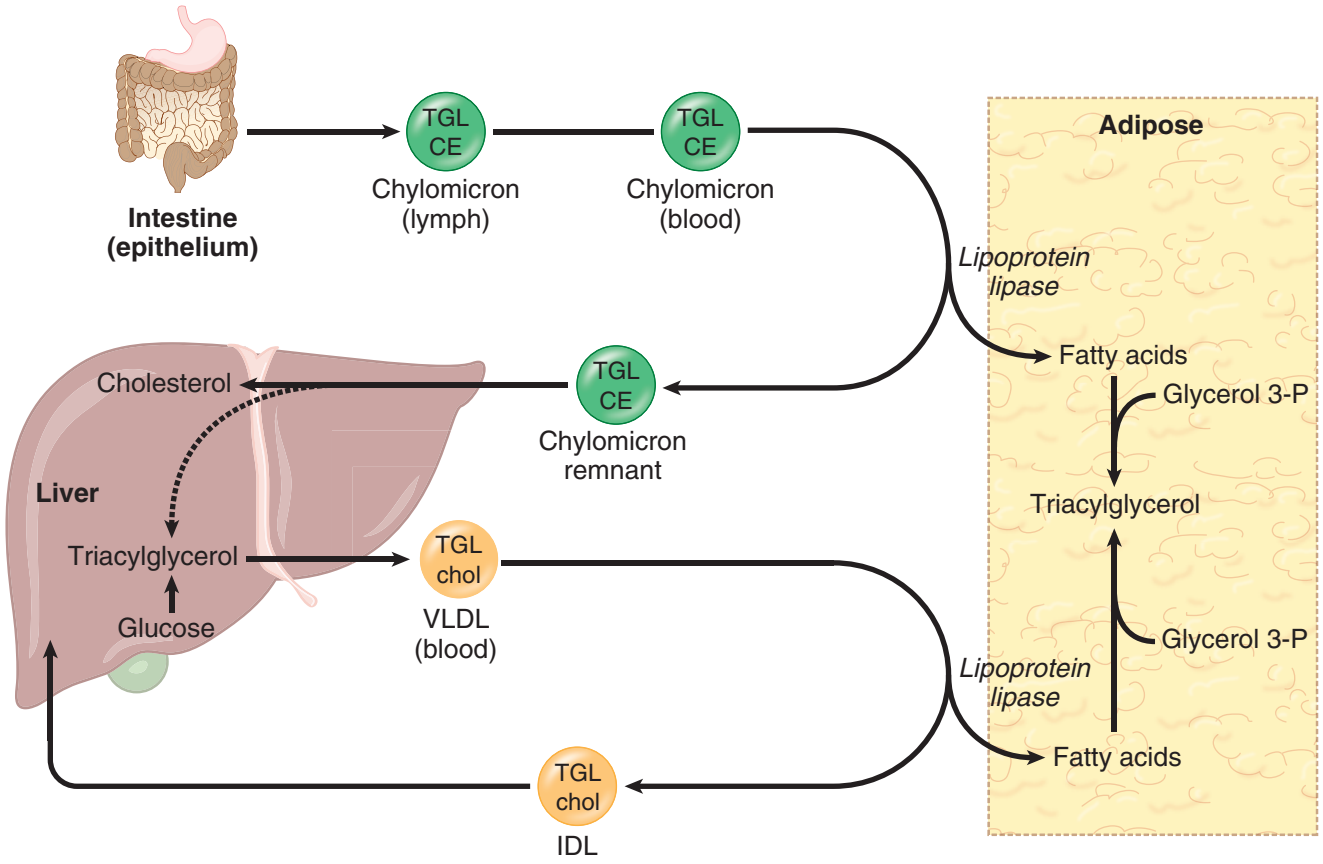

Figure 11.4. Lipid Transport in Lipoproteins
TGL = triacylglycerol; CE = cholesteryl esters; chol = cholesterol

LDL (LOW-DENSITY LIPOPROTEIN)

Although both LDL and HDL are primarily cholesterol particles, the majority of the cholesterol measured in blood is associated with **LDL**. The normal role of LDL is to deliver cholesterol to tissues for biosynthesis. However, cholesterol also plays an important role in cell membranes. In addition, bile acids and salts are made from cholesterol in the liver, and many other tissues require cholesterol for steroid hormone synthesis (steroidogenesis).

Real World

When a physician orders a blood test for cholesterol, they are actually measuring levels of LDL and HDL in the blood. HDL is often considered "good" cholesterol because it picks up excess cholesterol from blood vessels for excretion.

HDL (HIGH-DENSITY LIPOPROTEIN)

HDL is synthesized in the liver and intestines and released as dense, protein-rich particles into the blood. HDL contains apolipoproteins used for cholesterol recovery—that is, the cleaning up of excess cholesterol from blood vessels for excretion. HDL also delivers some cholesterol to steroidogenic tissues and transfers necessary apolipoproteins to some of the other lipoproteins.

APOLIPOPROTEINS

Apolipoproteins, also referred to as **apoproteins**, form the protein component of the lipoproteins described above. Apolipoproteins are receptor molecules and are involved in signaling. While it is highly unlikely that specific functions of each apolipoprotein will be tested on the MCAT, they are briefly summarized below to illustrate their diverse purposes:

- **apoA-I**: activates LCAT, an enzyme that catalyzes cholesterol esterification
- **apoB-48**: mediates chylomicron secretion
- **apoB-100**: permits uptake of LDL by the liver
- **apoC-II**: activates lipoprotein lipase
- **apoE**: permits uptake of chylomicron remnants and VLDL by the liver

MCAT Concept Check 11.3:

Before you move on, assess your understanding of the material with these questions.

1. What is the primary method of transporting free fatty acids in the blood?

_____

_____

2. Order the lipoproteins from greatest percentage of protein to least percentage of protein. Circle the molecules that are primarily involved in triacylglycerol transport.

_____

3. Lipoproteins are synthesized primarily by which two organs?

_____

_____

11.4 Cholesterol Metabolism

Cholesterol is a ubiquitous component of all cells in the human body and plays a major role in the synthesis of cell membranes, steroid hormones, bile acids, and vitamin D.

SOURCES

Most cells derive their cholesterol from LDL or HDL, but some cholesterol may be synthesized *de novo*. *De novo* synthesis of cholesterol occurs in the liver and is driven by acetyl-CoA and ATP. The **citrate shuttle** carries mitochondrial acetyl-CoA into the cytoplasm, where synthesis occurs. NADPH (from the pentose phosphate pathway) supplies reducing equivalents. Synthesis of ***mevalonic acid*** in the smooth endoplasmic reticulum (SER) is the rate-limiting step in cholesterol biosynthesis and is catalyzed by ***3-hydroxy-3-methylglutaryl*** (**HMG**) ***CoA reductase***. Cholesterol synthesis is regulated in several ways. First, increased levels of cholesterol can inhibit further synthesis by a feedback inhibition mechanism. Next, insulin promotes cholesterol synthesis. Control over *de novo* cholesterol synthesis is also dependent on regulation of HMG-CoA reductase gene expression in the cell.

SPECIFIC ENZYMES

Specialized enzymes involved in the transport of cholesterol include LCAT and CETP. ***Lecithin–cholesterol acyltransferase*** (**LCAT**) is an enzyme found in the bloodstream that is activated by HDL apoproteins. LCAT adds a fatty acid to cholesterol, which produces soluble cholesteryl esters such as those in HDL. HDL cholesteryl esters can be distributed to other lipoproteins like IDL, which becomes LDL by acquiring these cholesteryl esters. The **cholesteryl ester transfer protein** (**CETP**) facilitates this transfer process.

MCAT Concept Check 11.4:

Before you move on, assess your understanding of the material with these questions.

1. Under what conditions is HMG-CoA reductase most active? In what cellular region does it exist?

_____

_____

_____

2. What proteins are specific to the formation and transmission of cholesteryl esters, and what are their functions?

_____

_____

11.5 Fatty Acids and Triacylglycerols ★★★

Fatty acids are long-chain carboxylic acids. The carboxyl carbon is carbon 1, and carbon 2 is referred to as the **α-carbon**. Fatty acids found within the body occur as salts that are capable of forming micelles or are esterified to other compounds, such as the membrane lipids discussed in Chapter 8 of *MCAT Biochemistry Review*.

NOMENCLATURE

When describing a fatty acid, the total number of carbons is given along with the number of double bonds, written as *carbons:double bonds*. Further description can be given by indicating the position and isomerism of the double bonds in an unsaturated fatty acid. **Saturated fatty acids** have no double bonds while **unsaturated fatty acids** have one or more double bonds. Humans can synthesize only a few of the unsaturated fatty acids; the rest come from essential fatty acids found in the diet that are transported in chylomicrons as triacylglycerols from the intestine. Two important essential fatty acids are **α-linolenic acid** and **linoleic acid**. These polyunsaturated fatty acids, as well as other acids formed from them, are important in maintaining cell membrane fluidity, which is critical for proper functioning of the cell. The **omega (ω) numbering system** is also used for unsaturated fatty acids. The ω designation describes the position of the last double bond relative to the end of the chain and identifies the major precursor fatty acid. For example, linoleic acid (18:2 *cis*,*cis*-9,12) is the precursor of the ω-6 family, which includes *arachidonic acid*. α-linolenic acid (18:3 all-*cis*-9,12,15) is the primary precursor of the ω-3 family. Double bonds in natural fatty acids are generally in the *cis* configuration.

Real World

Trans double bonds are uncommon in natural fatty acids; they predominate in fatty acids found in margarine and other foods that use partial hydrogenation of vegetable oils in their preparation. Compared with liquid oils, these partially hydrogenated fatty acids are solids at room temperature. These fatty acids contribute to arterial diseases and decreased membrane fluidity.

SYNTHESIS

Fatty acids used by the body for fuel are supplied primarily by the diet. In addition, excess carbohydrate and protein acquired from the diet can be converted to fatty acids and stored as energy reserves in the form of triacylglycerols. Lipid and carbohydrate synthesis are often called **nontemplate synthesis** processes because they do not rely directly on the coding of a nucleic acid, unlike protein and nucleic acid synthesis.

Fatty Acid Biosynthesis

Fatty acid biosynthesis, shown in Figure 11.5, occurs in the liver and its products are subsequently transported to adipose tissue for storage. Adipose tissue can also synthesize smaller quantities of fatty acids. Both of the major enzymes of fatty acid synthesis, *acetyl-CoA carboxylase* and *fatty acid synthase*, are also stimulated by insulin. ***Palmitic acid*** (***palmitate***) is the primary end product of fatty acid synthesis.

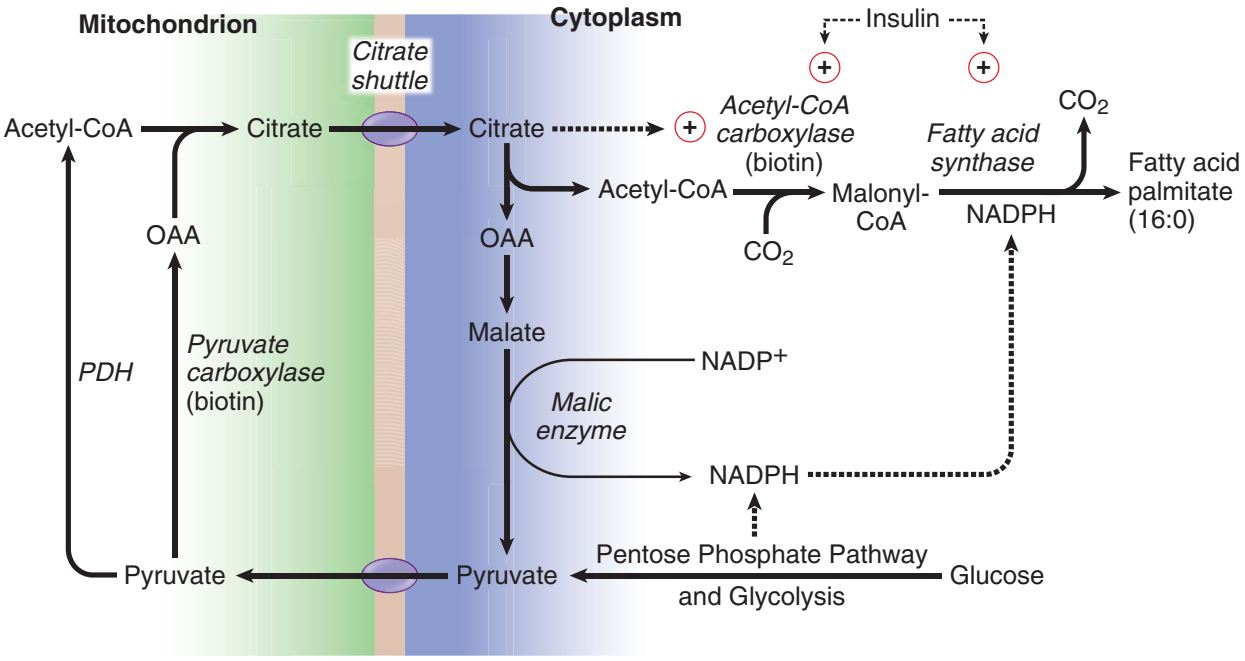

Figure 11.5. Fatty Acid Synthesis from Glucose

Acetyl-CoA Shuttling

Following a large meal, acetyl-CoA accumulates in the mitochondrial matrix and needs to be moved to the cytosol for fatty acid biosynthesis. Acetyl-CoA is the product of the ***pyruvate dehydrogenase complex***, and it couples with *oxaloacetate* to form *citrate* at the beginning of the citric acid cycle. Remember that *isocitrate dehydrogenase* is the rate-limiting enzyme of citric acid cycle; as the cell becomes energetically satisfied, it slows the citric acid cycle, which causes citrate accumulation. Citrate can then diffuse across the mitochondrial membrane. In the cytosol, ***citrate lyase*** splits citrate back into acetyl-CoA and oxaloacetate. The oxaloacetate can then return to the mitochondrion to continue moving acetyl-CoA.

Acetyl-CoA Carboxylase

Acetyl-CoA is activated in the cytoplasm for incorporation into fatty acids by acetyl-CoA carboxylase, the rate-limiting enzyme of fatty acid biosynthesis. **Acetyl-CoA carboxylase** requires biotin and ATP to function, and adds CO_2 to acetyl-CoA to form *malonyl-CoA*. The enzyme is activated by insulin and citrate. The CO_2 added to form malonyl-CoA is never actually incorporated into the fatty acid because it is removed by fatty acid synthase during addition of the activated acetyl group to the fatty acid.

Fatty Acid Synthase

Fatty acid synthase is more appropriately called ***palmitate synthase*** because palmitate is the only fatty acid that humans can synthesize *de novo*. Fatty acid synthase

is a large multienzyme complex found in the cytosol that is rapidly induced in the liver following a meal high in carbohydrates because of elevated insulin levels. The enzyme complex contains an acyl carrier protein (ACP) that requires *pantothenic acid* (vitamin B_5). NADPH is also required to reduce the acetyl groups added to the fatty acid. Eight acetyl-CoA groups are required to produce palmitate (16:0). Fatty acyl-CoA may be elongated and desaturated, to a limited extent, using enzymes associated with the smooth endoplasmic reticulum (SER). The steps involved in fatty acid biosynthesis are shown in Figure 11.6 and include attachment to an acyl carrier protein, bond formation between activated malonyl-CoA (malonyl-ACP) and the growing chain, reduction of a carbonyl group, dehydration, and reduction of a double bond. These reactions occur over and over again until the sixteen-carbon palmitate molecule is created. Many of these reactions are reversed in β-oxidation.

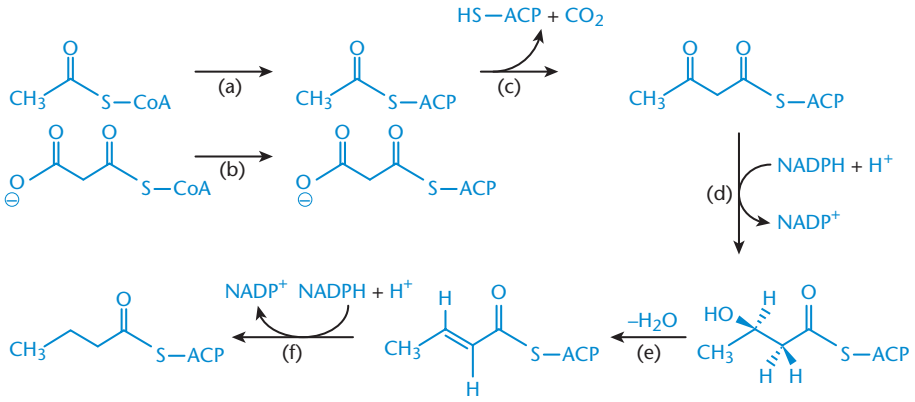

Figure 11.6. Action of Fatty Acid Synthase
Reactions include activation of the growing chain (a) and malonyl-CoA (b) with ACP, bond formation between these activated molecules (c), reduction of a carbonyl to a hydroxyl group (d), dehydration (e), and reduction to a saturated fatty acid (f).

Triacylglycerol (Triglyceride) Synthesis

Triacylglycerols, the storage form of fatty acids, are formed by attaching three fatty acids (as fatty acyl-CoA) to glycerol. Triacylglycerol formation from fatty acids and *glycerol 3-phosphate* occurs primarily in the liver and somewhat in adipose tissue, with a small contribution directly from the diet, as well. In the liver, triacylglycerols are packaged and sent to adipose tissue as very-low-density lipoproteins (VLDL), leaving only a small amount of stored triacylglycerols.

Key Concept

Fatty acid synthesis and β-oxidation are reverse processes. Both involve transport across the mitochondrial membrane, followed by a series of redox reactions, but always in the opposite direction of one another. Understanding one process will enable you to answer questions about both pathways.

OXIDATION

Most fatty acid catabolism proceeds via **β-oxidation** that occurs in the mitochondria; however, peroxisomal β-oxidation also occurs. Branched-chain fatty acids may also undergo α-oxidation, depending on the branch points, while ω-oxidation in the endoplasmic reticulum produces dicarboxylic acids. You should be aware that these processes exist; however, the mechanisms are beyond the scope of the MCAT.

We will take an in-depth look at β-oxidation, which will be much more heavily tested. Insulin indirectly inhibits β-oxidation while glucagon stimulates this process.

Activation

When fatty acids are metabolized, they first become activated by attachment to CoA, which is catalyzed by ***fatty-acyl-CoA synthetase***. The product is generically referred to as a fatty acyl-CoA or acyl-CoA. Specific examples would be acetyl-CoA containing a 2-carbon acyl group, or palmitoyl-CoA with a 16-carbon acyl group.

Fatty Acid Entry Into Mitochondria

Short-chain fatty acids (two to four carbons) and medium-chain fatty acids (six to twelve carbons) diffuse freely into mitochondria, where they are oxidized. In contrast, while long-chain fatty acids (14 to 20 carbons) are also oxidized in the mitochondria, they require transport via a carnitine shuttle, as shown in Figure 11.7.

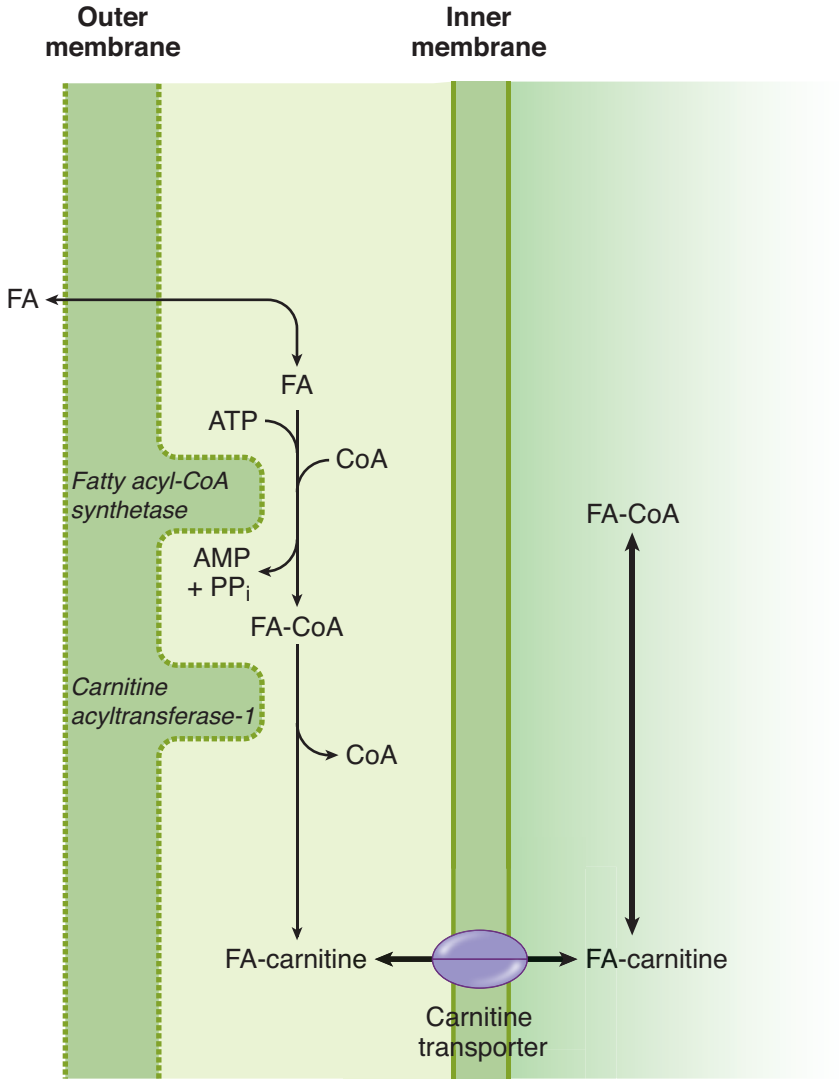

Figure 11.7. Fatty Acid Activation and Transport

Carnitine acyltransferase I is the rate-limiting enzyme of fatty acid oxidation. Very long chain fatty acids (over 20 carbons) are oxidized elsewhere in the cell.

β-Oxidation in Mitochondria

β-Oxidation reverses the process of fatty acid synthesis by oxidizing and releasing (rather than reducing and linking) molecules of acetyl-CoA. The pathway is a repetition of four steps; each four-step cycle releases one acetyl-CoA and reduces NAD^+ and FAD (producing NADH and $FADH_2$). The $FADH_2$ and NADH are oxidized in the electron transport chain, producing ATP. In muscle and adipose tissue, acetyl-CoA enters the citric acid cycle. In the liver, acetyl-CoA, which cannot be converted to glucose, stimulates gluconeogenesis by activating *pyruvate carboxylase*. In a fasting state, the liver produces more acetyl-CoA from β-oxidation than is used in the citric acid cycle. Much of the acetyl-CoA is used to synthesize ketone bodies (essentially two acetyl-CoA molecules linked together) that are released into the bloodstream and transported to other tissues.

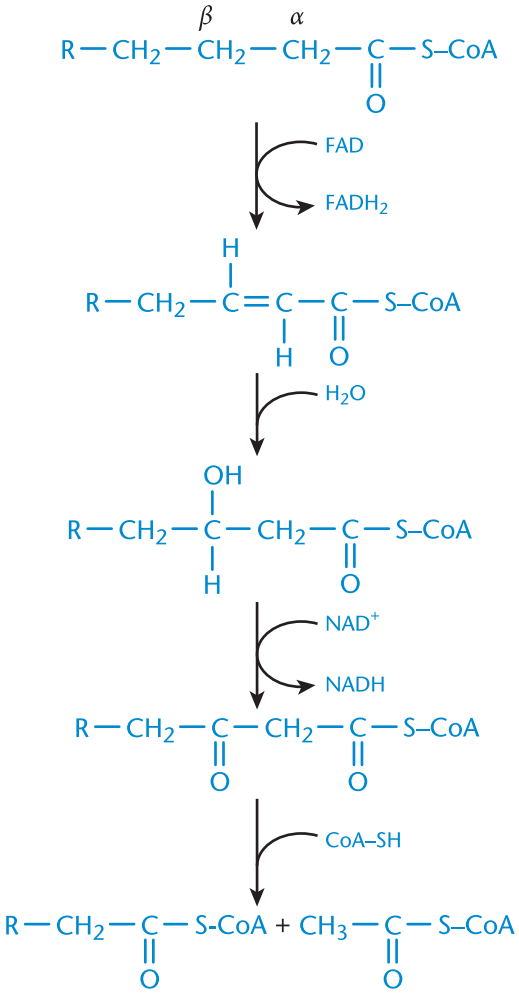

Figure 11.8. β-Oxidation

The four steps of β-oxidation, illustrated in Figure 11.8, are:

1. Oxidation of the fatty acid to form a double bond
2. Hydration of the double bond to form a hydroxyl group
3. Oxidation of the hydroxyl group to form a carbonyl (β-ketoacid)
4. Splitting of the β-ketoacid into a shorter acyl-CoA and acetyl-CoA

This process then continues until the chain has been shortened to two carbons, creating a final acetyl-CoA.

Fatty acids with an odd number of carbon atoms undergo β-oxidation in the same manner as even-numbered carbon fatty acids for the most part. The only difference is observed during the final cycle, where even-numbered fatty acids for the most part yield two acetyl-CoA molecules (from the four-carbon remaining fragment) and odd-numbered fatty acids yield one acetyl-CoA and one *propionyl-CoA* (from the five-carbon remaining fragment), as shown in Figure 11.9. Propionyl-CoA is converted to *methylmalonyl-CoA* by ***propionyl-CoA carboxylase***, which requires biotin (vitamin B_7). Methylmalonyl-CoA is then converted into *succinyl-CoA* by ***methylmalonyl-CoA mutase***, which requires cobalamin (vitamin B_{12}). Succinyl-CoA is a citric acid cycle intermediate and can also be converted to malate to enter the gluconeogenic pathway in the cytosol. Odd-carbon fatty acids thus represent an exception to the rule that fatty acids cannot be converted to glucose in humans.

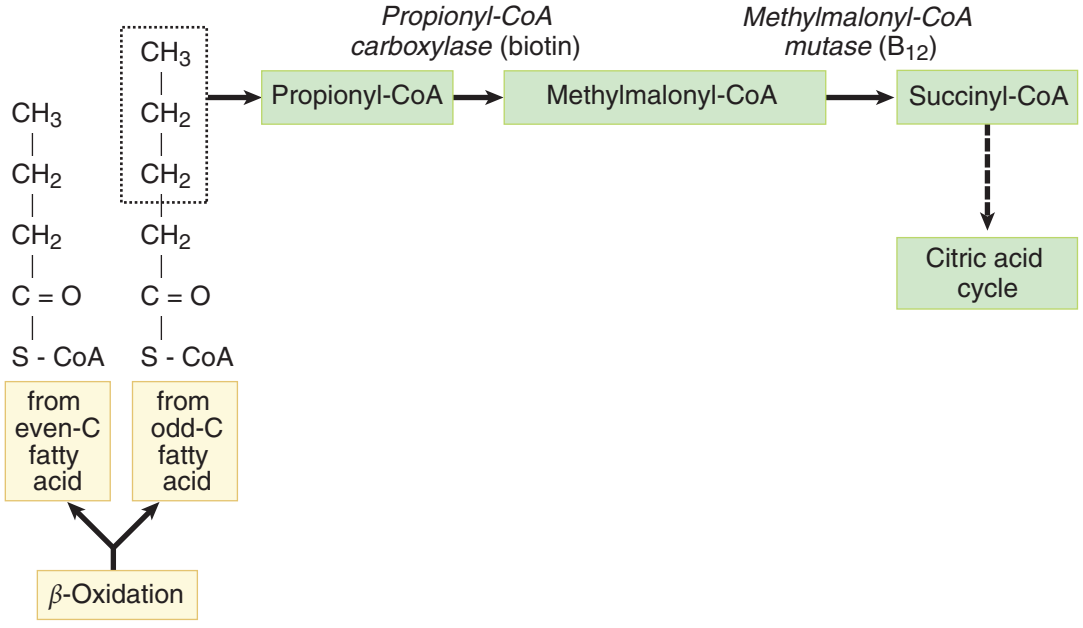

Figure 11.9. The Propionic Acid Pathway

Until now we've been discussing the oxidation of saturated fatty acids. In unsaturated fatty acids, two additional enzymes are necessary because double bonds can disturb the stereochemistry needed for oxidative enzymes to act on the fatty acid. To function, these enzymes can have at most one double bond in their active site; this bond must be located between carbons 2 and 3. ***Enoyl-CoA isomerase***, shown in Figure 11.10, rearranges *cis* double bonds at the 3,4 position to *trans* double bonds at the 2,3 position once enough acetyl-CoA has been liberated to isolate the double bond within the first three carbons. In monounsaturated fatty acids this single step permits β-oxidation to proceed.

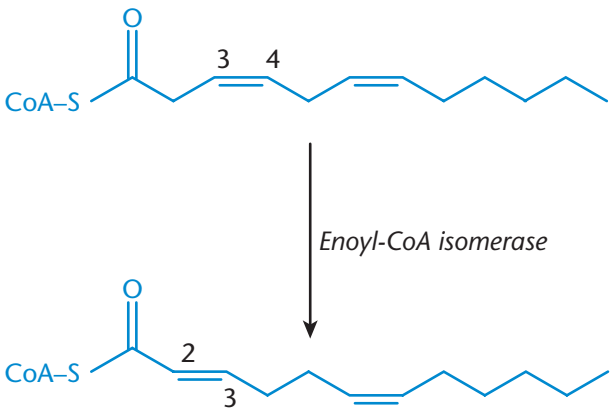

Figure 11.10. Reaction of Enoyl-CoA Isomerase

In polyunsaturated fatty acids, a further reduction is required using ***2,4-dienoyl-CoA reductase*** to convert two conjugated double bonds to just one double bond at the 3,4 position, where it will undergo the same rearrangement as monounsaturated fatty acids, as shown in Figure 11.11.

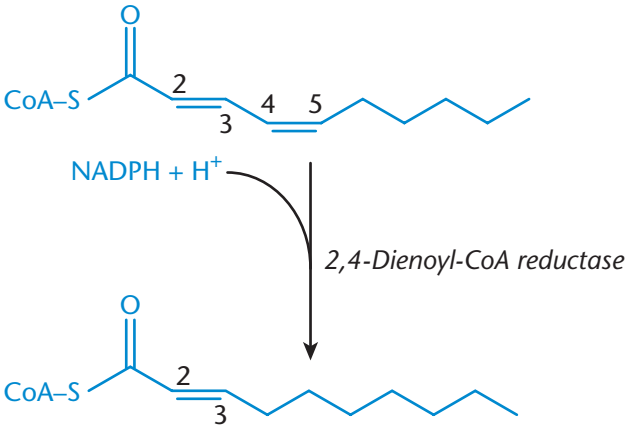

Figure 11.11. Reaction of 2,4-Dienoyl-CoA Reductase

MCAT Concept Check 11.5:

Before you move on, assess your understanding of the material with these questions.

1. Draw the following fatty acids: palmitic acid, 18:3 (all-*cis*-9,12,15), ω-6.

2. What are the five steps in the addition of acetyl-CoA to a growing fatty acid chain?

   1. _____
   2. _____
   3. _____
   4. _____
   5. _____

3. How does β-oxidation of unsaturated fatty acids differ from that of saturated fatty acids?

   _____

   _____

   _____

4. True or False: Fatty acids are synthesized in the cytoplasm and modified by enzymes in the smooth endoplasmic reticulum.

11.6 Ketone Bodies

In the fasting state, the liver converts excess acetyl-CoA from β-oxidation of fatty acids into the **ketone bodies** ***acetoacetate*** and ***3-hydroxybutyrate*** (***β-hydroxybutyrate***), which can be used for energy in various tissues. Cardiac and skeletal muscle, and the renal cortex, can metabolize acetoacetate and 3-hydroxybutyrate to acetyl-CoA. During fasting periods, muscle will metabolize ketones as rapidly as the liver releases them, preventing accumulation in the bloodstream. After a week of fasting, ketones reach a concentration in the blood that is high enough for the brain to begin metabolizing them. The processes of ketogenesis and ketolysis are shown in Figure 11.12.

Key Concept

Ketone bodies are essentially transportable forms of acetyl-CoA. They are produced by the liver and used by other tissues during prolonged starvation.

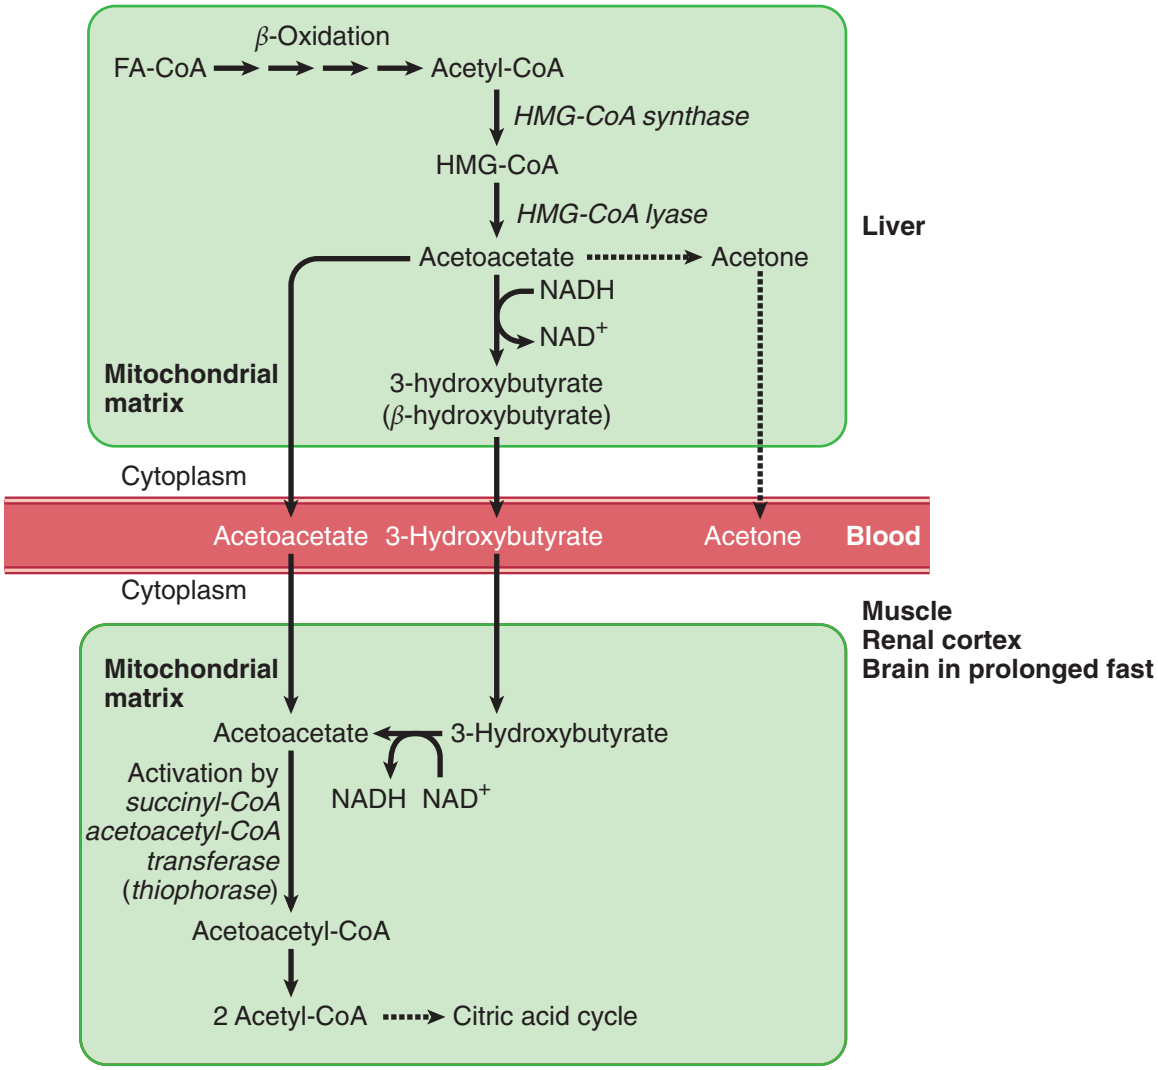

Figure 11.12. Ketogenesis and Ketolysis

KETOGENESIS

Ketogenesis occurs in the mitochondria of liver cells when excess acetyl-CoA accumulates in the fasting state. ***HMG-CoA synthase*** forms HMG-CoA, and ***HMG-CoA lyase*** breaks down HMG-CoA into acetoacetate, which can subsequently be reduced to 3-hydroxybutyrate. Acetone is a minor side product that is formed but will not be used as energy for tissues.

KETOLYSIS

Acetoacetate picked up from the blood is activated in the mitochondria by ***succinyl-CoA acetoacetyl-CoA transferase*** (commonly called ***thiophorase***), an enzyme

Real World

A significant increase in ketone levels in the blood can lead to ketoacidosis, a potentially dangerous medical condition. This occurs most often with fatty acid breakdown in type 1 (insulin-dependent) diabetes mellitus.

present only in tissues outside the liver. During this reaction, 3-hydroxybutyrate is oxidized to acetoacetate. The liver lacks this enzyme, so it cannot catabolize the ketone bodies that it produces.

Ketolysis in the Brain

During a prolonged fast (longer than one week), the brain begins to derive up to two-thirds of its energy from ketone bodies. In the brain, when ketones are metabolized to acetyl-CoA, pyruvate dehydrogenase is inhibited. Glycolysis and glucose uptake in the brain decreases. This important switch spares essential protein in the body, which otherwise would be catabolized to form glucose by gluconeogenesis in the liver, and allows the brain to indirectly metabolize fatty acids as ketone bodies.

MCAT Concept Check 11.6:

Before you move on, assess your understanding of the material with these questions.

1. Why are fatty acids used to create ketone bodies instead of creating glucose?

_____

_____

_____

2. What conditions and tissues favor ketogenesis? Ketolysis?
   - Ketogenesis:

     _____
   - Ketolysis:

     _____

11.7 Protein Catabolism ★★

Key Concept

Metabolism is directed toward conserving tissues to the greatest extent possible, especially the brain and heart. Digestion of protein compromises muscle—potentially that of the heart—so it is unlikely to occur under normal conditions.

Protein is very rarely used as an energy source because it is so important for other functions; routinely breaking down protein would result in serious illness. However, under conditions of extreme energy deprivation, proteins can be used for energy. In order to provide a reservoir of amino acids for protein building by the cell, proteins must be digested and absorbed.

Digestion of protein begins in the stomach with ***pepsin*** and continues with the pancreatic proteases ***trypsin***, ***chymotrypsin***, and ***carboxypeptidases A*** and ***B***, all of

which are secreted as zymogens. Protein digestion is completed by the small intestinal brush-border enzymes ***dipeptidase*** and ***aminopeptidase***. The main end products of protein digestion are amino acids, dipeptides, and tripeptides. Absorption of amino acids and small peptides through the luminal membrane is accomplished by secondary active transport linked to sodium. At the basal membrane, simple and facilitated diffusion transports amino acids into the bloodstream. Figure 11.13 illustrates the major transport mechanisms involved in moving amino acids across the luminal and basal membranes of intestinal cells.

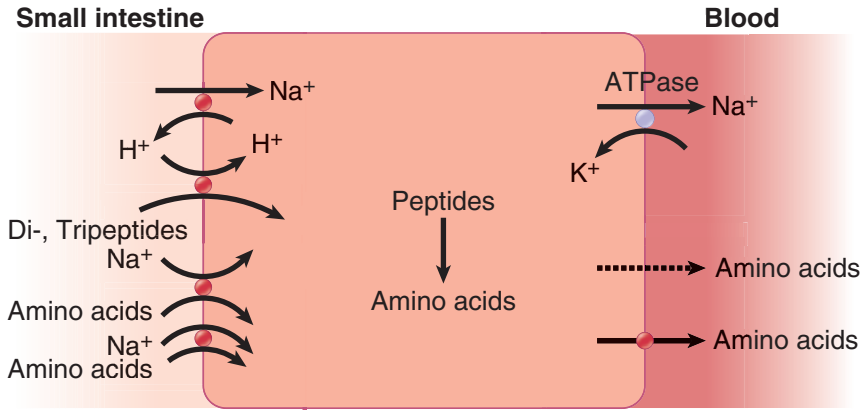

Figure 11.13. Absorption of Amino Acids and Peptides in the Intestine

Protein obtained from the diet or from the body (during prolonged fasting or starvation) may be used as an energy source. Body protein is catabolized primarily in muscle and liver. Amino acids released from proteins usually lose their amino group through **transamination** or **deamination**. The remaining carbon skeleton can be used for energy. Amino acids are classified by their ability to turn into specific metabolic intermediates: **glucogenic** amino acids (all but leucine and lysine) can be converted into glucose through gluconeogenesis; **ketogenic** amino acids (leucine and lysine, as well as isoleucine, phenylalanine, threonine, tryptophan, and tyrosine, which are also glucogenic as well) can be converted into acetyl-CoA and ketone bodies.

The amino groups removed by transamination or deamination constitute a potential toxin to the body in the form of ammonia, and must be excreted safely. The **urea cycle**, shown in Figure 11.14, occurs in the liver and is the body's primary way of removing excess nitrogen from the body. The MCAT is highly unlikely to test on the steps and intermediates of the urea cycle directly, but it is provided here as a point of reference.

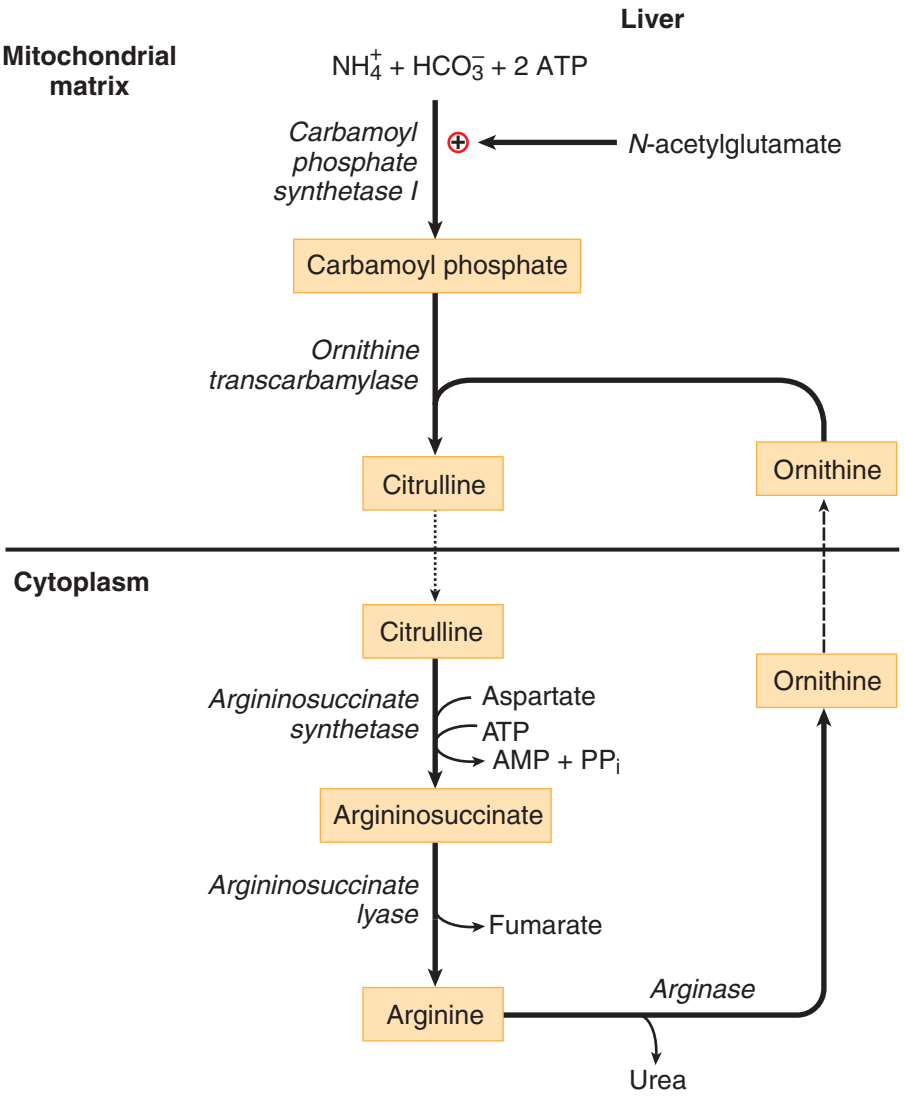

Figure 11.14. The Urea Cycle

The fate of the side chain from each amino acid depends on its chemistry. Basic amino acid side chains feed into the urea cycle, while the other side chains act like the carbon skeleton and produce energy through gluconeogenesis or ketone production.

MCAT Concept Check 11.7:

Before you move on, assess your understanding of the material with these questions.

1. True or False: Bodily proteins will commonly be broken down to provide acetyl-CoA for lipid synthesis.

2. Where does the bulk of protein digestion occur?

_____

3. During protein processing, what is the eventual fate of each of the following components: carbon skeleton, amino group, and side chains?
   - Carbon skeleton:

     _____
   - Amino group:

     _____
   - Side chains:

     _____

Conclusion

At this point, we have examined all of the vital metabolic processes of the cell. In this chapter, we reviewed dietary lipids and different ways that lipids are metabolized in the cell. We also covered lipid transport in blood and lymphatic fluid and the mobilization of lipids from adipocytes. In addition, we went over the structure, synthesis, and breakdown of fatty acids required to address the energy needs of the cell. The importance of ketone bodies and how they are utilized by the cell during periods of starvation were also reviewed. Finally, we went over digestion and metabolism of proteins and amino acids.

Metabolism of the different macromolecules does not occur in isolation, as you've already seen: the acetyl-CoA produced in fatty acid oxidation regulates the pyruvate dehydrogenase complex and pyruvate carboxylase to create a shift in carbohydrate metabolism from glycolysis and the citric acid cycle to gluconeogenesis. In the next chapter, we'll dive into how the different pathways fit together and will integrate the metabolic knowledge that you've compiled in Chapters 9, 10, and 11 of *MCAT Biochemistry Review*.

CONCEPT SUMMARY

Lipid Digestion and Absorption

- Mechanical digestion of lipids occurs primarily in the mouth and stomach.
- Chemical digestion of lipids occurs in the small intestine and is facilitated by **bile**, **pancreatic lipase**, **colipase**, and **cholesterol esterase**.
- Digested lipids may form **micelles** for absorption or be absorbed directly.
- Short-chain fatty acids are absorbed across the intestine into the blood.
- Long-chain fatty acids are absorbed as micelles and assembled into **chylomicrons** for release into the lymphatic system.

Lipid Mobilization

- Lipids are mobilized from adipocytes by **hormone-sensitive lipase**.
- Lipids are mobilized from lipoproteins by **lipoprotein lipase**.

Lipid Transport

- **Chylomicrons** are the transport mechanism for dietary triacylglycerol molecules and are transported via the lymphatic system.
- **VLDL** transports newly synthesized triacylglycerol molecules from the liver to peripheral tissues in the bloodstream.
- **IDL** is a **VLDL remnant** in transition between triacylglycerol and cholesterol transport; it picks up cholesteryl esters from HDL.
- **LDL** primarily transports cholesterol for use by tissues.
- **HDL** is involved in the reverse transport of cholesterol.
- **Apoproteins** control interactions between lipoproteins.

Cholesterol Metabolism

- Cholesterol may be obtained through dietary sources or through *de novo* synthesis in the liver.
- The key enzyme in cholesterol biosynthesis is **HMG-CoA reductase**.
- **LCAT** catalyzes the formation of cholesteryl esters for transport with HDL.
- **CETP** catalyzes the transition of IDL to LDL by transferring cholesteryl esters from HDL.

Fatty Acids and Triacylglycerols

- Fatty acids are carboxylic acids, typically with a single long chain, although they can be branched.
- **Saturated fatty acids** have no double bonds between carbons. **Unsaturated fatty acids** have one or more double bonds.

- Fatty acids are synthesized in the cytoplasm from acetyl-CoA transported out of the mitochondria.
  - Synthesis includes five steps: activation, bond formation, reduction, dehydration, and a second reduction.
  - These steps are repeated eight times to form **palmitic acid**, the only fatty acid that humans can synthesize.
- Fatty acid oxidation occurs in the mitochondria following transport by the carnitine shuttle.
  - **β-oxidation** uses cycles of oxidation, hydration, oxidation, and cleavage.
  - Branched and unsaturated fatty acids require special enzymes.
  - Unsaturated fatty acids use an **isomerase** and an additional **reductase** during cleavage.

Ketone Bodies

- Ketone bodies form (**ketogenesis**) during a prolonged starvation state due to excess acetyl-CoA in the liver.
- **Ketolysis** regenerates acetyl-CoA for use as an energy source in peripheral tissues.
- The brain can derive up to two-thirds of its energy from ketone bodies during prolonged starvation.

Protein Catabolism

- Protein digestion occurs primarily in the small intestine.
- Catabolism of cellular proteins occurs only under conditions of starvation.
- Carbon skeletons of amino acids are used for energy, either through gluconeogenesis or ketone body formation. Amino groups are fed into the **urea cycle** for excretion. The fate of a side chain depends on its chemistry.

ANSWERS TO CONCEPT CHECKS

11.1

1. Physical digestion is accomplished in the mouth and the stomach, reducing the particle size. Beginning in the small intestine, pancreatic lipase, colipase, cholesterol esterase, and bile assist in the chemical digestion of lipids. In the more distal portion of the small intestine, absorption occurs.
2. False. Small free fatty acids enter the circulation directly.
3. Micelles are collections of lipids with their hydrophobic ends oriented toward the center and their charged ends oriented toward the aqueous environment. Micelles collect lipids within their hydrophobic centers.

11.2

1. In the postabsorptive and prolonged fasting states, lipid mobilization is favored. A decrease in insulin levels, as well as an increase in epinephrine or cortisol, will increase lipid mobilization from adipocytes.
2. The ratio of free fatty acids to glycerol is 3:1. A triacylglycerol molecule is composed of glycerol and three fatty acids.

11.3

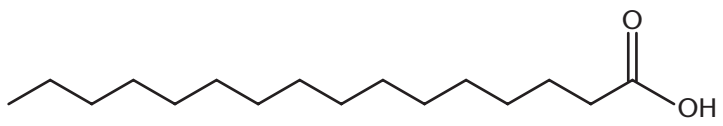
1. Free fatty acids remain in the blood, bonded to albumin and other carrier proteins. A much smaller amount will remain unbonded.
2. With respect to protein content, HDL > LDL > IDL > VLDL > chylomicrons. VLDL and chylomicrons are the primary triacylglycerol transporters. HDL and LDL are mostly involved in cholesterol transport.
3. Lipoproteins are synthesized primarily by the intestine and liver.

11.4

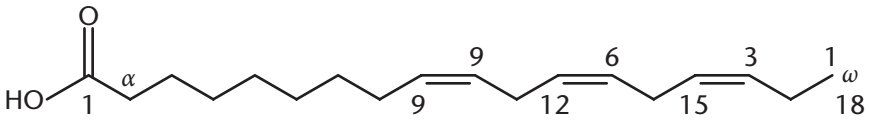
1. HMG-CoA reductase is most active in the absence of cholesterol and when stimulated by insulin. Cholesterol reduces the activity of HMG-CoA reductase, which is located in the smooth endoplasmic reticulum.
2. LCAT catalyzes the esterification of cholesterol to form cholesteryl esters. CETP promotes the transfer of cholesteryl esters from HDL to IDL, forming LDL.

11.5

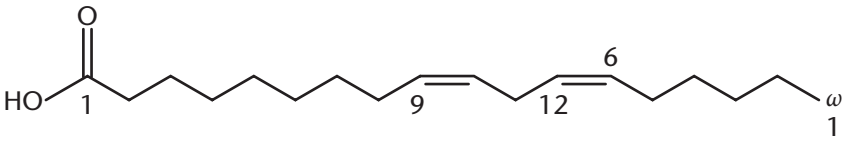
1. Palmitic acid (16:0):



α-linolenic acid (18:3 all-*cis*-9,12,15), an ω-3 fatty acid:



Linoleic acid (18:2 *cis*,*cis*-9,12), an ω-6 fatty acid:



Note: as long as the last double bond is in the same position relative to the end of the chain, many answers are possible for the ω-6 fatty acid.

2. The steps in the attachment of acetyl-CoA to a fatty acid chain are attachment to acyl carrier protein, bond formation between molecules, reduction of a carbonyl group, dehydration, and reduction of a double bond. These steps are shown in Figure 11.6.
3. There is an additional isomerase and an additional reductase for the β-oxidation of unsaturated fatty acids, which provide the stereochemistry necessary for further oxidation.
4. True.

11.6

1. Fatty acid degradation results in large amounts of acetyl-CoA, which cannot enter the gluconeogenic pathway to produce glucose. Only odd-numbered fatty acids can act as a source of carbon for gluconeogenesis; even then, only the final malonyl-CoA molecule can be used. Energy is packaged into ketone bodies for consumption by the brain and muscles.
2. Ketogenesis is favored by a prolonged fast and occurs in the liver. It is stimulated by increasing concentrations of acetyl-CoA. Ketolysis is also favored during a prolonged fast, but is stimulated by a low-energy state in muscle and brain tissues and does not occur in the liver.

11.7

1. False. Proteins are more valuable to the cell than lipids, thus they will not commonly be broken down for lipid synthesis.
2. The bulk of protein digestion occurs in the small intestine.
3. The carbon skeleton is transported to the liver for processing into glucose or ketone bodies. The amino group will feed into the urea cycle for excretion. Side chains are processed depending on their composition. Basic side chains will be processed like amino groups, while other functional groups will be treated like the carbon skeleton.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following enzymes is NOT used for lipid digestion in the digestive tract?

A. Pancreatic lipase
B. Hormone-sensitive lipase
C. Cholesterol esterase
D. Colipase

2. What is the fate of long-chain fatty acids that are contained within micelles?

A. Transport into chylomicrons released into the lymphatic system
B. Transport into chylomicrons released into the circulatory system
C. Direct diffusion across the intestine into the lymphatic system
D. Direct diffusion across the intestine into the circulatory system

3. During fatty acid mobilization, which of the following occur(s)?

I. HSL is activated.
II. Free fatty acids are released.
III. Gluconeogenesis proceeds in adipocytes.

A. I only
B. III only
C. I and II only
D. II and III only

4. How do chylomicrons and VLDL differ?

A. Chylomicrons contain apoproteins, VLDL do not.
B. Chylomicrons are synthesized in the intestine, VLDL are synthesized in the liver.
C. Chylomicrons transport triacylglycerol, VLDL transport cholesterol.
D. VLDL are another term for chylomicron remnants; they differ in age.

5. Which of the following could result from an absence of apolipoproteins?

I. An inability to secrete lipid transport lipoproteins.
II. An inability to endocytose lipoproteins.
III. A decreased ability to remove excess cholesterol from blood vessels.

A. I only
B. III only
C. I and II only
D. I, II, and III

6. Statin drugs inhibit HMG-CoA reductase. As such, they are likely prescribed for:

A. hypercholesterolemia (high cholesterol).
B. hypertriglyceridemia (high triacylglycerol).
C. hypocholesterolemia (low cholesterol).
D. visceral adiposity (obesity).

7. What is the function of LCAT?

A. LCAT catalyzes the production of cholesteryl esters.
B. LCAT catalyzes the production of cholesterol.
C. LCAT catalyzes the transfer of cholesteryl esters.
D. LCAT catalyzes the transfer of cholesterol.

8. Which fatty acid can be synthesized by humans?

A. 12:0
B. 16:0
C. 16:1
D. 18:3

9. Which of the following best characterizes the process of fatty acid synthesis?

A. Two reductions followed by a dehydration and bond formation.
B. Reduction followed by activation, bond formation, dehydration, and reduction.
C. Activation followed by bond formation, reduction, dehydration, and reduction.
D. Activation followed by bond formation, oxidation, dehydration, and reduction.

10. Where does β-oxidation of fatty acids occur within the cell?

A. Cytosol
B. Mitochondria
C. Smooth endoplasmic reticulum
D. Plasma membrane

11. The majority of triacylglycerols stored in adipocytes originate from:

A. synthesis in the adipocyte.
B. dietary intake.
C. ketone bodies.
D. synthesis in the liver.

12. 2,4-dienoyl-CoA reductase is used in the oxidation of:

A. saturated fatty acids.
B. monounsaturated fatty acids.
C. polyunsaturated fatty acids.
D. cholesterol.

13. Which of the following is true regarding ketolysis?

A. Ketolysis occurs only in the brain.
B. Ketolysis occurs in the liver.
C. Ketolysis generates acetyl-CoA.
D. Ketolysis increases glucose metabolism.

14. Which of the following amino acids will provide the most energy when degraded?

A. Glycine
B. Alanine
C. Valine
D. Isoleucine

15. Which of the following is LEAST likely to result from protein degradation and processing by the liver?

A. Fatty acids
B. Glucose
C. Acetoacetate
D. 3-Hydroxybutyrate

Explanations to Discrete Practice Questions

1. B

Hormone-sensitive lipase responds to low insulin levels as well as cortisol and epinephrine to mobilize fatty acids from adipocytes. It is not involved in digestion, but rather mobilization of fatty acids.

2. A

Short-chain fatty acids are soluble in the intestinal lumen, and thus do not interact with micelles as longer fatty acid chains do. The long-chain fatty acids are taken up by the intestinal cells and packaged into triacylglycerols for transport as chylomicrons. Chylomicrons exit the intestine through lacteals that feed into the lymphatic system, which joins with the bloodstream in the base of the neck through the thoracic duct.

3. C

During fatty acid mobilization, there is a breakdown of triacylglycerols in adipocytes by hormone-sensitive lipase (HSL). This breakdown results in the release of three fatty acids and a glycerol molecule. The glycerol may be used by the liver for gluconeogenesis, but adipocytes do not have the ability to carry out gluconeogenesis.

4. B

Chylomicrons and VLDL are very similar. Both contain apolipoproteins and primarily transport triacylglycerols, eliminating **choices (A)** and **(C)**. The only major difference between them is the tissue of origin. Chylomicrons transport dietary triacylglycerol and originate in the small intestine, while VLDL transport newly synthesized triacylglycerols and originate in the liver.

5. D

While the transport and lipid binding functions of most lipoproteins are independent of the apolipoprotein component, the interaction of these lipoproteins with the environment is controlled almost exclusively by apolipoproteins. Lipoproteins cannot exit or enter cells without apolipoproteins, and are unable to transfer lipids without specialized apolipoproteins or cholesterol-specific enzymes.

6. A

Statins are drugs that are prescribed to treat high cholesterol and act as competitive inhibitors of HMG-CoA reductase. HMG-CoA reductase is the rate-limiting enzyme of *de novo* cholesterol synthesis; inhibition of this enzyme lowers production of cholesterol, thus lowering overall levels of cholesterol.

7. A

LCAT adds a fatty acid to cholesterol, producing cholesteryl esters, which dissolve in the core of HDL, allowing HDL to transport cholesterol from the periphery to the liver.

8. B

Humans can only synthesize one fatty acid, palmitic acid. Palmitic acid is fully saturated and therefore does not contain any double bonds. Palmitic acid has 16 carbons, and is synthesized from eight molecules of acetyl-CoA. In shorthand notation, palmitic acid is written as 16:0 (16 carbons, no double bonds).

9. C

The steps in fatty acid synthesis are activation (attachment to acyl carrier protein), bond formation (between malonyl-CoA and the growing fatty acid chain), reduction (of a carboxyl group), dehydration, and reduction (of a double bond).

10. B

β-Oxidation occurs within the mitochondria, along with the electron transport chain. In contrast, fatty acid synthesis occurs in the cytosol, **choice (A)**. Fatty acyl carriers like the carnitine shuttle allow entry into the mitochondrion for breakdown.

11. D

The liver is the major metabolic organ in the body and is responsible for much of the synthesis and interconversion of fuel sources. Most of the triacylglycerols that are synthesized in the liver are transported as VLDL to adipose tissue for storage. Both the adipocytes, **choice (A)** and dietary intake, **choice (B)**, constitute a minor source of triacylglycerols.

12. C

In order for the enzymes of fatty acid oxidation to operate, there can be, at most, one double bond in the area of enzyme activity, and it must be oriented between carbons 2 and 3. In order to accomplish this in monounsaturated fatty acids, an isomerase is employed. When there are multiple double bonds that fall within the enzymatic binding site, both an isomerase and 2,4-dienoyl-CoA reductase are required for the oxidative enzymes to act on the fatty acid. For this question, simply recognizing that *dienoyl* refers to having multiple double bonds is sufficient to arrive at the answer.

13. C

Ketolysis is the breakdown of ketone bodies to acetyl-CoA for energy. This process occurs in the brain and muscle tissues, but cannot occur in the liver, which lacks an enzyme necessary for ketone body breakdown. Ketolysis is not associated with an increase in glucose metabolism because it most often occurs under conditions of starvation.

14. D

The energy contribution of an amino acid depends on its ability to be turned into glucose through gluconeogenesis (glucogenic amino acids), ketone bodies (ketogenic amino acids), or both. All of the amino acids listed in the answer choices are glucogenic; isoleucine is also ketogenic. The energy acquired from an amino acid will also depend on the number of carbons it can donate to these energy-creating processes, which depends on the size of its side chain. Isoleucine has the largest side chain of the answer choices, and will thus contribute the most energy per molecule.

15. A

The degradation of protein and processing by the liver implies a prolonged starvation state; protein will not be used for energy unless absolutely necessary. Thus, gluconeogenesis is the most likely process. When gluconeogenesis is not possible, easily metabolized molecules, such as ketone bodies, are synthesized. Fatty acid production occurs when energy is being stored; proteins would not be broken down to store energy in fatty acids.

Introduction

You got up this morning with a really ambitious plan: study for the MCAT! The day started with a big breakfast, and then you dove into *MCAT Biochemistry Review*. A few chapters in you noticed your stomach growling, but you were having so much fun that you ignored it. A little while later, your body realized it wasn't getting any more food for a while, but it still needed energy. Where does it come from?

The human body is an incredible system. When we skip lunch on a study day, we produce hormones that help raise the level of certain energy molecules in the bloodstream, mainly glucose. This is a good thing because the brain relies solely on glucose for most of its metabolism, and we always want to be thinking at our peak. Glucose in the blood comes from either our diet, such as when we eat a big breakfast, or from our fuel stores, through the processes of gluconeogenesis and glycogenolysis. These processes, just like the formation and consumption of ATP, are highly regulated.

In this chapter, we'll highlight the basic principles of bioenergetics, including thermodynamics: the sources of energy and the reactions that play a key role in moving that energy

around. Then we'll examine the different energy states of the body before taking a look at the intimate relationship of hormones with metabolism. We'll spend some time examining the regulation of metabolism, regulatory enzymes for some common pathways, and how specific tissues preferentially metabolize particular macronutrients. By the end of this chapter, you'll be able to tell where and how your food is being used, and you probably won't choose to skip lunch again—no matter how much fun you're having!

12.1 Thermodynamics and Bioenergetics

If we take a look back at what we've learned about thermodynamics in Chapter 3 of *MCAT Physics and Math Review* and Chapter 7 of *MCAT General Chemistry Review*, it becomes evident that we already know quite a bit. However, most of the data that we've seen so far has been obtained under standard-state conditions (25°C, 1 atm pressure, and 1 *M* concentrations). These assumptions work in a chemistry lab, but must be adjusted for application in the human body.

MCAT Expertise

The energy of chemical reactions is described as part of general chemistry, while work is generally associated with physics. Be aware that on Test Day, you will see crossover that allows you to draw on knowledge of the other subjects and to use that background information to your advantage.

BIOLOGICAL SYSTEMS

Biological systems are often considered **open systems** because they can exchange both energy and matter with the environment. Energy is exchanged in the form of mechanical work when something is moved over a distance, or as heat energy. Matter is exchanged through food consumption and elimination, as well as respiration. Most biochemical studies are performed on the cellular or subcellular level rather than in an entire organism. These systems can be considered **closed** because there is no exchange of matter with the environment. In such a system, we can make useful simplifications about the internal energy, U. **Internal energy** is the sum of all of the different interactions between and within atoms in a system; vibration, rotation, linear motion, and stored chemical energies all contribute.

Because the system is closed, the change in internal energy can come only in the form of work or heat. This can be represented mathematically through the First Law of Thermodynamics, $\Delta U = Q - W$. Work in thermodynamics refers to changes in pressure and volume. These are constant in most living systems, so the only quantity of interest in determining internal energy is heat.

ENTHALPY, ENTROPY, AND FREE ENERGY

Bioenergetics is used to describe energy states in biological systems. Changes in **free energy** (ΔG) provide information about chemical reactions and can predict whether a chemical reaction is favorable and will occur. In biological systems, ATP plays a crucial role in transferring energy from energy-releasing catabolic processes to energy-requiring anabolic processes.

Whether a chemical reaction proceeds is determined by the degree to which enthalpy and entropy change during a chemical reaction. **Enthalpy** measures the overall change in heat of a system during a reaction. At constant pressure and volume, enthalpy (ΔH) and thermodynamic heat exchange (Q) are equal. Changes in **entropy** (ΔS) measure the degree of disorder or energy dispersion in a system. While the MCAT will not test on the level of statistical thermodynamics, this conceptual understanding of entropy (ΔS) will be helpful. Entropy carries the units $\frac{\text{J}}{\text{K}}$.

When combined together mathematically, along with temperature (T), these quantities can be related through the Gibbs free energy equation:

$$\Delta G = \Delta H - T\Delta S$$

Equation 12.1

which predicts the direction in which a chemical reaction proceeds spontaneously. Spontaneous reactions proceed in the forward direction, exhibit a net loss of free energy, and therefore have a negative ΔG. In contrast, nonspontaneous reactions, which would be spontaneous in the reverse direction, exhibit a net gain of energy and have a positive ΔG. Free energy approaches zero as the reaction proceeds to equilibrium and there is no net change in concentration of reactants or products.

Bridge

Enthalpy, entropy, and free energy are discussed more thoroughly in Chapter 7 of *MCAT General Chemistry Review*.

PHYSIOLOGICAL CONDITIONS

The change in free energy (ΔG) that we have been discussing up to this point predicts changes occurring at any concentration of products and reactants and at any temperature. In contrast, standard free energy (ΔG°) is the energy change that occurs at standard concentrations of 1 M, pressure of 1 atm, and temperature of 25°C. These can be related by the equation:

$$\Delta G = \Delta G^\circ + \text{R}T \ln (Q)$$

Equation 12.2

where R is the universal gas constant, T is the temperature, and Q is the reaction quotient. Biochemical analysis works well under all standard conditions except one: pH. A 1 M concentration of protons would correspond to a pH of 0, which is far too acidic for most biochemical reactions. Therefore, in the **modified standard state**, $[\text{H}^+] = 10^{-7}$ M, and the pH is 7. With this additional condition, ΔG° is given the special symbol $\Delta G^{\circ\prime}$, indicating that it is standardized to the neutral buffers used in biochemistry. Note that if the concentrations of other reactants and products differ from 1 M, these must still be adjusted for in the equation above.

The shift in ΔG as a result of changing concentration is not universally toward or away from spontaneity. There is a general trend that reactions with more products than reactants have a more negative ΔG, while reactions with more reactants than products have a more positive ΔG. While this trend is useful for making quick assessments, always double check with numbers on Test Day.

MCAT Concept Check 12.1:
Before you move on, assess your understanding of the material with these questions.

1. What conditions does $\Delta G^{\circ\prime}$ adjust for that are not considered with ΔG°?

_____

2. Why can heat be used as a measure internal energy in living systems?

_____

_____

3. Complete the following table relating the change in entropy and enthalpy of a reaction with whether the reaction is spontaneous.

	$+\Delta H$	$-\Delta H$
$+\Delta S$		
$-\Delta S$		

12.2 The Role of ATP

The human body can make use of different energy sources with roughly the same efficiency, but all nutrient molecules are not created equally. For example, fats are much more energy-rich than carbohydrates, proteins, or ketones. Complete combustion of fat results in 9 $\frac{\text{kcal}}{\text{g}}$ of energy, compared with only 4 $\frac{\text{kcal}}{\text{g}}$ derived from carbohydrates, proteins, or ketones. Because fats are so much more energy-dense than other biomolecules, they are preferred for long-term energy storage. Think of the difference between fats and carbohydrates like the difference between a 16 GB and an 8 GB storage drive. The storage drive with a greater capacity occupies the same amount of physical space, but holds twice as much data. While different energy sources provide greater or lesser caloric values, the end goal is to have energy in a readily available form. For the cell, this is **adenosine triphosphate** (**ATP**), shown in Figure 12.1.

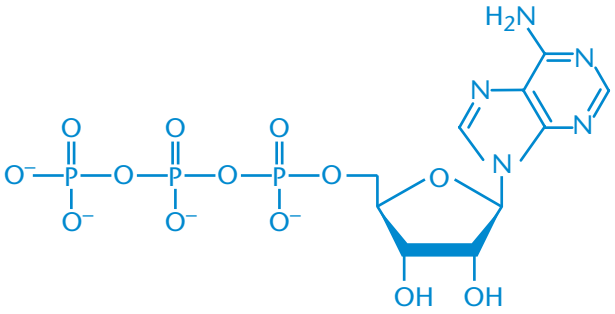

Figure 12.1. Adenosine Triphosphate (ATP)

ATP AS AN ENERGY CARRIER

ATP is the major energy currency in the body. It is a mid-level energy carrier, as seen in Table 12.1, and is formed from **substrate-level phosphorylation** as well as **oxidative phosphorylation**. Why do we want ATP to be a mid-level carrier and not a higher-level one? Think about your wallet. If you never had the ability to get change back after a purchase, what type of bill would you want in abundance? One dollar bills! Similarly, ATP cannot get back the "leftover" free energy after a reaction, so it's best to use a carrier with a smaller free energy. ATP provides about $30\,\frac{\text{kJ}}{\text{mol}}$ of energy under physiological conditions. If a reaction only requires $10\,\frac{\text{kJ}}{\text{mol}}$ to overcome a positive ΔG value, then $20\,\frac{\text{kJ}}{\text{mol}}$ have been wasted. The waste would be even higher with a higher-energy compound like creatine phosphate.

Compound	$\Delta G^{\circ\prime}\left(\frac{\text{kJ}}{\text{mol}}\right)$	Function
cAMP	−50.4	Second messenger
Creatine phosphate	−43.3	Direct phosphorylation in muscle
ATP	−30.5	Energy turnover in all cell types
Glucose 6-phosphate	−13.9	Intermediate of glycolysis and gluconeogenesis
AMP	−9.2	ATP synthesis

Table 12.1. Free Energy of Hydrolysis for Key Metabolic Phosphate Compounds

Remember that most of the ATP in a cell is produced by mitochondrial *ATP synthase*, as described in Chapter 10 of *MCAT Biochemistry Review*, but some ATP is produced during glycolysis and (indirectly from GTP) in the citric acid cycle. ATP consists of an adenosine molecule attached to three phosphate groups, and is generated from ADP and P_i with energy input from an exergonic reaction or electrochemical gradient. ATP is consumed either through hydrolysis or the transfer of a phosphate group to another molecule. If one phosphate group is removed, **adenosine diphosphate** (**ADP**) is produced; if two

phosphate groups are removed, **adenosine monophosphate** (**AMP**) is the result. In a single day, an average-sized person uses about 90 percent of her weight in ATP but only has about 50 grams of ATP available at any given time. Continuous recycling of ATP, ADP, and P_i more than 1000 times per day accounts for this discrepancy.

What makes ATP such a good energy carrier is its high-energy phosphate bonds. The negative charges on the phosphate groups experience repulsive forces with one another, and the ADP and P_i molecules that form after hydrolysis are stabilized by resonance. While ATP doesn't rapidly break down on its own in the cell, it is much more stable after hydrolysis. This accounts for the very negative value of ΔG. Under standard conditions ΔG° is about $-55\frac{kJ}{mol}$. At pH 7 and with excess magnesium, the standard free energy change is still $-30.5\frac{kJ}{mol}$. ADP, which also displays charge repulsion and resonance stabilization after hydrolysis, has similar ΔG values, but AMP has a much smaller ΔG° near $-9.2\frac{kJ}{mol}$.

HYDROLYSIS AND COUPLING

ATP hydrolysis is most likely to be encountered in the context of **coupled reactions**. Many coupled reactions use ATP as an energy source. For example, the movement of sodium and potassium against their electrochemical gradients requires energy, which is harnessed from the hydrolysis of ATP.

Key Concept

ATP is used to fuel energetically unfavorable reactions or to activate or inactivate other molecules.

ATP cleavage is the transfer of a high-energy phosphate group from ATP to another molecule. Generally, this activates or inactivates the target molecule. With these **phosphoryl group transfers**, the overall free energy of the reaction will be determined by taking the sum of the free energies of the individual reactions.

PHOSPHORYL GROUP TRANSFERS

Bridge

Hess's law, discussed in Chapter 7 of *MCAT General Chemistry Review*, applies for all of the state functions, including pressure, density, temperature, volume, enthalpy, internal energy, free energy, and entropy.

ATP can provide a phosphate group as a reactant. For example, in the phosphorylation of glucose in the early stages of glycolysis, ATP donates a phosphate group to glucose to form glucose 6-phosphate. The information in Table 12.1 indicates the free energy of hydrolysis, which can be conceptualized as the transfer of the phosphate group to water. To determine the free energy of phosphoryl group transfer to another biological molecule, one could use Hess's law and calculate the difference in free energy between the reactants and products:

$$\text{Creatine phosphate} + H_2O \rightarrow \text{Creatine} + P_i \qquad \Delta G^{\circ\prime} = -43.3\frac{kJ}{mol}$$

$$\text{(reverse reaction from Table 12.1)} \qquad ADP + P_i \rightarrow ATP + H_2O \qquad \Delta G^{\circ\prime} = 30.5\frac{kJ}{mol}$$

$$\text{Creatine phosphate} + ADP \rightarrow \text{Creatine} + ATP \qquad \Delta G^{\circ\prime} = -12.8\frac{kJ}{mol}$$

MCAT Concept Check 12.2:
Before you move on, assess your understanding of the material with these questions.

1. How does coupling with ATP hydrolysis alter the energetics of a reaction?

_____

_____

2. Explain why ATP is an inefficient molecule for long-term energy storage.

_____

_____

_____

3. Using Table 12.1, calculate the free energy change for the synthesis of ATP from cAMP and inorganic phosphate. Note: cAMP is hydrolyzed to AMP, and the free energy of hydrolysis for ATP and ADP is approximately equal.

_____

_____

_____

_____

12.3 Biological Oxidation and Reduction

Many key enzymes in ATP synthesis and other biochemical pathways have oxidoreductase activity.

HALF-REACTIONS

Just as you practiced with general chemistry, an important skill in biochemistry is to be able to divide oxidation–reduction reactions into their **half-reaction** components to determine the number of electrons being transferred. For example, in lactic acid fermentation, pyruvate and NADH are converted to lactate and NAD^+ by *lactate dehydrogenase*. This reaction can be broken down into half-reactions as follows:

$$C_3H_4O_3 + NADH + H^+ \rightarrow C_3H_6O_3 + NAD^+ \quad \text{Overall reaction}$$

$$C_3H_4O_3 + 2\,H^+ + 2\,e^- \rightarrow C_3H_6O_3 \quad \text{Reduction}$$

$$NADH \rightarrow NAD^+ + H^+ + 2\,e^- \quad \text{Oxidation}$$

Bridge

Oxidation–reduction reactions, discussed in Chapter 11 of *MCAT General Chemistry Review* and Chapter 4 of *MCAT Organic Chemistry Review*, are a staple of general chemistry and are characteristic of oxidoreductase enzymes. Take a moment to identify the oxidizing and reducing agents in the reaction catalyzed by lactate dehydrogenase.

Real World

Deficiency of riboflavin, a key component of flavoproteins, leads to a lack of growth, failure to thrive, and eventual death in experimental models. In humans, riboflavin deficiency is very rare, but may occur in severely malnourished individuals.

Remember that spontaneous oxidation–reduction reactions have a negative value of ΔG and a positive value of E (electromotive force).

ELECTRON CARRIERS

In the cytoplasm, there are several molecules that act as **high-energy electron carriers**. These are all soluble and include NADH, NADPH, $FADH_2$, ubiquinone, cytochromes, and glutathione. Some of these electron carriers are used by the mitochondrial electron transport chain, which leads to the oxidative phosphorylation of ADP to ATP. As electrons are passed down the electron transport chain, they give up their free energy to form the proton-motive force across the inner mitochondrial membrane. In addition to soluble electron carriers, there are membrane-bound electron carriers embedded within the inner mitochondrial membrane. One such carrier is flavin mononucleotide (FMN), which is bonded to complex I of the electron transport chain and can also act as a soluble electron carrier. In general, proteins with prosthetic groups containing iron–sulfur clusters are particularly well suited for the transport of electrons.

Flavoproteins

Flavoproteins contain a modified vitamin B_2, or ***riboflavin***. They are nucleic acid derivatives, generally either ***flavin adenine dinucleotide*** (**FAD**) or ***flavin mononucleotide*** (**FMN**). Flavoproteins are most notable for their presence in the mitochondria and chloroplasts as electron carriers. Flavoproteins are also involved in the modification of other B vitamins to active forms. Finally, flavoproteins function as coenzymes for enzymes in the oxidation of fatty acids, the decarboxylation of pyruvate, and the reduction of glutathione.

MCAT Concept Check 12.3:

Before you move on, assess your understanding of the material with these questions.

1. What is an advantage of analyzing the half-reactions in biological oxidation and reduction reactions?

_____

_____

2. Name three soluble electron carriers and their relevant metabolic pathways in the cell.

Electron Carrier	Metabolic Pathway(s)

12.4 Metabolic States

One of the key differences between general chemistry and biochemistry is whether or not equilibrium is seen as a desirable state. Biochemists emphatically believe that it is not! Equilibrium is a fixed state, which prevents us from storing any energy for later use or creating an excitable environment. Instead, biochemists seek a state of homeostasis. **Homeostasis** is a physiological tendency toward a relatively stable state that is maintained and adjusted, often with the expenditure of energy. Most compounds in the body are actually maintained at a homeostatic level that is different from equilibrium, which allows us to store potential energy; for example, keeping sodium concentrations much higher outside a neuron than inside it creates a gradient that stores energy. In this state, reactions can proceed such that equilibrium is put off for a long time (someone born today can delay equilibrium for about 80 years).

The pathways that are operational in fuel metabolism depend on the nutritional status of the organism. Shifts between storage and mobilization of a particular fuel, as well as shifts among the types of fuel being used, are very pronounced when going from the well-fed state to an overnight fast, and finally to a prolonged state of starvation. We'll take a look at how fuel metabolism is regulated in each state. Remember that in addition to the "big-picture view" discussed here, the specific regulatory steps of each pathway are discussed in the previous chapters of *MCAT Biochemistry Review*: Chapter 9 (glycolysis, glycogenesis, glycogenolysis, gluconeogenesis, and the pentose phosphate pathway), Chapter 10 (the citric acid cycle, electron transport chain, and oxidative phosphorylation), and Chapter 11 (fatty acid and cholesterol synthesis, β-oxidation, ketogenesis and ketolysis, and amino acid metabolism).

POSTPRANDIAL (ABSORPTIVE) STATE

The **postprandial state**, also called the **absorptive** or **well-fed state**, occurs shortly after eating. This state is marked by greater **anabolism** (synthesis of biomolecules) and fuel storage than **catabolism** (breakdown of biomolecules for energy). Nutrients flood in from the gut and make their way via the hepatic portal vein to the liver, where they can be stored or distributed to other tissues of the body. The postprandial state generally lasts three to five hours after eating a meal.

Just after eating, blood glucose levels rise and stimulate the release of insulin. The three major target tissues for insulin are the liver, muscle, and adipose tissue, as shown in Figure 12.2. Insulin promotes glycogen synthesis in liver and muscle. After the glycogen stores are filled, the liver converts excess glucose to fatty acids and triacylglycerols. Insulin promotes triacylglycerol synthesis in adipose tissue and protein synthesis in muscle, as well as glucose entry into both tissues. After a meal, most of the energy needs of the liver are met by the oxidation of excess amino acids.

Two types of cells—nervous tissue and red blood cells—are notably insensitive to insulin. Nervous tissue derives energy from oxidizing glucose to CO_2 and water in both the well-fed and normal fasting states. Only in prolonged fasting does this situation change. Red blood cells can only use glucose anaerobically for all their energy needs, regardless of the individual's metabolic state.

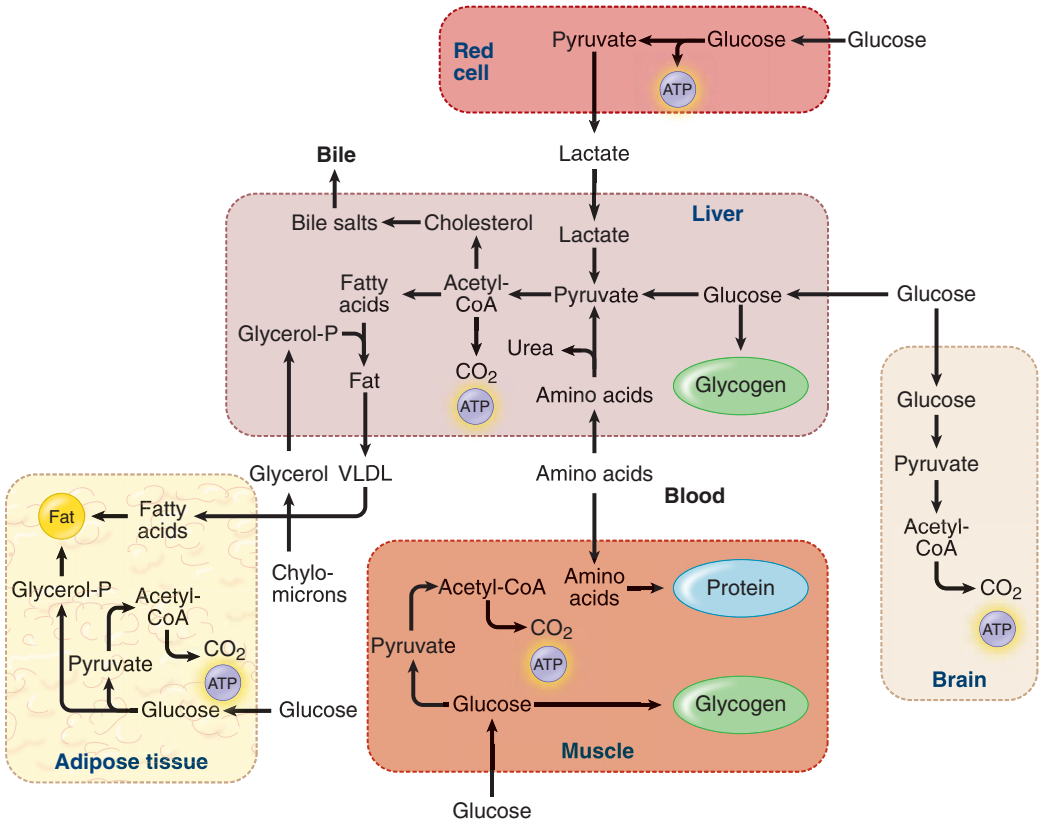

Figure 12.2. Metabolic Profile of the Postprandial (Absorptive) State

POSTABSORPTIVE (FASTING) STATE

Glucagon, cortisol, epinephrine, norepinephrine, and growth hormone oppose the actions of insulin. These hormones are sometimes termed **counterregulatory hormones** because of their effects on skeletal muscle, adipose tissue, and the liver, which are opposite to the actions of insulin. In the liver, glycogen degradation and the release of glucose into the blood are stimulated, as shown in Figure 12.3. Hepatic gluconeogenesis is also stimulated by glucagon, but the response is slower than that of glycogenolysis. Whereas glycogenolysis begins almost immediately at the beginning of the postabsorptive state, gluconeogenesis takes about 12 hours to hit maximum velocity.

The release of amino acids from skeletal muscle and fatty acids from adipose tissue are both stimulated by the decrease in insulin and by an increase in levels of epinephrine. Once carried into the liver, amino acids and fatty acids can provide the necessary carbon skeletons and energy required for gluconeogenesis.

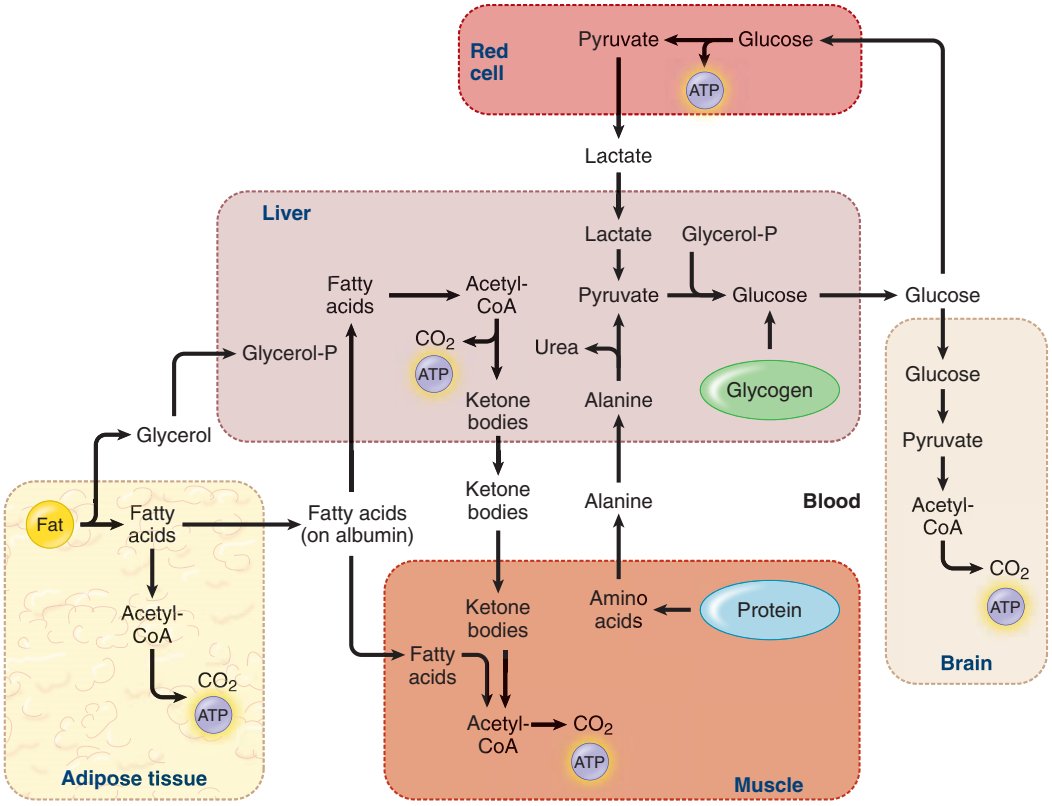

Figure 12.3. Metabolic Profile of the Postabsorptive (Fasting) State

PROLONGED FASTING (STARVATION)

Levels of glucagon and epinephrine are markedly elevated during starvation. Increased levels of glucagon relative to insulin result in rapid degradation of glycogen stores in the liver. As liver glycogen stores are depleted, gluconeogenic activity continues and plays an important role in maintaining blood glucose levels during prolonged fasting; after about 24 hours, gluconeogenesis is the predominant source of glucose for the body. Lipolysis is rapid, resulting in excess acetyl-CoA that is used in the synthesis of ketone bodies. Once levels of fatty acids and ketones are high enough in the blood, muscle tissue will utilize fatty acids as its major fuel source and the brain will adapt to using ketones for energy. After several weeks of fasting, the brain derives approximately two-thirds of its energy from ketones and one-third from glucose. The shift from glucose to ketones as the major fuel reduces the quantity of amino acids

that must be degraded to support gluconeogenesis, which spares proteins that are vital for other functions. Cells that have few, if any, mitochondria, like red blood cells, continue to be dependent on glucose for their energy.

MCAT Concept Check 12.4:

Before you move on, assess your understanding of the material with these questions.

1. Provide an example of disequilibrium that is maintained at the expense of cellular energy.

_____

_____

2. What tissue is least able to change its fuel source in periods of prolonged starvation?

_____

3. During what stage is there the greatest decrease in the circulating concentration of insulin?

_____

12.5 Hormonal Regulation of Metabolism

If each cell were acting independently of one another, metabolism would be a random process that could not be coordinated with outside events like meals or exertion. In order to make the most efficient use of the resources available, metabolism must be regulated across the entire organism. This regulation is accomplished best through hormonal means. Water-soluble **peptide hormones**, like insulin, are able to rapidly adjust the metabolic processes of cells via second messenger cascades, while certain fat-soluble **amino acid-derivative hormones**, like thyroid hormones, and **steroid hormones**, like cortisol, enact longer-range effects by exerting regulatory actions at the transcriptional level. Hormone levels are regulated by feedback loops with other endocrine structures, such as the hypothalamic–pituitary axis, or by the biomolecule upon which they act; for example, insulin causes a decrease in blood glucose, which removes the trigger for continued insulin release. Next, we'll examine the specific actions of several hormones involved in the regulation of metabolism and in maintaining homeostasis, including insulin and glucagon, epinephrine, glucocorticoids, and thyroid hormones.

INSULIN AND GLUCAGON

Insulin

Insulin is a peptide hormone secreted by the **β-cells** of the pancreatic islets of Langerhans, as shown in Figure 12.4. It is a key player in the uptake and storage of glucose. Glucose is absorbed by peripheral tissues via facilitated transport mechanisms that utilize glucose transporters located in the cell membrane. The tissues that require insulin for effective uptake of glucose are adipose tissue and resting skeletal muscle. Tissues in which glucose uptake is not affected by insulin include:

- Nervous tissue
- Kidney tubules
- Intestinal mucosa
- Red blood cells (erythrocytes)
- β-cells of the pancreas

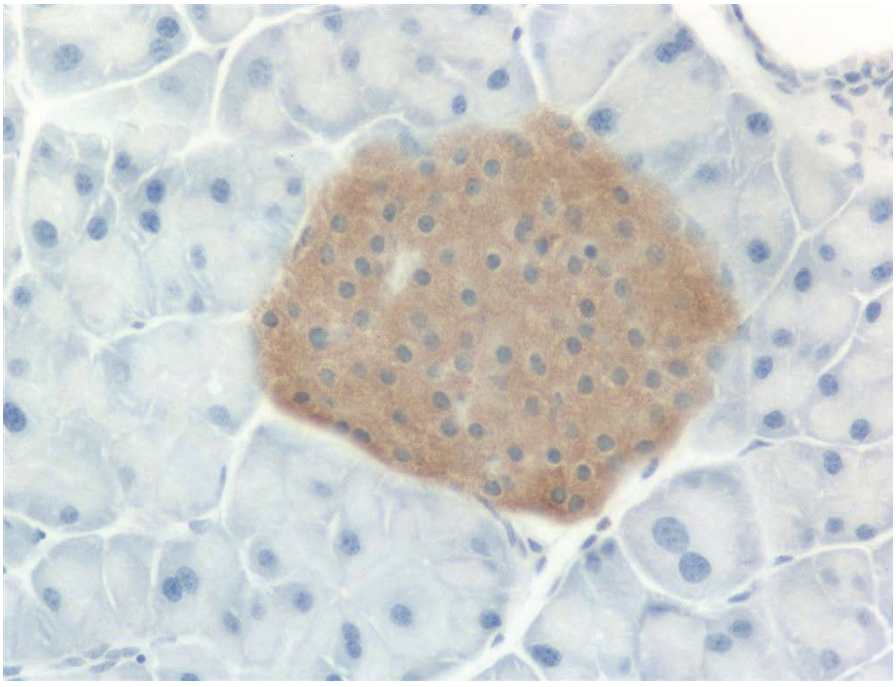

Figure 12.4. Insulin (light brown) in Pancreatic β-Cells

Take note of the differences between these types of tissues. Some tissues that require insulin actively store glucose when it is present in high concentrations, while other tissues that do not require insulin must still be able to absorb glucose even when the glucose concentration is low.

Insulin impacts the metabolism of the different nutrient classes in different ways. For carbohydrates, insulin increases the uptake of glucose and increases carbohydrate metabolism in muscle and fat. Increased glucose in muscle can be used as additional fuel to burn during exercise, or can be stored as glycogen. Insulin also increases glycogen synthesis in the liver by increasing the activity of *glucokinase* and *glycogen synthase*, while decreasing the activity of enzymes that promote glycogen breakdown (*glycogen phosphorylase* and *glucose-6-phosphatase*).

While the primary effects of insulin are on carbohydrate metabolism, it also changes the way that the body processes other macromolecules. For instance, insulin increases amino acid uptake by muscle cells, thereby increasing levels of protein synthesis and decreasing breakdown of essential proteins. Insulin also exhibits a significant impact on the metabolism of fats, especially in the liver and adipocytes. The effects of insulin on the metabolism of fats are described below.

Insulin increases:

- Glucose and triacylglycerol uptake by fat cells
- *Lipoprotein lipase* activity, which clears VLDL and chylomicrons from the blood
- Triacylglycerol synthesis (lipogenesis) in adipose tissue and the liver from acetyl-CoA

Insulin decreases:

- Triacylglycerol breakdown (lipolysis) in adipose tissue
- Formation of ketone bodies by the liver

The most important controller of insulin secretion is plasma glucose. Above a threshold of 100 $\frac{\text{mg}}{\text{dL}}$, or about 5.6 m$M$ glucose, insulin secretion is directly proportional to plasma glucose. For glucose to promote insulin secretion, it must not only enter the β-cell but also be metabolized, increasing intracellular ATP concentration. Increased ATP leads to calcium release in the cell, which promotes exocytosis of preformed insulin from intracellular vesicles. Insulin secretion is also affected by signaling initiated by other hormones, such as glucagon and somatostatin.

Glucagon

Glucagon is a peptide hormone secreted by the **α-cells** of the pancreatic islets of Langerhans, as shown in Figure 12.5. The primary target for glucagon action is the hepatocyte. Glucagon acts through second messengers to cause the following effects:

- Increased liver glycogenolysis. Glucagon activates glycogen phosphorylase and inactivates glycogen synthase.
- Increased liver gluconeogenesis. Glucagon promotes the conversion of pyruvate to phosphoenolpyruvate by *pyruvate carboxylase* and *phosphoenolpyruvate carboxykinase* (PEPCK). Glucagon increases the conversion of fructose 1,6-bisphosphate to fructose 6-phosphate by *fructose-1,6-bisphosphatase.*
- Increased liver ketogenesis and decreased lipogenesis.
- Increased lipolysis in the liver. Glucagon activates *hormone-sensitive lipase* in the liver. Because the action is on the liver and not the adipocyte, glucagon is not considered a major fat-mobilizing hormone.

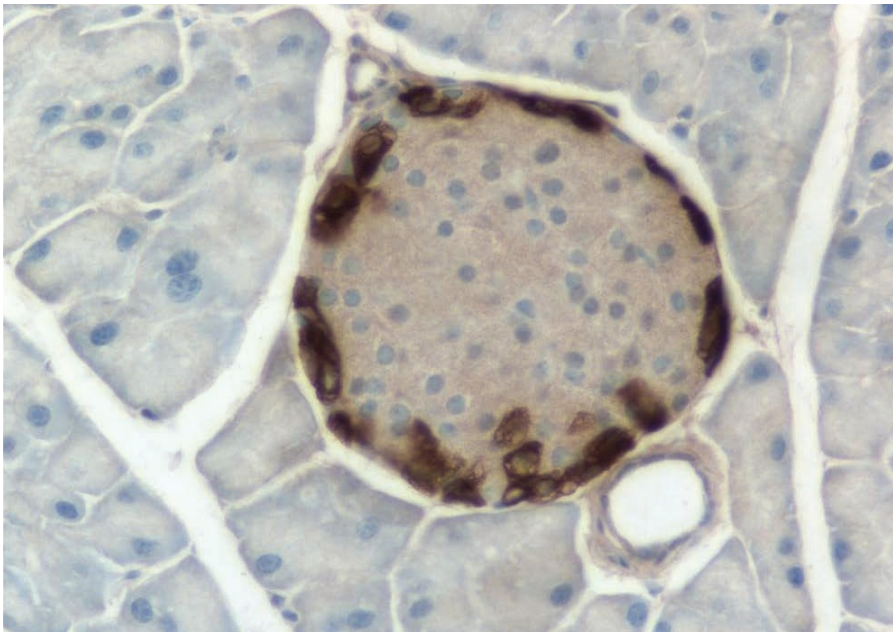

Figure 12.5. Glucagon (dark brown) in Pancreatic α-Cells

Low plasma glucose (hypoglycemia) is the most important physiological promoter of glucagon secretion, and elevated plasma glucose (hyperglycemia) is the most important inhibitor. Amino acids, especially basic amino acids (arginine, lysine, histidine), also promote the secretion of glucagon. Thus, glucagon is secreted in response to the ingestion of a meal rich in proteins.

Real World

Patients with type 1 diabetes mellitus are incapable of synthesizing insulin, but still synthesize glucagon. This combination increases blood sugar much more than if an individual were to lose all pancreatic function or to develop insulin insensitivity.

Functional Relationship of Glucagon and Insulin

Insulin, associated with a well-fed, absorptive metabolic state, and glucagon, associated with a postabsorptive metabolic state, usually oppose each other with respect to pathways of energy metabolism. Enzymes that are phosphorylated by glucagon are generally dephosphorylated by insulin; enzymes that are phosphorylated by insulin are generally dephosphorylated by glucagon. Figure 12.6 displays a feedback diagram of the interaction of insulin and glucagon on plasma glucose concentration, as well as fat and protein metabolism.

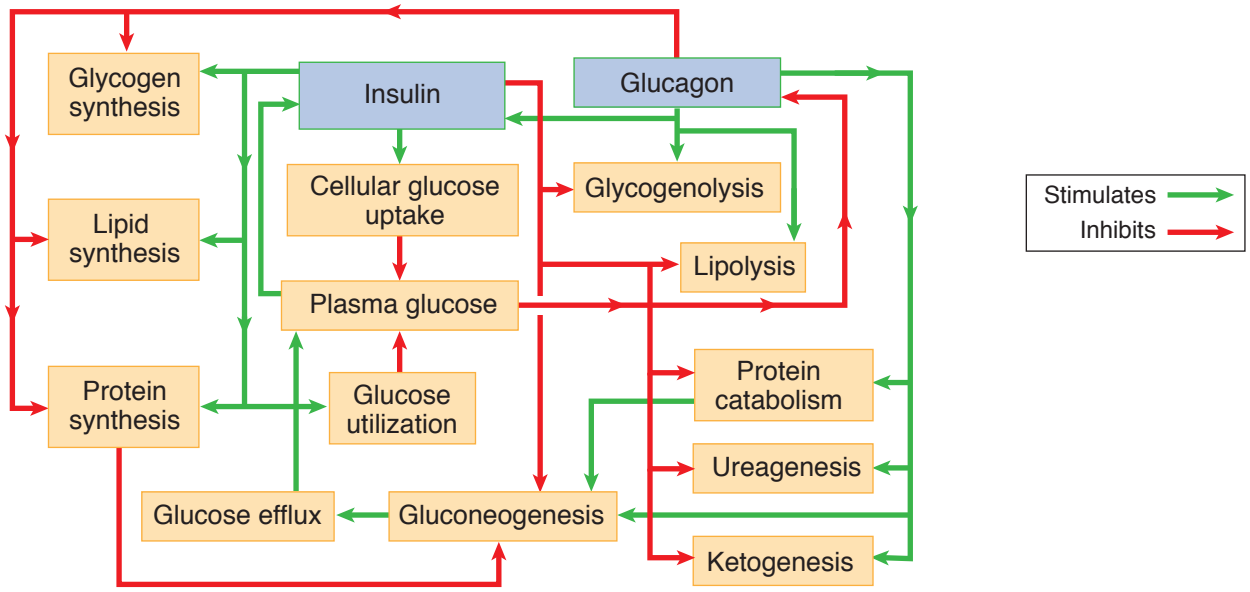

Figure 12.6. Relationship of Glucagon and Insulin in Metabolism

GLUCOCORTICOIDS

Glucocorticoids from the adrenal cortex are responsible for part of the stress response. In order to make a getaway in the "fight-or-flight" response, glucose must be rapidly mobilized from the liver in order to fuel actively contracting muscle cells while fatty acids are released from adipocytes. Glucocorticoids, especially **cortisol**, are secreted with many forms of stress, including exercise, cold, and emotional stress. Cortisol, shown in Figure 12.7, is a steroid hormone that promotes the mobilization of energy stores through the degradation and increased delivery of amino acids and increased lipolysis. Cortisol also elevates blood glucose levels, increasing glucose availability for nervous tissue through two mechanisms. First, cortisol inhibits glucose uptake in most tissues (muscle, lymphoid, and fat) and increases hepatic output of glucose via gluconeogenesis, particularly from amino acids. Second, cortisol has a permissive function that enhances the activity of glucagon, epinephrine, and other catecholamines. Long-term exposure to glucocorticoids may be required clinically,

Bridge

The endocrine system, discussed in Chapter 5 of *MCAT Biology Review*, is a major regulator of homeostasis. Like the glucocorticoids and catecholamines, mineralocorticoids and sex hormones are also synthesized by the adrenal glands and play a more minor role in metabolism.

but causes persistent hyperglycemia, which stimulates insulin. This actually promotes fat storage in the adipose tissue, rather than lipolysis.

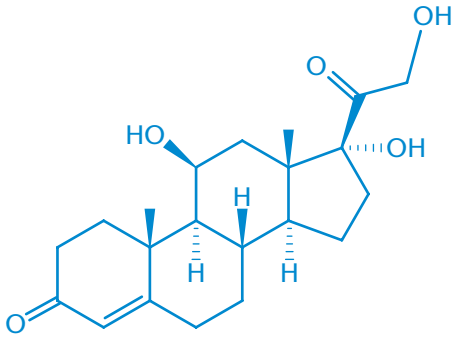

Figure 12.7. Structure of Cortisol

An enlarged adrenal gland (with a tumor of the adrenal cortex) is shown in Figure 12.8. While the adrenal cortex produces steroid hormones (glucocorticoids, mineralocorticoids, and sex hormones), the adrenal medulla produces catecholamines.

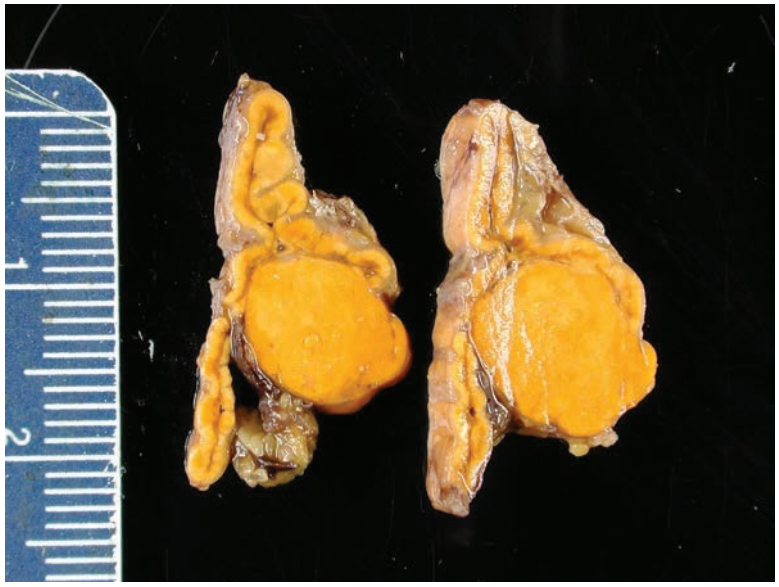

Figure 12.8. Adrenal Gland (Enlarged)
Adrenal cortex (yellow) and adrenal medulla (brown interior) visible on both slices.

CATECHOLAMINES

Catecholamines are secreted by the adrenal medulla and include **epinephrine** and **norepinephrine**, also known as **adrenaline** and **noradrenaline**. The structures of these hormones are shown in Figure 12.9. Catecholamines increase the activity of liver and muscle glycogen phosphorylase, thus promoting glycogenolysis. This increases glucose output by the liver. Glycogenolysis also increases in skeletal muscle, but because muscle lacks glucose-6-phosphatase, glucose cannot be released by skeletal muscle into the bloodstream; instead, it is metabolized by the muscle tissue itself. Catecholamines act on adipose tissue to increase lipolysis by increasing the activity of hormone-sensitive lipase. Glycerol from triacylglycerol breakdown is a minor substrate for gluconeogenesis. Epinephrine also acts directly on target organs like the heart to increase the basal metabolic rate through the sympathetic nervous system. This increase in metabolic function is often associated with an *adrenaline rush*.

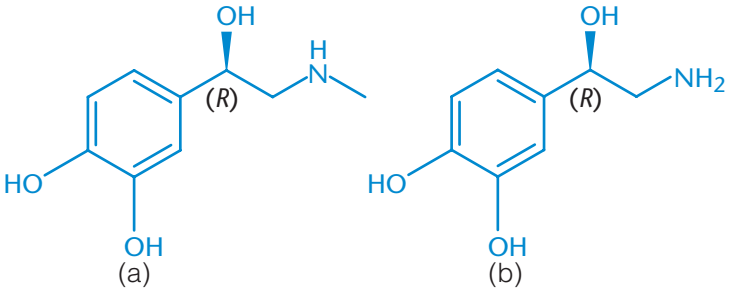

Figure 12.9. Structures of Adrenal Catecholamines
(a) Epinephrine; (b) Norepinephrine

THYROID HORMONES

Thyroid hormone activity is largely permissive. In other words, thyroid hormone levels are kept more or less constant, rather than undulating with changes in metabolic state. Thyroid hormones increase the basal metabolic rate, as evidenced by increased O_2 consumption and heat production when they are secreted. The increase in metabolic rate produced by a dose of ***thyroxine*** ($\mathbf{T_4}$) occurs after a latency of several hours but may last for several days, while ***triiodothyronine*** ($\mathbf{T_3}$) produces a more rapid increase in metabolic rate and has a shorter duration of activity. The

subscript numbers refer to the number of iodine atoms in the hormone; iodine atoms are represented by purple spheres in the structures shown in Figure 12.10. T_4 can be thought of as the precursor to T_3; *deiodonases* (enzymes that remove iodine from a molecule) are located in target tissues and convert T_4 to T_3. Thyroid hormones have their primary effects in lipid and carbohydrate metabolism. They accelerate cholesterol clearance from the plasma and increase the rate of glucose absorption from the small intestine. Epinephrine requires thyroid hormones to have a significant metabolic effect.

Real World

While thyroid hormones are not responsible for day-to-day adjustments in metabolism, insufficient thyroid hormone levels (hypothyroidism) can cause symptoms including cold intolerance, fatigue, weight gain, and depression as metabolism suffers. Excessive thyroid hormone levels (hyperthyroidism) can cause rapid weight loss, anxiety, jitteriness, and fever.

MCAT Concept Check 12.5:
Before you move on, assess your understanding of the material with these questions.

1. Describe the primary metabolic function of each of the following hormones:
   - Insulin:

     _____

   - Glucagon:

     _____

   - Cortisol:

     _____

   - Catecholamines:

     _____

   - Thyroid hormones (T_3/T_4):

     _____

2. Thyroid storm is a potentially lethal state of extreme hyperthyroidism in which T_3 and T_4 levels are significantly above normal limits. What vital sign abnormalities might be expected in a patient with thyroid storm?

   _____

   _____

12.6 Tissue-Specific Metabolism

Tissues have evolved so that their metabolic needs are met in a way corresponding to their form and function. The major sites of metabolic activity in the body are the liver, skeletal and cardiac muscles, brain, and adipocytes. Connective tissue and epithelial cells do not make major contributions to the consumption of energy. Remember though, that epithelial cells are the primary secretory cells, so they are involved in the regulation of metabolism. We have already discussed how the body operates under different nutritional conditions. The organ-specific patterns of fuel utilization in the well-fed and fasting states are summarized in Table 12.2.

Organ	Well-Fed	Fasting
Liver	Glucose and amino acids	Fatty acids
Resting skeletal muscle	Glucose	Fatty acids, ketones
Cardiac muscle	Fatty acids	Fatty acids, ketones
Adipose tissue	Glucose	Fatty acids
Brain	Glucose	Glucose (ketones in prolonged fast)
Red blood cells	Glucose	Glucose

Table 12.2. Preferred Fuels in the Well-Fed and Fasting States

LIVER

Two major roles of the liver in fuel metabolism are to maintain a constant level of blood glucose under a wide range of conditions and to synthesize ketones when excess fatty acids are being oxidized. After a meal, glucose concentration in the portal blood is elevated. The liver extracts excess glucose and uses it to replenish its glycogen stores. Any glucose remaining in the liver is then converted to acetyl-CoA and used for fatty acid synthesis. The increase in insulin after a meal stimulates both glycogen synthesis and fatty acid synthesis in the liver. The fatty acids are converted to triacylglycerols and released into the blood as **very-low-density lipoproteins** (**VLDL**). In the well-fed state, the liver derives most of its energy from the oxidation of excess amino acids. Between meals and during prolonged fasts, the liver releases glucose into the blood. The increase in glucagon during fasting promotes both glycogen degradation and gluconeogenesis. Lactate from anaerobic metabolism, glycerol from triacylglycerols, and amino acids provide carbon skeletons for glucose synthesis.

ADIPOSE TISSUE

After a meal, elevated insulin levels stimulate glucose uptake by adipose tissue. Insulin also triggers fatty acid release from VLDL and **chylomicrons** (which carry triacylglycerols absorbed from the gut). Lipoprotein lipase, an enzyme found in the capillary bed of adipose tissue, is also induced by insulin. The fatty acids that are released from lipoproteins are taken up by adipose tissue and re-esterified to triacylglycerols for storage. The glycerol phosphate required for triacylglycerol synthesis comes from glucose that is metabolized in adipocytes as an alternative product of glycolysis. Insulin can also effectively suppress the release of fatty acids from adipose tissue. During the fasting state, decreased levels of insulin and increased epinephrine activate **hormone-sensitive lipase** in fat cells, allowing fatty acids to be released into the circulation.

SKELETAL MUSCLE

Resting Muscle

The major fuels of skeletal muscle are glucose and fatty acids. Because of its enormous bulk, skeletal muscle is the body's major consumer of fuel. After a meal, insulin promotes glucose uptake in skeletal muscle, which replenishes glycogen stores and amino acids used for protein synthesis. Both excess glucose and amino acids can also be oxidized for energy. In the fasting state, resting muscle uses fatty acids derived from free fatty acids circulating in the bloodstream. Ketone bodies may also be used if the fasting state is prolonged.

Active Muscle

The primary fuel used to support muscle contraction depends on the magnitude and duration of exercise as well as the major fibers involved. A very short-lived source of energy (2–7 seconds) comes from **creatine phosphate**, which transfers a phosphate group to ADP to form ATP. Skeletal muscle has stores of both glycogen and some triacylglycerols. Blood glucose and free fatty acids may also be used. Short bursts of high-intensity exercise are also supported by anaerobic glycolysis drawing on stored muscle glycogen. During moderately high-intensity, continuous exercise, oxidation of glucose and fatty acids are both important, but after 1 to 3 hours of continuous exercise at this level, muscle glycogen stores become depleted, and the intensity of exercise declines to a rate that can be supported by oxidation of fatty acids.

Bridge

Fast-twitch muscle fibers have a high capacity for anaerobic glycolysis but are quick to fatigue. They are involved primarily in short-term, high-intensity exercise. Slow-twitch muscle fibers in arm and leg muscles are well vascularized and primarily oxidative. They are used during prolonged, low-to-moderate intensity exercise and resist fatigue. Slow-twitch fibers and the number of their mitochondria increase dramatically in trained endurance athletes. The musculoskeletal system is discussed in Chapter 11 of *MCAT Biology Review*.

CARDIAC MUSCLE

Unlike other tissues of the body, cardiac myocytes prefer fatty acids as their major fuel, even in the well-fed state. When ketones are present during prolonged fasting, they can also be used. Thus, not surprisingly, cardiac myocytes most closely parallel skeletal muscle during extended periods of exercise. In patients with cardiac hypertrophy (thickening of the heart muscle), this situation reverses to some extent. In a failing heart, glucose oxidation increases and β-oxidation falls.

BRAIN

Although the brain represents only 2 percent of total body weight, it obtains 15 percent of the cardiac output, uses 20 percent of the total O_2, and consumes 25 percent of the total glucose, the brain's primary fuel. Blood glucose levels are tightly regulated to maintain a sufficient glucose supply for the brain (and sufficient concentration while studying). Normal function depends on a continuous glucose supply from the bloodstream. In hypoglycemic conditions ($<70\,\frac{\text{mg}}{\text{dL}}$), hypothalamic centers in the brain sense a fall in blood glucose level, and the release of glucagon and epinephrine is triggered. Fatty acids cannot cross the blood–brain barrier and are therefore not used at all as an energy source. Between meals, the brain relies on blood

glucose supplied by either hepatic glycogenolysis or gluconeogenesis. Only during prolonged fasting does the brain gain the capacity to use ketone bodies for energy, and even then, the ketone bodies only supply approximately two-thirds of the fuel; the remainder is glucose.

MCAT Concept Check 12.6:

Before you move on, assess your understanding of the material with these questions.

1. What is the preferred fuel for most cells in the well-fed state? What is the exception and its preferred fuel?
   - Preferred fuel: _____
   - Exception: _____ Preferred fuel: _____
2. What organ consumes the greatest amount of glucose relative to its percentage of body mass?

_____

3. Describe the major metabolic functions of the liver.

_____

_____

_____

12.7 Integrative Metabolism ★★

ANALYSIS OF METABOLISM

There are several methods of analyzing metabolic control of an organism. In humans, levels of glucose, thyroid hormones and thyroid-stimulating hormone, insulin, glucagon, oxygen, and carbon dioxide can all be measured in the blood. Because these hormones and substrates have a predictable effect on metabolism, they can be used as indicators of metabolic function. They can also be used as indicators of disorders, as in the case of blood glucose or thyroid-stimulating hormone.

MCAT Expertise

The MCAT does not expect you to know what levels are healthy for any of these indicators, but can easily pose data interpretation questions related to them.

Respirometry allows accurate measurement of the respiratory quotient, which differs depending on the fuels being used by the organism. The **respiratory quotient** (**RQ**) can be measured experimentally, and can be calculated as:

$$\text{RQ} = \frac{\text{CO}_2 \text{ produced}}{\text{O}_2 \text{ consumed}}$$

Equation 12.3

for the complete combustion of a given fuel source. The respiratory quotient for carbohydrates is around 1.0, while the respiratory quotient for lipids is around 0.7. In resting individuals, the respiratory quotient is generally around 0.8, indicating that both fat and glucose are consumed. The respiratory quotient changes under conditions of high stress, starvation, and exercise as predicted by the actions of different hormones.

Calorimeters can measure **basal metabolic rate** (**BMR**) based on heat exchange with the environment. Human calorimetry makes use of large insulated chambers with specialized heat sinks to determine energy expenditure. Because of the isolationist nature of testing and the expense of creating a calorimetry chamber, other measures of BMR are preferred. Because of previous experimentation, BMR can be estimated based on age, weight, height, and gender.

REGULATION OF BODY MASS

Until now, we've been discussing metabolism on a very small scale, but metabolic controls are also involved in maintaining body mass (weight loss or gain). Body mass is determined by several factors, including water, carbohydrates, proteins, and lipids, while nucleic acids do not contribute significantly to its maintenance. The overall mass of carbohydrates and proteins tends to be stable over time, although it can be modified slightly by periods of prolonged starvation or by significant muscle-building activities. Water is very quickly adjusted by the endocrine system and the kidneys; therefore, it does not factor into our discussion of obesity and weight regulation. Water is the primary source of frequent minor weight fluctuations because it is subject to rapid adjustment. Therefore, lipids, stored in adipocytes, are the primary factor in the gradual change of body mass over time.

An individual who is maintaining his weight consumes the same amount of energy that is spent on average each day. If energy consumed is greater than energy expenditure over a significant period of time, then fat stores begin to accumulate. The opposite is also seen. If an energy deficit exists where calories consumed are less than calories burned, then a decrease in weight is observed. As individuals increase in mass, basal metabolic rate (the amount of energy required for one sedentary day) also increases. Thus, a caloric excess will cause an increase in body mass until equilibrium is reached between the new basal metabolic rate and the existing intake. In weight loss the reverse trend is seen.

This effect does have a **threshold** that differs between individuals. Small adjustments in intake, even over a prolonged period of time, are partially or fully compensated by changes in energy expenditure. Similarly, a small increase or decrease in activity level will be compensated by changes in hunger. Deliberate

alterations of body mass require alterations above this threshold level, which is larger in negative energy balance than in positive energy balance—in other words, larger changes must be made to lose weight than to gain it.

Diet (energy intake) and exercise (energy expenditure), genetics, socioeconomic status, and geography all play key roles in weight control. As described earlier, hormonal control by thyroid hormones, cortisol, epinephrine, glucagon, and insulin is critical to the integration of metabolism. In addition, there are hormones that control hunger and satiety, including *ghrelin*, *orexin*, and *leptin*. Have you ever wondered why, even if you don't feel hungry, when you walk into your favorite restaurant you're suddenly ravenous? This is the job of ghrelin and orexin. **Ghrelin** is secreted by the stomach in response to signals of an impending meal. Sight, sound, taste, and especially smell all act as signals for its release. Ghrelin increases appetite and also stimulates secretion of orexin. **Orexin** further increases appetite, and is also involved in alertness and the sleep–wake cycle. Hypoglycemia is also a trigger for orexin release. **Leptin** is a hormone secreted by fat cells that decreases appetite by suppressing orexin production. Genetic variations in the leptin molecule and its receptors have been implicated in obesity; a knockout mouse unable to produce leptin is shown on the left in Figure 12.11. These messengers and receptors are the target of current research; for now, questions regarding body mass modifications on the MCAT mostly come down to diet and exercise.

Bridge

Motivation, a psychological concept discussed in Chapter 5 of *MCAT Behavioral Sciences Review*, is often linked with physiological drives and signaling pathways. The hypothalamus, which produces orexin and responds to leptin and ghrelin, is responsible for regulating hunger, thirst, and libido.

Figure 12.11. Leptin Knockout Mouse (left) Compared to Normal Mouse (right)

Body mass can be measured and tracked using the **body mass index** (**BMI**), which is given by:

$$\text{BMI} = \frac{\text{mass}}{\text{height}^2}$$

Equation 12.4

where mass is measured in kilograms and height is measured in meters. A normal BMI is considered to be between 18.5 and 25; values lower than this are considered underweight. A BMI between 25 and 30 is considered overweight, whereas a BMI over 30 is considered **obese**.

MCAT Concept Check 12.7:

Before you move on, assess your understanding of the material with these questions.

1. How is the respiratory quotient expected to change when a person transitions from resting to brief exercise?

_____

_____

_____

2. True or False: Body mass can be predicted by the leptin receptor phenotype and caloric intake alone.
3. True or False: It is easier to gain weight than to lose weight.
4. If you were designing a study to assess metabolism, which measurement method would you choose? Defend your answer.

_____

_____

_____

Conclusion

In this chapter, we reviewed the principles of thermodynamics and thermochemistry that were introduced in general chemistry and physics and their applications to biological systems. We looked at the specific energy molecules of human metabolism, sources of energy, and key reaction types in ATP synthesis and hydrolysis. We compared different energy states and their impact on overall metabolism and tissue-specific metabolism.

At this point you should have a decent idea about how to determine what energy sources are being used from experimental data, and be able to make predictions about the changes in metabolism under varying conditions. Congratulations, because this is the last chapter of *MCAT Biochemistry Review* and you're just about ready to tackle any of the challenges that you will face on Test Day. Continue practicing, and try not to skip lunch!

CONCEPT SUMMARY

Thermodynamics and Bioenergetics

- Biological systems are considered:
  - **Open**, wherein matter and energy can be exchanged with the environment, or
  - **Closed**, wherein only energy can be exchanged with the environment.
  - This determination is made based on the examination of the entire organism or an isolated process.
- Changes in **enthalpy** in a closed biological system are equal to changes in **internal energy**, which is equal to **heat exchange** within the environment.
- No work is performed in a closed biological system because pressure and volume remain constant.
- **Entropy** is a measure of energy dispersion in a system.
- Physiological concentrations are usually much less than standard concentrations.
- Free energy calculations must be adjusted for pH ($\Delta G^{\circ\prime}$), temperature (37°C = 98.6°F = 310 K), and concentrations.

The Role of ATP

- ATP is a mid-level energy molecule.
- ATP contains high-energy phosphate bonds that are stabilized upon hydrolysis by resonance, ionization, and loss of charge repulsion.
- ATP provides energy through **hydrolysis** and **coupling** to energetically unfavorable reactions.
- ATP can also participate in **phosphoryl group transfers** as a phosphate donor.

Biological Oxidation and Reduction

- Biological **oxidation** and **reduction** reactions can be broken down into component **half-reactions**.
- Half-reactions provide useful information about stoichiometry and thermodynamics.
- Many oxidation–reduction reactions involve an electron carrier to transport high-energy electrons.
- **Electron carriers** may be soluble or membrane-bound.
  - **Flavoproteins** are one subclass of electron carriers that are derived from riboflavin (vitamin B_2).

Metabolic States

- **Equilibrium** is an undesirable state for most biochemical reactions because organisms need to harness free energy to survive.
- In the **postprandial/well-fed** (**absorptive**) state, insulin secretion is high and anabolic metabolism prevails.
- In the **postabsorptive** (**fasting**) state, insulin secretion decreases while glucagon and catecholamine secretion increases.
  - This state is observed in short-term fasting (overnight).
  - There is a transition to catabolic metabolism.
- Prolonged fasting (**starvation**) dramatically increases glucagon and catecholamine secretion.
  - Most tissues rely on fatty acids.
  - At maximum, $\frac{2}{3}$ of the brain's energy can be derived from ketone bodies.

Hormonal Regulation of Metabolism

- **Insulin** and **glucagon** have opposing activities during most aspects of metabolism.
  - Insulin causes a decrease in blood glucose levels by increasing cellular uptake.
  - Insulin increases the rate of anabolic metabolism.
  - Insulin secretion by pancreatic β-cells is regulated by blood glucose levels.
  - Glucagon increases blood glucose levels by promoting gluconeogenesis and glycogenolysis in the liver.
  - Glucagon secretion by pancreatic α-cells is stimulated by both low glucose and high amino acid levels.
- **Glucocorticoids** increase blood glucose in response to stress by mobilizing fat stores and inhibiting glucose uptake.
  - Glucocorticoids increase the impact of glucagon and catecholamines.
- **Catecholamines** promote glycogenolysis and increase basal metabolic rate through their sympathetic nervous system activity.
- **Thyroid hormones** modulate the impact of other metabolic hormones and have a direct impact on basal metabolic rate.
  - T_3 is more potent than T_4, but has a shorter half-life and is available in lower concentrations in the blood.
  - T_4 is converted to T_3 at the tissues.

Tissue-Specific Metabolism

- The liver is the most metabolically diverse tissue.
  - Hepatocytes are responsible for the maintenance of blood glucose levels by glycogenolysis and gluconeogenesis in response to pancreatic hormone stimulation.
  - The liver also participates in the processing of lipids and cholesterol, bile, urea, and toxins.
- Adipose tissue stores lipids under the influence of insulin and releases them under the influence of epinephrine.
- Skeletal muscle metabolism differs based on the current activity level and fiber type.
  - Resting muscle conserves carbohydrates in glycogen stores and uses free fatty acids from the bloodstream.
  - Active muscle may use anaerobic metabolism, oxidative phosphorylation of glucose, direct phosphorylation from creatine phosphate, or fatty acid oxidation, depending on fiber type and exercise duration.
- Cardiac muscle uses fatty acid oxidation in both the well-fed and fasting states.
- The brain and other nervous tissues consume glucose in all metabolic states, except for prolonged fasts, where up to $\frac{2}{3}$ of the brain's fuel may come from ketone bodies.

Integrative Metabolism

- Metabolic rates can be measured using **calorimetry**, **respirometry**, consumption tracking, or measurement of blood concentrations of substrates and hormones.
- Composition of fuel that is actively consumed by the body is estimated by the **respiratory quotient** (**RQ**).
- Body mass regulation is multifactorial with consumption and activity as modifiable factors.
  - The hormones **leptin**, **ghrelin**, and **orexin**, as well as their receptors, play a role in body mass.
  - Long-term changes in body mass result from changes in lipid storage.
  - Changes in consumption or activity must surpass a **threshold** to cause weight change. The threshold is lower for weight gain than for weight loss.
  - Body mass can be measured and tracked using the **body mass index** (**BMI**).

ANSWERS TO CONCEPT CHECKS

12.1

1. $\Delta G^{\circ\prime}$ adjusts only for the pH of the environment by fixing it at 7. Temperature and concentrations of all other reagents are still fixed at their values from standard conditions and must be adjusted for if they are not 1 *M*.
2. The cellular environment has a relatively fixed volume and pressure, which eliminates work from our calculations of internal energy; if $\Delta U = Q - W$ and $W = 0$, $\Delta U = Q$.

3.

	$+\Delta H$	$-\Delta H$
$+\Delta S$	Spontaneous at high temperatures	Spontaneous
$-\Delta S$	Nonspontaneous	Spontaneous at low temperatures

12.2

1. ATP hydrolysis yields about $30 \frac{\text{kJ}}{\text{mol}}$ of energy, which can be harnessed to drive other reactions forward. This may either allow a nonspontaneous reaction to occur or increase the rate of a spontaneous reaction.
2. ATP is an intermediate-energy storage molecule and is not energetically dense. The high-energy bonds in ATP and the presence of a significant charge make it an inefficient molecule to pack into a small space. Long-term storage molecules are characterized by energy density and stable, nonrepulsive bonds, primarily seen in lipids.
3. $\text{cAMP} + \text{H}_2\text{O} \rightarrow \text{AMP} \qquad \Delta G^{\circ\prime} = -50.4 \frac{\text{kJ}}{\text{mol}}$

   $\text{AMP} + \text{P}_\text{i} \rightarrow \text{ADP} + \text{H}_2\text{O} \qquad \Delta G^{\circ\prime} = 30.5 \frac{\text{kJ}}{\text{mol}}$

   $\text{ADP} + \text{P}_\text{i} \rightarrow \text{ATP} + \text{H}_2\text{O} \qquad \Delta G^{\circ\prime} = 30.5 \frac{\text{kJ}}{\text{mol}}$

   $\text{cAMP} + 2\,\text{P}_\text{i} \rightarrow \text{ATP} + \text{H}_2\text{O} \qquad \Delta G^{\circ\prime} = 10.6 \frac{\text{kJ}}{\text{mol}}$

12.3

1. Analyzing half-reactions can help to determine the number of electrons being transferred. This type of analysis also facilitates balancing equations and the determination of electrochemical potential if reduction potentials are provided.

2.

Electron Carrier	Metabolic Pathway(s)
NADH	Glycolysis, fermentation, citric acid cycle, electron transport chain
NADPH	Pentose phosphate pathway, lipid biosynthesis, bleach formation, oxidative stress, photosynthesis
Ubiquinone (CoQ)	Electron transport chain
Cytochromes	Electron transport chain
Glutathione	Oxidative stress

12.4

1. Any excitable cell is maintained in a state of disequilibrium. Classic examples include muscle tissue and neurons. In addition, cell volume and membrane transport are regulated by the action of the sodium–potassium pump, which can maintain a stable disequilibrium state in most tissues.
2. Cells that rely solely on anaerobic respiration are the least adaptable to different energy sources. Therefore, red blood cells are the least flexible during periods of prolonged starvation and stay reliant on glucose.
3. During the postabsorptive state, there is the greatest decrease in insulin levels. The concentrations of the counterregulatory hormones (glucagon, cortisol, epinephrine, norepinephrine, and growth hormone) begin to rise.

12.5

1. Insulin promotes glucose uptake by adipose tissue and muscle, glucose utilization in muscle cells, and macromolecule storage (glycogenesis, lipogenesis). Glucagon increases blood glucose levels by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. Cortisol increases lipolysis and amino acid mobilization, while decreasing glucose uptake in certain tissues and enhancing the activity of other counterregulatory hormones. Catecholamines increase glycogenolysis in muscle and liver and lipolysis in adipose tissue. Thyroid hormones increase basic metabolic rate and potentiate the activity of other hormones.
2. Thyroid storm presents with hyperthermia (high temperature), tachycardia (fast heart rate), hypertension (high blood pressure), and tachypnea (high respiratory rate).

12.6

1. The preferred fuel for most cells in the well-fed state is glucose; the exception is cardiac muscle, which prefers fatty acids.
2. The brain consumes the greatest amount of glucose relative to its percentage of body mass.
3. The liver is responsible for maintaining a steady-state concentration of glucose in the blood through glucose uptake and storage, glycogenolysis, and gluconeogenesis. The liver also participates in cholesterol and fat metabolism, the urea cycle, bile synthesis, and the detoxification of foreign substances.

12.7

1. As a person begins to exercise, the proportion of energy derived from glucose increases. This transition to almost exclusively carbohydrate metabolism will cause the respiratory quotient to approach 1.
2. False; energy expenditure, genetics, socioeconomic status, geography, and other hormones also play a role in body mass regulation.
3. True; the threshold is lower for uncompensated weight gain than it is for uncompensated weight loss. Therefore, it is easier to surpass this threshold and gain weight than to lose weight.
4. The methods described in the text include chemical analysis, which is objective and can quantify specific metabolic substrates, products, and enzymes; calorimetry, which is most accurate for basal metabolic rate but also most expensive; respirometry, which provides basic information about fuel sources; and caloric analysis at constant weight (food and exercise logs) which is the least invasive. Any of these answers could be defended.

EQUATIONS TO REMEMBER

(12.1) **Gibbs free energy:** $\Delta G = \Delta H - T\Delta S$

(12.2) **Modified standard state:** $\Delta G = \Delta G^{\circ} + RT \ln (Q)$

(12.3) **Respiratory quotient:** $\text{RQ} = \dfrac{\text{CO}_2 \text{ produced}}{\text{O}_2 \text{ consumed}}$

(12.4) **Body mass index:** $\text{BMI} = \dfrac{\text{mass}}{\text{height}^2}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Adding heat to a closed biological system will do all of the following EXCEPT:

A. increase the internal energy of the system.
B. increase the average of the vibrational, rotational, and translational energies.
C. cause the system to do work to maintain a fixed internal energy.
D. increase the enthalpy of the system.

2. At 25°C the $\Delta G°$ for a certain reaction $A \rightleftharpoons B + 2\ C$ is 0. If the concentration of A, B, and C in the cell at 25°C are all 10 m*M*, how does the ΔG compare to the measurement taken with 1 *M* concentrations?

A. ΔG is greater than $\Delta G°$, thus the reaction is spontaneous.
B. ΔG is less than $\Delta G°$, thus the reaction is spontaneous.
C. ΔG is greater than $\Delta G°$, thus the reaction is nonspontaneous.
D. ΔG is less than $\Delta G°$, thus the reaction is nonspontaneous.

3. Which of the following statements is true about the hydrolysis of ATP?

A. The free energy of ATP hydrolysis is independent of pH.
B. One mole of creatine phosphate can phosphorylate two moles of ADP.
C. The free energy of hydrolysis of ATP is nearly the same as for ADP.
D. ATP yields cyclic AMP after two hydrolysis reactions.

4. The reduction half-reaction in the last step of the electron transport chain is:

A. $O_2 + 4\ e^- + 4\ H^+ \rightarrow 2\ H_2O$
B. $NADPH \rightarrow NADP^+ + e^- + H^+$
C. $NADP^+ + e^- + H^+ \rightarrow NADPH$
D. Ubiquinone (Q) $\rightarrow$ Ubiquinol (QH_2)

5. The ability to exist in both an oxidized and a reduced state is characteristic of:

A. adenosine triphosphate (ATP).
B. electron carriers.
C. regulatory enzymes.
D. peptide hormones.

6. What energy state was described in the introduction to this chapter?

A. Absorptive
B. Postabsorptive
C. Starvation
D. Vegetative

7. With prolonged fasting, the brain can turn to which alternative fuel for energy?

A. Fructose
B. Lactate
C. Ketone bodies
D. Fatty acids

8. How do hormonal controls of glycogen metabolism differ from allosteric controls?

A. Hormonal control is systemic and covalent.
B. Hormonal control is local and covalent.
C. Hormonal control is systemic and noncovalent.
D. Hormonal control is local and noncovalent.

9. Which of the following tissues is most dependent on insulin?

A. Active skeletal muscle
B. Resting skeletal muscle
C. Cardiac muscle
D. Smooth muscle

10. Glucocorticoids have been implicated in stress-related weight gain because:

A. they increase appetite and decrease satiety signals.
B. they increase the activity of catabolic hormones.
C. they increase glucose levels, which causes insulin secretion.
D. they interfere with activity of the leptin receptor.

11. In the absence of oxygen, which tissue will experience damage most rapidly?

A. Skin
B. Brain
C. Red blood cells
D. Liver

12. A respiratory quotient approaching 0.7 indicates metabolism primarily of which macromolecule?

A. Carbohydrates
B. Lipids
C. Nucleic acids
D. Amino acids

13. Which of the following side effects would be anticipated in someone taking leptin to promote weight loss?

A. Drowsiness
B. Increased appetite
C. Irritability
D. Fever

14. Which of the following statements is FALSE?

A. Growth hormone participates in glucose counter-regulation.
B. T_4 acts more slowly than T_3.
C. ATP stores are turned over more than 10,000 times daily.
D. Catecholamines stimulate the sympathetic nervous system.

15. Which process is expected to begin earliest in a prolonged fast?

A. Ketone bodies are used by the brain.
B. Glycogen storage is halted.
C. Proteins are broken down.
D. Enzyme phosphorylation and dephosphorylation.

Explanations to Discrete Practice Questions

1. C

In a closed biological system, enthalpy, heat, and internal energy are all directly related because there is no change in pressure or volume. Because pressure and volume are fixed, work cannot be done, thus **choice (C)** is correct.

2. B

To solve this question, we can use the equation $\Delta G = \Delta G^\circ + RT \ln Q$. Q, the reaction quotient, is $\frac{[B][C]^2}{[A]}$ for this reaction. Plugging in the variables, we get:

$$\Delta G = 0 + RT \ln \frac{[10 \times 10^{-3}][10 \times 10^{-3}]^2}{[10 \times 10^{-3}]} = RT \ln 10^{-4} = -4RT.$$

Because both R and T are positive, we know that ΔG must be negative and therefore lower than the original value. A negative ΔG corresponds to a spontaneous reaction.

3. C

The hydrolysis of ATP is energetically favorable because there are repulsive negative charges that are relieved when hydrolyzed, and the new compounds are stabilized by resonance. This is true of both ATP and ADP. Some of the other answer choices are tempting, though. In **choice (A)**, ATP hydrolysis relies on pH because a protonated ATP molecule contains less negative charge and therefore experiences less repulsive force. For **choice (B)**, the energy released by one mole of creatine phosphate upon hydrolysis is not sufficient to phosphorylate two moles of ADP according to Table 12.1; creatine phosphate donates one phosphate group to a molecule of ADP, so one mole of creatine phosphate will phosphorylate one mole of ADP. For **choice (D)**, the removal of two phosphate groups from ATP yields AMP, not cyclic AMP.

4. A

Reduction is a gain of electrons, which eliminates **choice (B)** because it is an oxidation reaction. NADPH, **choice (C)**, is a product of the pentose phosphate pathway. Ubiquinone, **choice (D)**, transfers electrons during the course of the electron transport chain, but is not the final electron acceptor. This title belongs to oxygen.

5. B

In order to transport electrons, electron carriers like flavoproteins must be able to exist in a stable oxidized state and a stable reduced form. ATP can be dephosphorylated but is generally not oxidized or reduced. Regulatory enzymes may also be phosphorylated or dephosphorylated but are not generally oxidized or reduced.

6. B

Skipping a single meal is not a prolonged fast. However, the increase in hormones that promote gluconeogenesis and glycogenolysis indicates that the absorptive phase has ended.

7. C

The brain is almost exclusively dependent on glucose for energy; however, in a prolonged fast, ketone bodies can be used for up to $\frac{2}{3}$ of the brain's energy requirement.

8. A

Hormonal controls are coordinated to regulate the metabolic activity of the entire organism, while allosteric controls can be local or systemic. The modification of the enzymes of glycogen metabolism by insulin and glucagon is either through phosphorylation or dephosphorylation, both of which modify covalent bonds.

9. B

Adipose tissue and resting skeletal muscle require insulin for glucose uptake. Active skeletal muscle, **choice (A)**, uses creatine phosphate and glycogen (regulated by epinephrine and AMP) to maintain its energy requirements.

10. C

Short-term glucocorticoid exposure causes a release of glucose and the hydrolysis of fats from adipocytes. However, if this glucose is not used for metabolism, it causes an increase in glucose level which promotes fat storage. The net result is the release of glucose from the liver to be converted into lipids in the adipose tissue under insulin stimulation.

11. B

The brain uses aerobic metabolism of glucose exclusively and therefore is very sensitive to oxygen levels. The extremely high oxygen requirement of the brain (20% of the body's oxygen content) relative to its size (2% of total body weight) implies that brain is the most sensitive organ to oxygen deprivation.

12. B

The respiratory quotient (RQ) gives an indication of the primary fuel being utilized. An RQ around 0.7 indicates lipid metabolism, 0.8–0.9 indicates amino acid metabolism, **choice (C)**, and 1.0 indicates carbohydrate metabolism, **choice (A)**. Nucleic acids do not contribute significantly to the respiratory quotient.

13. A

Leptin acts to decrease appetite by inhibiting the production of orexin. Orexin is also associated with alertness, so decreasing the level of orexin in the body is expected to cause drowsiness. Even without this information, the answer should be apparent because the body tends to maintain an energy balance. If consumption decreases, energy expenditures are expected to decrease as well.

14. C

ATP stores are turned over about 1,000 times per day, not 10,000.

15. D

A prolonged fast is characterized by an increase in glucagon, which accomplishes its cellular activity by phosphorylating and dephosphorylating metabolic enzymes. Glycogen storage, **choice (B)**, is then halted, but this requires enzyme regulation by glucagon to occur. Later in the postabsorptive state, protein breakdown, **choice (C)**, begins. Eventually, in starvation, ketone bodies, **choice (A)**, are used by the brain for its main energy source.

Glossary

Absolute configuration—The nomenclature system used for the three-dimensional arrangement of atoms in isomers; the most common systems are D/L and (*R*)/(*S*).

Acetal—A carbon atom bonded to an alkyl group, two –OR groups, and a hydrogen.

Acetyl-CoA—An important metabolic intermediate that links glycolysis and β-oxidation to the citric acid cycle; can also be converted into ketone bodies.

Activation—The conversion of a biomolecule to its active or usable form, such as activation of tRNA with an amino acid or activation of a fatty acid with CoA to form fatty acyl-CoA.

Activation energy—The energy required to change the state of a molecule or group of molecules to the transition state; the energy required for a reaction to occur.

Active site—The catalytically active portion of an enzyme.

Active transport—The movement of a molecule against its concentration gradient with energy investment; primary active transport uses ATP, whereas secondary active transport uses a favorable transport gradient of a different molecule.

Activity—The measure of the catalytic activity of an enzyme, also called the velocity or rate. It is often measured as a v_{max} and may be analyzed after protein isolation.

Activity analysis—The determination of the enzymatic activity of an isolated protein by interaction with a substrate; usually colorimetric in nature.

Adenosine triphosphate (ATP)—The primary energy molecule of the body; it releases energy by breaking the bond with the terminal phosphate to form ADP and inorganic phosphate.

Adipocyte—A cell specializing in fat storage.

Aerobic respiration—A collection of energy-producing metabolic processes that require oxygen, including the citric acid cycle, electron transport chain, and oxidative phosphorylation.

Aldose—A sugar in which the highest-order functional group is an aldehyde; can be categorized by number of carbons (triose, tetrose, pentose, hexose, etc.).

Allosteric enzymes—Enzymes that experience changes in their conformation as a result of interactions at sites other than the active site, called allosteric sites; conformational changes may increase or decrease enzyme activity.

α-Helix—An element of secondary structure, marked by clockwise coiling of amino acids around a central axis.

Alternative splicing—The production of multiple different but related mRNA molecules from a single primary transcript of hnRNA.

Amino acid—A dipolar compound containing an amino group ($-NH_2$) and a carboxyl group (–COOH).

Amphipathic—Having both hydrophilic and hydrophobic regions.

Amphoteric—The ability to act as an acid or base.

Amplification—Increased transcription (and translation) of a gene in response to hormones, growth factors, and other intracellular conditions.

Anabolism—The series of metabolic processes that result in the consumption of energy and the synthesis of molecules.

Anaerobic respiration—The series of energy-producing metabolic processes that do not require oxygen, including glycolysis and fermentation.

Anomers—A subtype of epimers in which the chiral carbon with inverted configuration was the carbonyl carbon (anomeric carbon).

Antibody—A specialized protein molecule produced by lymphocytes for interaction with antigens; antibodies consist of two heavy and two light chains that have constant and variable regions. Antibodies, also called immunoglobulins, are mediators of the immune response.

Anticodon—A three-nucleotide sequence on a tRNA molecule that pairs with a corresponding mRNA codon during translation.

Antigen—The region of a molecule that interacts with an antibody; in most cases, antigens are proteins.

Apoenzyme—An enzyme devoid of the prosthetic group, coenzyme, or cofactor necessary for normal activity.

Apolipoproteins—Protein molecules responsible for the interaction of lipoproteins with cells and the transfer of lipid molecules between lipoproteins; also called apoproteins.

Aromaticity—The ability of a molecule to delocalize π electrons around a conjugated ring, creating exceptional stability.

Basal metabolic rate—The amount of energy consumed in a given period of time by a resting organism.

β-oxidation—The catabolism of fatty acids to acetyl-CoA.

β-pleated sheet—An element of secondary structure, marked by peptide chains lying alongside one another, forming rows or strands.

Bile—A mixture of salts, pigments, and cholesterol that acts to emulsify lipids in the small intestine.

Bradford protein assay—A colorimetric method of determining the concentration of protein in an isolate against a protein standard; relies on a transition of absorption between bound and unbound Coomassie Brilliant Blue dye.

Cahn–Ingold–Prelog system—The system used to name isomers ((*E*) *vs*. (*Z*); (*R*) *vs*. (*S*)), based on the atomic numbers of their substituents and their orientation in three-dimensional space.

Calorimeter—A device for measuring the heat change during the course of a reaction.

Carboxylation—The addition of carboxylic acid groups to a molecule.

Carotenoids—A group of molecules that are tetraterpenes (made of eight isoprene units).

Catabolism—The series of metabolic processes that result in the release of energy and the breakdown of molecules.

Catecholamines—Mediators of the sympathetic nervous system and adrenal gland; include epinephrine and norepinephrine.

Cell adhesion molecules—Specialized structural proteins that are involved in cell–cell junctions as well as transient cellular interactions; common cell adhesion molecules are cadherins, integrins, and selectins.

Central dogma of molecular biology—The major steps in the transfer of genetic information, from transcription of DNA to RNA to translation of that RNA to protein.

Centrifugation—The process of separating components on the basis of their density and resistance to flow by spinning a sample at very high speeds; the highest density materials form a solid pellet and the lowest density materials remain in the supernatant (liquid portion).

Ceramide—The simplest sphingolipid, with a single hydrogen as its head group.

Cerebroside—A sphingolipid containing a carbohydrate as a head group.

Chaperones—Proteins that assist in protein folding during posttranslational processing.

Chemiosmotic coupling—The utilization of the proton-motive force generated by the electron transport chain to drive ATP synthesis in oxidative phosphorylation.

Chiral—Describes a molecule with a nonsuperimposable mirror image.

Chiral center—A carbon atom bonded to four different substituents; a chiral compound must have at least one chiral center.

Cholesterol—A molecule containing four linked aromatic rings; cholesterol provides both fluidity and stability to cell membranes and is the precursor for steroid hormones.

Chromatography—The process of separating molecules by their interactions with a stationary phase and a mobile phase; most chromatographic methods rely on the chemical similarity of molecules, with the exception of size-exclusion chromatography.

Citric acid cycle—A metabolic pathway that produces GTP, energy carriers, and carbon dioxide as it burns acetyl-CoA; also called the Krebs cycle or tricarboxylic acid (TCA) cycle; can share intermediates with many other metabolic processes including fatty acid and cholesterol synthesis, gluconeogenesis, amino acid metabolism, and others.

Closed system—A system capable of exchanging energy, but not matter, with the environment.

Coding strand—The strand of DNA that is not used as a template during transcription; also called the sense strand.

Codon—A three-nucleotide sequence in an mRNA molecule that pairs with an appropriate tRNA anticodon during translation.

Coenzyme—An organic molecule that helps an enzyme carry out its function.

Cofactor—An inorganic molecule or ion that helps an enzyme carry out its function.

Colligative properties—Physical properties that change according to the concentration of solutes, but not their identity. Colligative properties include vapor pressure depression, boiling point elevation, freezing point depression, and osmotic pressure.

Competitive inhibition—A decrease in enzyme activity that results from the interaction of an inhibitor with the active site of an enzyme; competitive inhibition can be overcome by addition of excess substrate.

Condensation reaction—A reaction in which the removal of a water molecule accompanies the formation of a bond; also called a dehydration reaction.

Conformational coupling—A less-accepted mechanism of ATP synthase activity in which the protons cause a conformational change that releases ATP from ATP synthase.

Conjugated protein—A protein that derives part of its function from covalently attached molecules (prosthetic groups).

Cooperativity—The interaction between subunits of a multi-subunit protein in which binding of substrate to one subunit increases the affinity of other subunits for the substrate; unbinding of substrate from one unit decreases the affinity of other subunits for the substrate.

Corepressor—A species that binds with a repressor, allowing the complex to bind to the operator region of an operon, stopping transcription of the relevant gene.

Cristae—The infoldings of the inner mitochondrial membrane that increase the surface area available for electron transport chain complexes.

C-terminus—The free carboxyl end of a polypeptide.

Degeneracy—A characteristic of the genetic code, in which more than one codon can specify a single amino acid.

Denaturation—The loss of secondary, tertiary, or quaternary structure in a protein, leading to loss of function.

Deoxyribonucleic acid (DNA)—A nucleic acid found exclusively in the nucleus that codes for all the of the genes necessary for life; transcribed to mRNA and always read 5′ to 3′.

Desmosomes—Cell–cell junctions that anchor layers of epithelial cells to one another.

Diastereomers—Compounds with at least one—but not all—chiral carbons in inverted configurations; differ in physical properties.

Diprotic—Containing two hydrogens (acid), or being able to pick up two hydrogens (base).

Disulfide bond—A covalent interaction between the –SH groups of two cysteine residues; an element of tertiary and quaternary structure.

Edman degradation—A stepwise process for determining the amino acid sequence in an isolated protein.

Electrochemical gradient—An uneven separation of ions across a biological membrane, resulting in potential energy.

Electrophoresis—The process of separating compounds on the basis of size and charge using a porous gel and an electric field; protein electrophoresis generally uses polyacrylamide, while nucleic acid electrophoresis generally uses agarose.

Elongation—The three-step cycle that is repeated for each amino acid being added to a protein during translation.

Enantiomers—Compounds that are nonsuperimposable mirror images; have the same physical and chemical properties except for rotation of plane-polarized light and interaction with a chiral environment.

Endocytosis—The transport of molecules into a cell through the invagination of cell membrane and the formation of a vesicle; phagocytosis is the endocytosis of solid, pinocytosis is the endocytosis of liquid.

Endothermic reaction—A reaction that requires heat (positive ΔH).

Enhancer—A collection of several response elements that allow for the control of one gene's expression by multiple signals.

Enthalpy—The overall change in heat of a system during a reaction.

Entropy—The disorder of a system; systems in which entropy is increased are generally favored.

Enzyme—A biological molecule with catalytic activity; includes many proteins and some RNA molecules.

Epimers—A subtype of diastereomers that differ in absolute configuration at exactly one chiral carbon.

Euchromatin—The looser, less-dense collections of DNA that appear light-colored under a microscope; transcriptionally active.

Exocytosis—The transport of molecules out of a cell by release from a transport

vesicle; the vesicle fuses to the cell membrane during secretion.

Exon—A portion of hnRNA that is spliced with other exons to form mature mRNA.

Exothermic reaction—A reaction that releases heat (negative ΔH).

Facilitated diffusion—The movement of solute molecules across the cell membrane down their concentration gradients through a transport protein or channel; used for ions and large or polar molecules.

Fatty acid—A monocarboxylic acid without additional substituents; fatty acids may be saturated (all single bonds) or unsaturated (contain at least one double bond); natural fatty acids are in the *cis* conformation.

Feedback inhibition—The inhibition of an enzyme by its product (or a product further down in a metabolic pathway); used to maintain homeostasis.

Feed-forward activation—The stimulation of an enzyme by an intermediate that precedes the enzyme in a metabolic pathway.

Fermentation—The conversion of pyruvate to either ethanol and carbon dioxide (yeast) or lactic acid (animal cells); does not require oxygen.

Fibrous protein—A protein composed of long sheets or strands, such as collagen.

Fischer projection—A method of drawing organic molecules in which horizontal lines are coming out of the page (wedges) and vertical lines are going into the page (dashes).

Flavin adenine dinucleotide (FAD)—An energy carrier that accepts electrons and feeds them into the electron transport chain.

Flavoprotein—A protein bonded to FAD.

Fluid mosaic model—The representation of the plasma membrane as a dynamic phospholipid bilayer with interactions of cholesterol, proteins, and carbohydrates.

Frameshift mutation—A change in DNA in which the reading frame of the codons in mRNA is shifted due to the insertion or deletion of nucleotides (other than in multiples of three).

Fructose—A monosaccharide found predominantly in fruit and honey.

Furanose—A five-membered ring sugar.

G protein-coupled receptors—A special class of membrane receptors with an associated GTP-binding protein; activation of a G protein-coupled receptor involves dissociation and GTP hydrolysis.

Galactose—A monosaccharide found predominantly in dairy.

Ganglioside—A sphingolipid with a head group containing an oligosaccharide and one or more *N*-acetylneuraminic acid (NANA) molecules.

Gap junctions—Cell–cell junctions that allow for the passage of small molecules between adjacent cells.

Gene—A unit of DNA that encodes a specific protein or RNA molecule.

Globoside—A sphingolipid with multiple carbohydrate groups attached as a head group.

Globular protein—A protein with a roughly spherical structure, such as myoglobin.

Glucagon—A mediator of glucose release that is secreted by pancreatic α-cells; rises in response to low blood glucose.

Glucogenic—Describes amino acids that can be converted into intermediates that feed into gluconeogenesis; all except leucine and lysine.

Gluconeogenesis—The production of glucose from other biomolecules; carried out by the liver and kidney.

Glucose—The primary monosaccharide used for fuel by all cells of the body, with the formula $C_6H_{12}O_6$.

Glycerol—A three-carbon alcohol that serves as the backbone for glycerophospholipids, sphingolipids, and triacylglycerols.

Glycerophospholipid—A lipid containing a glycerol backbone with a phosphate group, bonded by ester linkages to two fatty acids.

Glycogen—A branched polymer of glucose that represents a storage form of glucose.

Glycogenesis—The synthesis of glycogen granules.

Glycogenolysis—The breakdown of glycogen granules.

Glycolysis—The breakdown of glucose to two molecules of pyruvate, with the formation of energy carriers (NADH); occurs under both aerobic and anaerobic conditions.

Glycosidic linkage—The bond between the anomeric carbon of a sugar and another molecule.

Glycosphingolipid—A sphingolipid with a head group composed of sugars; includes cerebrosides and globosides.

Glycosylation—The addition of sugars to a molecule.

Haworth projection—A method for depicting cyclic sugars as planar rings with –OH groups sticking up or down from the plane of the sugar.

Hemiacetal—A carbon atom bonded to an alkyl group, an –OR group, an –OH group, and a hydrogen.

Hemiketal—A carbon atom bonded to two alkyl groups, an –OR group, and an –OH group.

Hess's law—A relationship that states that the total change in any state function is the same regardless of the path taken or the number of steps, and is equal to the difference between initial and final values of that state function.

Heterochromatin—The tightly coiled DNA that appears dark-colored under a microscope; transcriptionally inactive.

Heterogeneous nuclear RNA (hnRNA)—The precursor to processed mRNA; converted to mRNA by adding a poly-A tail and 5′ cap, and splicing out introns.

Histone—A structural protein about which DNA is coiled in eukaryotic cells.

Holoenzyme—An enzyme that has already bound a required prosthetic group, coenzyme, or cofactor.

Homeostasis—The stable internal state of an organism; homeostasis is not synonymous with equilibrium.

Homogenization—The process of breaking cell membranes and creating a uniform mixture of cell components for further separation; may be accomplished chemically or physically.

Hormone-sensitive lipase—The enzyme responsible for the mobilization of fatty acids from adipocytes; responds to a decrease in insulin levels.

Hydrolase—An enzyme that catalyzes the cleavage of a molecule with the addition of water.

Hydrolysis—Breaking a covalent bond with the assistance of a water molecule.

Hydrophilic—Being attracted to water; describes polar and charged compounds, and those that can participate in hydrogen bonding.

Hydrophobic—Being repelled by water; describes nonpolar, uncharged compounds (usually lipids or certain R groups of amino acids).

Hypertonic—A solution that has a greater concentration than the one to which it is being compared.

Hypotonic—A solution that has a lower concentration than the one to which it is being compared.

Induced fit model—The best-supported of the most prominent theories of enzyme specificity; states that the enzyme and substrate experience a change in conformation during binding to increase complementarity. Usually contrasted with the lock and key theory.

Inducible system—An operon that requires an inducer to remove a repressor protein from the operator site to begin transcription of the relevant gene.

Initiation—The start of translation, in which the small subunit of the ribosome binds to the mRNA molecule, and the first tRNA (methionine or *N*-formylmethionine) is bound to the start codon (AUG).

Insulin—The primary mediator of carbohydrate metabolism that is secreted by pancreatic β-cells; rises in response to high blood glucose.

Internal energy—The sum of all of the different interactions between and within atoms in a system; vibration, rotation, linear motion, and stored chemical energies all contribute.

Intron—A portion of hnRNA that is spliced out to form mRNA; remains in the nucleus during processing.

Irreversible inhibition—A decrease in enzyme activity that results from the interaction of an inhibitor that binds permanently at either the active site or an allosteric site; in laboratory settings, irreversible inhibitors are sometimes called suicide substrates.

Isoelectric focusing—A specialized method of separating proteins by their isoelectric point using electrophoresis; the gel is modified to possess a pH gradient.

Isoelectric point (pI)—The pH at which an amino acid is predominantly in zwitterionic form.

Isoform—A slightly different version of the same protein, often specific to a given tissue.

Isomerase—An enzyme that catalyzes the constitutional or stereochemical rearrangement of a molecule.

Isotonic—A solution that has the same concentration as the one to which it is being compared.

Jacob–Monod model—The description of the structure and function of operons in prokaryotes, in which operons have structural genes, an operator site, a promoter site, and a regulator gene.

Ketal—A carbon atom bonded to two alkyl groups and two –OR groups.

Ketogenesis—The synthesis of ketone bodies from the metabolic products of β-oxidation or amino acid metabolism; occurs under conditions of starvation.

Ketogenic—Describes amino acids that can be converted into ketone bodies.

Ketolysis—The breakdown of ketone bodies for use as acetyl-CoA.

Ketose—A sugar in which the highest-order functional group is a ketone; can be categorized by number of carbons (triose, tetrose, pentose, hexose, and so on).

Kinase—A specific transferase protein that catalyzes the movement of a phosphate group, generally from ATP, to a molecule of interest.

K_m—The concentration of substrate at which an enzyme runs at half its maximal velocity; a measure of enzyme affinity (the higher the K_m, the lower the affinity).

Lactose—A disaccharide composed of glucose and galactose.

Lariat—The lasso-shaped structure formed during the removal of introns in mRNA processing.

Ligase—An enzyme that catalyzes the synthesis of large polymeric biomolecules, most commonly nucleic acids.

Lipid—A molecule that is insoluble in water and soluble in nonpolar organic solvents.

Lipoprotein—The transport mechanism for lipids within the circulatory and lymphatic systems; includes chylomicrons and VLDL, which transport triacylglycerols; and HDL, IDL, and LDL, which transport cholesterol and cholesteryl esters.

Lock and key theory—One of the two most prominent theories of enzyme specificity; states that the enzyme and the substrate have a static but complementary state. Less-supported than the induced fit model.

Lyase—An enzyme that catalyzes the cleavage or synthesis of a molecule without the addition or loss of water.

Maltose—A disaccharide composed of two glucose molecules.

Matrix—The contents of the inner mitochondrial membrane; includes soluble enzymes of the electron transport chain and mitochondrial DNA.

Membrane receptors—Transmembrane protein molecules that act enzymatically or as ion channels to participate in signal transduction.

Messenger RNA (mRNA)—The strand of RNA formed after transcription of DNA; transfers to the cytoplasm to be translated.

Micelle—A collection of fatty acid or phospholipid molecules oriented to minimize free energy through hydrophobic and hydrophilic interactions; generally a sphere with a hydrophobic core and hydrophilic exterior.

Missense mutation—A mutation in which one amino acid is substituted for by a different amino acid.

Mitochondria—The organelle responsible for aerobic respiration, generating ATP from the breakdown products of other biomolecules and energy carriers reduced in various metabolic pathways; contains an inner and outer membrane.

Mixed inhibition—A decrease in enzyme activity that results from the interaction of an inhibitor with an allosteric site; mixed inhibitors bind to free enzyme and to substrate-bound enzyme with different affinities. They cannot be overcome by addition of substrate and impact both K_m and v_{max}.

Molten globules—Intermediate states in the folding of a protein.

Monocistronic—The coding pattern of eukaryotes in which one mRNA molecule codes for only one protein.

Monoprotic—Containing only one hydrogen (acid), or being able to pick up only one hydrogen (base).

Monosaccharide—A single sugar monomer; common examples are glucose, galactose, and fructose.

Motor proteins—Proteins that are involved in cell motility through interactions with structural proteins; motor proteins have ATPase activity and include myosin, kinesin, and dynein.

Mutarotation—The rapid interconversion between different anomers of a sugar.

Negative control—In prokaryotic genetics, an operon that requires the binding of a protein to decrease transcription.

Nicotinamide adenine dinucleotide (NAD^+)—An energy carrier that accepts electrons and feeds them into the electron transport chain.

Nicotinamide adenine dinucleotide phosphate ($NADP^+$)—An electron donor produced in the pentose phosphate

pathway that is involved in biosynthesis, oxidative stress, and immune function.

NMR spectroscopy—A method of determining molecular structure that uses the relative position of carbons and hydrogens determined by the relative shielding and spins of electrons observed when molecule is exposed to a magnetic field.

Noncompetitive inhibition—A decrease in enzyme activity that results from the interaction of an inhibitor with an allosteric site; noncompetitive inhibitors bind equally well to free enzyme and to substrate-bound enzyme. They cannot be overcome by addition of substrate.

Nonsense mutation—A mutation in which a coding codon is changed to a stop codon. Also called a truncation mutation.

Nontemplate synthesis—The method of *de novo* synthesis of lipids and carbohydrates that relies on gene expression and enzyme specificity rather than the genetic template of DNA or RNA.

N-terminus—The free amino end of a polypeptide.

Nuclear pore—A hole in the nuclear envelope that permits the entrance and exit of substrates.

Open system—A system capable of exchanging both matter and energy with the environment.

Operator site—A component of the operon in prokaryotes; a nontranscribable region of DNA that is capable of binding a repressor protein.

Operon—In prokaryotes, a cluster of genes transcribed as a single mRNA that can be regulated by repressors or inducers, depending on the system.

Osmosis—The simple diffusion of water.

Osmotic pressure—The pressure necessary to counteract the effect of an osmotic gradient against pure water; one of the colligative properties.

Oxidative phosphorylation—The transfer of a phosphate group, generally to ATP that is powered by a gradient formed by oxidation–reduction reactions; occurs in the mitochondria.

Oxidoreductase—An enzyme that catalyzes an oxidation–reduction reaction, often using an electron carrier as a cofactor.

Pancreatic lipase—The primary enzyme involved in the digestion of lipids.

Pancreatic proteases—The enzymes that are primarily responsible for the digestion of proteins in the small intestine; they include trypsin, chymotrypsin, and carboxypeptidases A and B, and are secreted as zymogens.

Paracellular transport—The transport of materials through the interstitial space without interactions with the cytoplasm or cell membrane.

Passive transport—The movement of a molecule down its concentration gradient without energy investment; includes simple and facilitated diffusion and osmosis.

Pentose phosphate pathway—A metabolic process that produces NADPH and ribose 5-phosphate for nucleotide synthesis.

Peptide—A molecule composed of more than one amino acid; can be subdivided into dipeptides (two amino acids), tripeptides (3), oligopeptides (up to 20), and polypeptides (more than 20).

Peptide bond—An amide bond between the carboxyl group of one amino acid and the amino group of another amino acid.

Phospholipid—A lipid containing a phosphate and alcohol (glycerol or sphingosine) joined to hydrophobic fatty acid tails.

Phosphorylation—The placement of a phosphate group onto a compound.

pK_a—The pH at which half of the of the molecules of a given acid are deprotonated; [HA] = [A^-].

Point mutation—The substitution of one nucleotide for another in DNA.

Polarity—An uneven sharing of electrons in a molecule, creating a slightly positive side and a slightly negative side.

Polycistronic—The coding pattern of prokaryotes, in which one mRNA may code for multiple proteins.

Polyprotic—Containing more than one hydrogen (acid), or being able to pick up more than one hydrogen (base).

Polysaccharide—A long chain of monosaccharides linked by glycosidic bonds; can be divided into homopolysaccharides (only one type of monosaccharide is used) and heteropolysaccharides (more than one type of monosaccharide is used).

Positive control—In prokaryotic genetics, an operon that requires the binding of a protein to increase transcription.

Prenylation—The addition of lipid groups to a molecule.

Primary structure—The linear sequence of amino acids in a polypeptide.

Promoter region—The portion of DNA upstream from a gene; contains the TATA box, which is the site where RNA polymerase II binds to start transcription.

Prostaglandin—A group of 20-carbon molecules that are unsaturated carboxylic acids derived from arachidonic acid; act as paracrine or autocrine hormones.

Prosthetic group—A cofactor or coenzyme that is covalently bonded to a protein to permit its function.

Proteinogenic—The ability of certain (20) amino acids to be integrated into proteins.

Proton-motive force—The proton concentration gradient across the inner mitochondrial membrane that is created in the electron transport chain and used in oxidative phosphorylation.

Pyranose—A six-membered ring sugar.

Pyruvate—An important metabolic intermediate that can feed into the citric acid cycle, fermentation, or gluconeogenesis.

Q cycle—The shuttling of electrons between ubiquinol and ubiquinone in the inner mitochondrial membrane as a part of Complex III's function.

Quaternary structure—The interaction between different subunits of a multisubunit protein; stabilized by R group interactions.

Reaction coupling—The tendency of unfavorable biological reactions to occur concurrently with favorable reactions, often catalyzed by a single enzyme.

Reducing sugar—A sugar that can reduce other compounds and can be detected by Tollen's or Benedict's reagent.

Release factor—The protein that binds to the stop codon during termination of translation.

Renaturation—The regaining of the correct secondary, tertiary, and quaternary structure after denaturation of a protein.

Repressible system—An operon that requires a repressor to bind to a corepressor before binding to the operator site to stop transcription of the relevant gene.

Repressor—For enzymes, an inhibitor of enzyme action; for operons, a species that binds to the operator region to stop transcription of the relevant gene.

Respiratory control—The coordinated regulation of the different aerobic metabolic processes.

Respiratory quotient—A numerical representation that can be used to determine the most prevalent type of biomolecule being used in metabolism; the ratio of carbon dioxide produced to oxygen consumed.

Respirometry—A method of measuring metabolism through the consumption of oxygen.

Resting membrane potential—The electrical potential that results from the unequal distribution of charge around the cell membrane; resting membrane potential characterizes a cell that has not been stimulated.

Ribonucleic acid (RNA)—A nucleic acid found in both the nucleus and cytoplasm and most closely linked with transcription and translation, as well as some gene regulation.

Ribosomal RNA (rRNA)—The structural and enzymatic RNA found in ribosomes that takes part in translation.

Ribozyme—An RNA molecule with enzymatic activity.

Saponification—The reaction between a fatty acid and a strong base, resulting in a negatively charged fatty acid anion bound to a metal ion; creates soap.

Saturation—The presence or absence of double bonds in a fatty acid; saturated fatty acids have only single bonds, whereas unsaturated fatty acids have at least one double bond.

Secondary structure—The local structure of neighboring amino acids; most common are α-helices and β-pleated sheets.

Sequencing—Determining the order of amino acids in a polypeptide, or of nucleotides in a nucleic acid.

Shine–Dalgarno sequence—The site of initiation of translation in prokaryotes.

Shuttle mechanism—A method of functionally transferring a compound across a membrane without the actual molecule crossing; common examples are the glycerol 3-phosphate shuttle and malate–aspartate shuttle.

Sialic acid—The common name of *N*-acetylneuraminic acid (NANA), which is the terminal portion of the head group in a ganglioside.

Side chain—The variable component of an amino acid that gives the amino acid its identity and chemical properties; also called an R group.

Silent mutation—A mutation in the wobble position of a codon or noncoding DNA that leads to no change in the protein produced during translation.

Simple diffusion—The movement of solute molecules through the cell membrane down their concentration gradients without a transport protein; used for small, nonpolar, lipophilic molecules and water.

Small nuclear ribonucleoproteins (snRNPs)—The protein portion of the spliceosome complex.

Small nuclear RNA (snRNA)—The RNA portion of the spliceosome complex.

Sodium–potassium pump—An ATPase that exchanges three sodium cations for two potassium cations; responsible for maintaining cell volume and the resting membrane potential.

Solvation layer—The layer of solvent particles that interacts directly with the surface of a dissolved species.

Sphingolipid—A lipid containing a sphingosine or sphingoid backbone, bonded to fatty acid tails; include ceramide, sphingomyelins, glycosphingolipids, and gangliosides.

Sphingomyelin—A sphingophospholipid containing a sphingosine backbone and a phosphate head group.

Spliceosome—The apparatus used for splicing out introns and bringing exons together during mRNA processing.

Starch—A branched polymer of glucose, used for energy storage in plants; common examples are amylose and amylopectin.

Start codon—The first codon in an mRNA molecule that codes for an amino acid (AUG for methionine or *N*-formylmethionine).

Stereoisomers—Compounds that have the same chemical formula and backbone, differing only in their spatial orientation; also called optical isomers.

Steroid—A derivative of cholesterol.

Stop codon—The last codon of translation (UAA, UGA, or UAG); release factor binds here, terminating translation.

Structural proteins—Proteins that are involved in the cytoskeleton and extracellular matrix; they are generally fibrous in nature and include collagen, elastin, keratin, actin, and tubulin.

Substrate—The molecule upon which an enzyme acts.

Substrate-level phosphorylation—The transfer of a phosphate group from a high-energy compound to ATP or another compound; occurs in glycolysis.

Sucrose—A disaccharide composed of glucose and fructose.

Surfactant—A compound that lowers the surface tension between two solutions, acting as a detergent or emulsifier.

TATA box—The site of binding for RNA polymerase II during transcription; named for its high concentration of thymine and adenine bases.

Tautomerization—The rearrangement of bonds within a compound, usually by moving a hydrogen and forming a double bond.

Template strand—The strand of DNA that is transcribed to form mRNA; also called the antisense strand.

Termination—The end of translation, in which the ribosome finds a stop codon and release factor binds it, allowing the peptide to be freed from the ribosome.

Terpene—A class of lipids built from isoprene moieties; have carbon groups in multiples of five.

Terpenoid—A terpene derivative that has undergone oxygenation or rearrangement of the carbon skeleton.

Tertiary structure—The three-dimensional shape of a polypeptide, stabilized by numerous interactions between R groups.

Thyroid hormones—The primary permissive metabolic hormones involved in the regulation of the basal metabolic rate.

Tight junctions—Cell–cell junctions that prevent the paracellular transport of materials; tight junctions form a collar around cells and link cells within a single layer.

Titration—A laboratory technique in which a solution of unknown concentration is mixed with a solution of known concentration to determine the unknown concentration.

Transcellular transport—The transport of materials through the cell; requires interaction with the cytoplasm and may require transport proteins.

Transcription—The production of an mRNA molecule from a strand of DNA.

Transcription factors—Proteins that help RNA polymerase II locate and bind to the promoter region of DNA.

Transfer RNA (tRNA)—A folded strand of RNA that contains a three-nucleotide anticodon that pairs with an appropriate mRNA codon during translation, and is charged with the corresponding amino acid.

Transferase—An enzyme that catalyzes the transfer of a functional group.

Translation—The production of a protein from an mRNA molecule.

Triacylglycerol—A glycerol molecule esterified to three fatty acid molecules; the most common form of fat storage within the body.

Uncompetitive inhibition—A decrease in enzyme activity that results from the interaction with an inhibitor at the allosteric site; uncompetitive inhibitors bind only to the substrate-bound enzyme and cannot be overcome by addition of substrate.

UV spectroscopy—A method of determining the concentration of protein in an isolate by comparison against a protein standard; relies on the presence of aromatic amino acids. It can also be used with nucleic acids and other compounds.

Vitamin—An organic essential coenzyme that assists an enzyme in carrying out its action.

Wax—A high-melting point lipid composed of a very long chain alcohol and a very long chain fatty acid.

Wobble—The third nucleotide of a codon that often plays no role in specifying an amino acid; an evolutionary development designed to protect against mutations.

X-ray crystallography—A method of determining molecular structure using apparent bond angles and diffraction and refraction of X-rays.

Zwitterion—A molecule that contains charges, but is neutral overall. Most often used to describe amino acids.

Zymogen—An enzyme that is secreted in an inactive form and must be activated by cleavage; common examples are digestive enzymes.

succinate dehydrogenase, 337, 344, 352
succinyl-CoA synthetase, 336–337, 352
α-ketoglutarate and CO_2 formation, 335–336
α-ketoglutarate dehydrogenase complex, 336, 340, 352
Cloning (DNA), 190–192, 202
Closed systems, 398
Coding strand (sense strand), 224
Codons, 217, 219–221, 220*f*
Coenzyme A (CoA; CoA–SH), 330, 330–331, 336
Coenzyme Q (CoQ; ubiquinone), 343–345, 352
Coenzymes, 46–47, 59, 143, 301, 331, 364
Cofactors, 46–47, 59
Colipase, 364, 386
Collagen, 21, 74
Colligative properties, 268–269
Column chromatography, 87, 88*f*, 95
Competitive inhibition, 54–56, 60
Complex carbohydrates, 118–122, 125
Conjugated proteins, 24, 28
Connexin, 264
Connexons (gap junctions), 264
Cooperative enzymes, 50, 60
Cooperativity, 23, 50
$CoQH_2$-cytochrome *c* oxidoreductase, 344–345, 352
Corepressors, 236
Cori cycle, 310
Cortisol
and hormone-sensitive triacylglycerol lipase, 367
as counterregulatory hormone, 307, 406
gluconeogenesis regulation, 309
structure, 413*f*
Counterregulatory hormones, 406
Creatine phosphate, 401, 418
Cristae, 274, 342
Cyanide, 329, 345
Cyclic adenosine monophosphate (cyclic AMP; cAMP), 146, 235
Cyclooxygenase (COX), 56, 146
Cysteine, 4, 5, 7, 21, 25, 26
Cystine, 21, 25, 27
Cytochrome *c* oxidase, 345, 352
Cytochromes, 329, 344, 345
Cytosine, 170

D

Debranching enzyme (glycosyl α-1,4:α-1,4 transferase, α-1,6 glucosidase), 305–306
Degenerate mutations, 221
Denaturation of proteins, 22, 24–25, 28
Deoxyribose, 116, 167*f*, 168
Deoxy sugars, 116
Desmosomes, 265, 277
Diabetes mellitus, 381, 411
Diabetes Mellitus,
Diastereomers, 110, 111, 124, 299
Dideoxyribonucleotides, 195–196
2,4-Dienoyl-CoA reductase, 379
Diffusion (simple diffusion), 267, 277
Dihydrolipoyl dehydrogenase, 330, 331
Dihydropropyl transacetylase, 331
Dihydroxyacetone, 108
Dihydroxyacetone phosphate (DHAP), 291, 295, 308, 346, 353
Dipeptidase, 383
Dipeptides, 16
Disaccharides, 118–119, 120, 125
Disulfide bonds, 21, 27
Diterpenes, 144
DNA-binding domain of transcription factors, 238
DNA cloning, 190–192, 202
DNA (deoxyribonucleic acid), general, 165–166, 199–202
DNA libraries, 192, 202–203
DNA ligase, 182, 186, 187, 189
DNA methylases, 241
DNA methylation, 186, 241
DNA polymerases, 181–183, 185–186, 187, 189, 194, 201–202
DNA repair
apurinic/apyrimidinic (AP; abasic) sites, 189
base excision repair, 188–189, 202
mismatch repair, 187, 202
nucleotide excision repair (NER), 187, 202
proofreading, 185–186
template strands, 186
tumor suppressor genes, 185, 202
DNA replication
daughter strands, synthesis, 180, 181–183
DNA ligase, 182, 186, 187, 189
DNA polymerases, 181–183, 185–186, 187, 189, 194, 201–202
DNA topoisomerase, 224
helicase, 180, 224, 239
leading and lagging strands, 181–182, 183
Okazaki fragments, 182, 186
origins of replication, 178–180, 201
parental strands, 180–181
proofreading, 185–186
replicating ends of chromosomes, 183–184
replication forks, 178–179, 181–182
replisome or replication complex, 178
RNA primase, 182
semiconservative replication, 180, 181*f*
single-stranded DNA binding protein, 180
sister chromatids, 177, 179
sliding clamp, 183
strand separation, 178–180, 181*f*
DNA sequencing, 19, 194–195
DNA structure
antisense strand, 224
B-DNA, 172–173
centromeres, 177, 179, 201
Chargaff's rules, 172, 200
coding strand (sense strand), 224
complementary base pairing, 171–172
denaturation, 173–174
deoxyribose in, 116, 167, 167*f*
double helix, 171–173
introns, 192
nomenclature, 168*t*
nucleosides, 166, 167*f*, 200
nucleotides, 166, 200
purines, 170–171
pyrimidines, 170–171
reannealing, 173
strand polarity, 169–170
Sugar-Phosphate Backbone, 168
supercoiling, 175, 180, 201
TATA box, 224, 225
telomeres, 177, 184, 201
template strands, 186, 216–217, 223–224
Watson-Crick model, 171–173, 200
Z-DNA, 173
DNA topoisomerase, 224
DNA transcription, 216–217, 223–225
Double helix, 171–173
Dyneins, 75

E

Edman degradation, 91
Elastin, 74
Electrochemical gradients, 270, 272, 345, 348, 353
Electron carriers, 274, 337, 350, 351, 404, 424
Electron transport chain (ETC)
ATP synthase, 345, 348–349, 350, 353, 401
complex III ($CoQH_2$-cytochrome *c* oxidoreductase), 344–345, 352
complex II (succinate-CoQ oxidoreductase), 344, 352
complex I (NADH-CoQ oxidoreductase), 343–344, 352
complex IV (cytochrome *c* oxidase), 345, 352
electron flow, 343–345
glycerol 3-phosphate shuttle, 346, 353
malate-aspartate shuttle, 347, 353
NADH shuttles, 345–346
proton-motive force, 342, 345, 348–349, 353
proton pumping, 344, 345
Q cycle, 345
respiratory complexes, 343–345

Electrophoresis
  gel electrophoresis and Southern blotting, 194
  isoelectric focusing, 85–86, 95
  migration velocity, 84
  native PAGE, 95
  polyacrylamide gel electrophoresis (PAGE), 85
  protein isolation, 83–85, 91, 95
  SDS-PAGE (sodium dodecyl sulfate-polyacrylamide gel electrophoresis), 85, 95
Elution, 89
Embedded proteins, 74, 262
Embryonic stem cells, 196, 198
Emulsification, 364
Enantiomers, 109–111, 124
Endocytosis, 271, 277
Endonucleases, 187, 189, 191–192
Enhancers, 23 ATP production 8–239
Enols, 116
Enoyl-CoA isomerase, 379
Enthalpy changes (ΔH), 22, 267, 399
Entropy changes (ΔS), 22, 267, 268, 399
Enzyme kinetics
  cooperative enzymes, 50, 60
  Lineweaver-Burk plots, 49, 54–55, 60, 81
  maximum velocity (v_{max}), 47–48, 54–55, 60, 81, 290
  Michaelis constant (K_m), 48–49
  Michaelis–Menten equation, 48–49, 60
  pH effects, 52, 60
  salinity effects, 52, 60
  saturation, 47, 60
  temperature effects, 51–52, 60, 194
Enzyme-linked receptors, 81, 95
Enzyme regulation
  allosteric activators, 56, 340
  allosteric enzymes, 56
  allosteric sites, 50, 54, 56, 61
  citric acid cycle regulation, 334, 338–340, 349
  competitive inhibition, 54–56, 60
  covalently modified enzymes, 56–57
  feedback regulation (feedback inhibition), 53, 60, 236, 339
  feed-forward activation, 294
  feed-forward regulation, 53, 294
  gluconeogenesis regulation, 307, 309–310, 406, 407
  glucose transporter regulation, 290–291
  glycogenesis regulation, 303
  glycogenolysis regulation, 305, 307
  glycogen synthase regulation, 304, 410
  glycolysis regulation, 293
  glycosylation of enzymes, 56–57, 61
  irreversible inhibition, 56, 60
  mixed inhibition, 55, 60
  negative feedback (feedback inhibition), 53, 59, 236, 339
  noncompetitive inhibition, 54–55, 60
  oxidative phosphorylation, 349
  pentose phosphate pathway regulation, 311
  phosphorylation of enzymes, 56, 61, 233
  pyruvate dehydrogenase complex regulation, 301, 309, 330, 339
  regulated enzymes, 56, 60
  reversible inhibition, 54–56, 60
  uncompetitive inhibition, 55, 60
  zymogens, 40–41, 57, 61, 383
Enzymes
  active sites, 44–45, 59
  allosteric enzymes, 56
  and activation energy, 42–43, 44, 60
  classifications, 40–41
  cofactors and coenzymes, 46–47, 59, 301
  cooperative enzymes, 50, 60
  covalently modified enzymes, 56–57
  enzyme-substrate complexes, 44–46, 48–49, 54–55, 60
  induced fit theory, 45–46, 59
  in gluconeogenesis, 309–311, 315–316
  in glycolysis, 291–293, 314
  lock and key theory, 44–45, 59
  mechanisms of activity, 44–47, 59
  regulated enzymes, 56, 60
  specificity, 40, 44, 59, 121
Epimers, 111, 124, 299
Epinephrine (adrenaline)
  and hormone-sensitive triacylglycerol lipase, 367
  as counterregulatory hormone, 307, 406
  gluconeogenesis regulation, 307, 407
  glycogenesis regulation, 303
  glycogenolysis regulation, 305, 307
  in postabsorptive state, 407
  in prolonged fasting (starvation), 406
  lipid mobilization, 367
  structure, 414
  target organs, 414
Erythrose, 111
Euchromatin, 176, 240
Excision endonucleases, 187
Exocytosis, 271, 277
Exons, 192, 226, 227
Expression (cDNA) libraries, 192*t*, 202

F

F_0 and F_1 portions of ATP synthase, 348–349, 353
Facilitated diffusion, 80, 269–270, 277
Fatty acids
  2,4-dienoyl-CoA reductase reaction, 379
  acetyl-CoA from, 308, 310, 332, 376–380
  activation, 376
  amphipathic molecules, 138
  arachidonic acid, 56, 146, 373
  enoyl-CoA isomerase reaction, 379
  free fatty acids, 149, 154, 310
  in biological membranes, 260
  in glycerophospholipids, 139, 260, 261*f*
  in micelles, 150–151, 154
  in phospholipids, 138–139
  in sphingolipids, 140
  in triacylglycerols, 148–149, 260, 261*f*
  in waxes, 140
  linoleic acid, 149, 260, 373, 389
  methylmalonyl-CoA mutase reaction, 378
  nomenclature, 373
  oleic acid, 149
  omega (ω) numbering system, 373
  oxidation (β-oxidation), 309, 332, 377–380, 387
  palmitic acid (palmitate), 149*f*, 373
  propionic acid pathway, 378
  propionyl-CoA carboxylase reaction, 378
  saponification and, 149, 150*f*, 154
  saturated fatty acids, 139, 260, 373, 386
  synthesis, 373–375, 387
  transport into mitochondria, 376–377
  unsaturated fatty acids, 139, 260, 373, 379, 386
Fatty acid synthase (palmitate synthase), 373, 374–375
Fatty acyl CoA-synthetase, 376
Feedback loops, 408, 412
Feedback regulation (feedback inhibition), 53, 60, 236, 339
Feed-forward activation, 294
Feed-forward regulation, 53, 294
Fermentation, 294, 403
Fibroin (silk protein), 20
Fibrous proteins, 21, 74
First Law of Thermodynamics, 398
Fischer projections, 5, 110, 113, 124
Flagella, 75
Flavin adenine dinucleotide (FAD), 331, 343, 404
Flavin mononucleotide (FMN), 343, 404
Flavoproteins, 337, 343, 352, 404
Flippases, 259
Fluid mosaic model (biological membranes), 257–259, 262, 275, 276
Frameshift mutations, 221–222
Free energy (ΔG)
  ATP synthase reaction, 348
  from hydrolysis of phosphate compounds, 401
  Gibbs free energy equation, 399
  nonspontaneous reactions, 22, 267, 399
  physiological conditions, 399–400
  pyruvate dehydrogenase complex reaction, 330
  reaction diagrams, 42
  spontaneous reactions, 42*f*, 267, 399

Fructose, 299, 308, 315
Fructose-1,6-bisphosphatase, 309–310, 315, 411
Fumarase, 337, 352
Furanose rings, 112

G

G6PD deficiency (favism), 311
Galactokinase, 299
Galactose, 298–299, 308, 314
Galactose-1-phosphate uridyltransferase, 299
γ-Aminobutyric acid (GABA), 4, 81
Gangliosides, 141, 261
Gap junctions (connexons), 264, 277
Gene amplification, 238–239
Gene, definition, 216
Gene duplication, 239
Gene expression
  activation domain of transcription factors, 238
  chromatin structure regulation, 239–241, 245
  cis regulators, 238
  control in eukaryotes, 238–241, 245
  control in prokaryotes, 234–237, 244–245
  corepressors, 236
  DNA-binding domain of transcription factors, 238
  DNA methylation, 186, 241
  enhancers, 238–239
  gene amplification, 238–239
  gene duplication, 239
  histone acetylation, 240–241
  inducible systems, 235, 245
  Jacob-Monod model, 234
  lac operon, 235, 236
  operator sites, 234, 236
  operon structure, 234
  promoter sites, 224, 234, 238–239
  regulator genes, 234, 236
  repressible systems, 236, 237, 245
  repressor proteins, 234, 235
  retinoic acid and, 147
  steroid hormones and, 145
  structural genes, 234
  thymine dimers and, 187
  transcription factors, 224, 238–241, 245
  trp operon, 234, 236
Gene therapy, 195, 196
Genetic code
  central dogma of molecular biology, 216, 243
  codons, 217, 219–221, 220*f*
  degeneracy, 221
  flow of genetic information from DNA to protein, 217*f*
  gene, definition, 216
  start codon, 221, 227, 230
  stop codons, 221, 227, 232
  wobble position in codons, 221
Genomic libraries, 192, 202
Germline cells and transgenic animals, 197
Ghrelin, 421
Gibbs free energy equation, 399
Globosides, 140
globular proteins, 21
Globular proteins, 21
Glucagon
  and fatty acid oxidation, 376
  as counterregulatory hormone, 307, 406
  functional relationship of glucagon and insulin, 412
  gluconeogenesis regulation, 307, 309–310, 406
  glycogenesis regulation, 303
  glycogenolysis regulation, 305, 307
  glycolysis regulation, 293
  in postabsorptive state, 406
  in prolonged fasting (starvation), 406
Glucocorticoids, 412–413
Glucokinase
  and insulin, 290, 410
  glucose phosphorylation, 117, 293, 309, 314
  irreversible reaction, 295, 309
Gluconeogenesis
  enzymes, 309–311, 315–316
  fructose-1,6-bisphosphatase, 309–310, 315, 411
  glucogenic amino acids, 307–308, 310, 383
  glucose-6-phosphatase, 310, 316
  in postabsorptive state, 406
  in prolonged fasting (starvation), 406–407
  phosphoenolpyruvate carboxykinase (PEPCK), 309, 315, 411
  phosphoenolpyruvate (PEP), 309, 411
  pyruvate carboxylase, 301, 309–310, 315, 330, 377, 385
Glucose
  concentration in blood, 290, 398, 410
  cyclic anomeric forms, 113*f*
  esterification, 116–117
  phosphorylation, 116–117
  structure, 108
Glucose-6-phosphatase, 310, 316, 410
Glucose-6-phosphate dehydrogenase (G6PD), 311–312, 316
Glucose transporters, 290–291, 293, 314
Glutamic acid (glutamate), 3, 8, 15, 233
Glutamine, 7, 8, 9
Glutathione, protection against reactive oxygen species, 312–313
Glyceraldehyde, 108, 109–110, 299
Glyceraldehyde-3-phosphate dehydrogenase, 294, 314
Glycerol
  and saponification, 149
  from glycerol 3-phosphate, 295
  in glycerophospholipids, 139–140
  in triacylglycerols, 148–149, 260, 291–292, 310
Glycerol 3-phosphate, 295, 307, 308, 346, 375
Glycerol 3-phosphate shuttle, 346, 353
Glycerophospholipids (phosphoglycerides), 139–140, 153, 260, 261
Glycine, 4, 5, 12, 13–15, 26
Glycogen metabolism
  branching enzyme (glycosyl α-1,4:α-1,6 transferase), 304
  debranching enzyme (glycosyl α-1,4:α-1,4 transferase, α-1,6 glucosidase), 305–306
  glycogenesis, 303–305, 315
  glycogenolysis, 305–306, 315
  glycogen phosphorylase, 122, 293, 305–306, 315, 414
  glycogen storage diseases, 306
  glycogen synthase, 293, 303, 304, 315
Glycogen, structure and function, 122, 123, 148, 302
Glycolipids, 140–141
Glycolysis
  1,3-bisphosphoglycerate, 294, 295
  3-phosphoglycerate kinase, 294, 314
  ATP production, 293, 295, 329, 338, 353
  enzymes, 292–294, 314
  fermentation, 294, 403
  glyceraldehyde-3-phosphate dehydrogenase, 294, 314
  hexokinase, 117, 293, 295, 310, 314
  in red blood cells (erythrocytes), 291, 295–296
  irreversible reaction steps, 295
  lactate dehydrogenase, 294, 301, 308, 314, 403–404
  NADH production, 291, 294
  phosphoenolpyruvate (PEP), 294, 295
  phosphofructokinase-1 (PFK-1), 309, 310, 314
  phosphofructokinase-2 (PFK-2), 314
  pyruvate kinase, 294, 295, 309, 314
  substrate-level phosphorylation, 294, 295, 314
Glycoprotein coat around cells, 258, 263
Glycoproteins, definition, 24
Glycosides, 117
Glycosidic linkages (glycosidic bonds), 108, 117, 118–119, 119–121, 140
Glycosphingolipids, 140–141, 153
Glycosylation of enzymes, 56–57, 61
Glycosylation of proteins, 233
Goldman-Hodgkin-Katz voltage equation, 273
G protein-coupled receptors (GPCRs), 81–82, 95, 262, 264
G proteins, 81–82, 94, 262
Gramicidin, 5
Growth hormone, 406
Guanine, 170

H

Half-reactions (oxidation–reduction), 403–404
Haworth projections of carbohydrates, 113
Helicase, 180, 224, 239
Hemiacetals, 112–114, 115, 117
Hemidesmosomes, 265, 277
Hemiketals, 112
Hemoglobin
  2,3-bisphosphoglycerate (2,3-BPG) binding, 296–297
  cooperative bonding, 50
  effect of 2,3-bisphosphoglycerate, 295–296
  heme group, 24, 344
  in sickle cell anemia, 3
  oxygen dissociation curve, 295
  quaternary protein structure, 21, 23, 233
Hepatitis C, 215
Hess's law, 402
Heterochromatin, 176–177, 239–240, 241
Heterogeneous nuclear RNA (hnRNA), 225, 225–227
Heterotrimeric G protein, 81–82
Hexokinase, 117, 293, 295, 310, 314
High-energy electron carriers, 274, 337, 350, 351, 404, 424
Histidine, 8, 9, 411
Histone acetylases, 240
Histone acetylation, 240–241
Histone deacetylases, 241
Histones, 175–176, 200
HMG CoA reductase (3-hydroxy-3-methyl-glutaryl CoA reductase), 372
Homeostasis, 53, 364, 405, 408, 412
Homogenization, 83
Hormones
  fat-soluble peptide/amino acid-derived hormones, 408
  feedback loops, 408, 412
  hormonal regulation of metabolism, 408–416, 425
  water-soluble peptide hormones, 408
Hormone-sensitive lipase, 411, 414, 417
Hormone-sensitive triacylglycerol lipase (HSL), 367
Hückel's rule, 170
Hybridization, 174, 193, 203
Hydrogen bonds, 19, 20, 21–22, 25, 27
Hydrolases, 41, 59
3-Hydroxy-3-methyl-glutaryl (HMG) CoA reductase, 372
3-Hydroxybutyrate (β-hydroxybutyrate), 380–382
Hyperglycemia, 411
Hypertonic solutions, 268
Hypoglycemia, 411, 421
Hypotonic solutions, 268

I

Imidazole ring, 8
Immunoglobulins (Ig), 22, 77–78, 94
Induced fit theory, 45–46, 59
Inducible systems, 235*f*, 245
Inner mitochondrial membrane, 274
Inositol, 260
Insulin
  and cholesterol synthesis, 372
  and fatty acid oxidation, 376
  and fatty acid synthesis, 373, 375
  and hormone-sensitive triacylglycerol lipase, 367
  functional relationship of glucagon and insulin, 412
  function in postprandial state, 404–405
  gluconeogenesis regulation, 307, 310, 407
  glucose transporter regulation, 290–291
  glycogen synthase regulation, 304, 410
  glycolysis regulation, 293
  in postabsorptive state, 407
  pentose phosphate pathway regulation, 311
  post translational cleavage, 232
  pyruvate dehydrogenase regulation, 300
  recombinant human insulin, 190
  target tissues, 405
Integral proteins, 262
Integrative metabolism, 419–422, 426
Integrins, 77, 94
Internal energy changes (ΔU), 398
Introns, 192, 219, 226, 239
Ion channels
  F_0 portion of ATP synthase, 348–349, 353
  facilitated diffusion, 269–270
  leak channels, 272, 273
  ligand-gated channels, 81, 95, 264
  ungated channels, 80, 94
  voltage-gated channels, 80, 94
Ion-exchange chromatography, 88, 95
Irreversible inhibition, 56, 60
Isocitrate dehydrogenase, 335, 340, 349, 350, 352, 374
Isocitrate formation, 335
Isoelectric focusing, 85–86, 95
Isoelectric point (pI), 14, 26–27, 85, 95
Isoforms, 306, 346
Isoleucine, 5, 9, 220
Isomerases, 41, 59
Isoprene, 143–144
Isotonic solutions, 268

J

Jacob-Monod model, 234

K

Keratins, 19, 74, 94
Ketals, 117
Ketogenesis, 381, 411
Ketogenic amino acids, 307, 332, 383
Ketolysis, 381–382
Ketone bodies
  conversion to acetyl-CoA, 333
  from acetyl-CoA, 310, 377, 380, 381, 387, 407
  from amino acids, 307, 332, 383
Ketoses, 108, 116
Kinases, 41, 293, 309
Kinesins, 75
Knockout mice, 197, 421

L

Lac operon, 235, 236*f*
Lactase, 40, 235, 298
Lactate
  from anaerobic glycolysis, 294, 307, 417
  gluconeogenesis, 307, 308, 310
  gluconeogenic intermediate, 308
Lactate dehydrogenase, 294, 301, 308, 314, 403–404
Lacteals, 366
Lactones, 115
Lactose, 119, 120*f*, 235, 298
Lactose intolerance, 298
Lariat structures, 226
Leak channels, 272, 273
Lecithin-cholesterol acyltransferase (LCAT), 372
Lecithins, 151, 260
Leptin, 421
Leucine, 5, 6*f*, 9, 22
Ligand-binding domain (enzyme-linked receptors), 81
Ligases, 41, 59
Lineweaver-Burk plots, 49, 54–55, 60, 81
Lipid metabolism and transport
  absorption, 365, 366
  apolipoproteins (apoproteins), 368, 369, 370, 371
  chylomicrons, 260, 366, 367, 368–369, 386, 417
  digestion, 364, 365
  glycerophospholipids on lipoproteins, 260
  high-density lipoprotein (HDL), 368, 370
  hormone-sensitive triacylglycerol lipase (HSL), 367
  in postabsorptive state, 407
  in prolonged fasting (starvation), 406
  intermediate-density lipoprotein (IDL), 369
  lipoprotein lipase (LPL), 367, 371, 410, 417
  lipoproteins, definition, 24, 368
  lipoproteins, functions of, 368–369
  lipoprotein structure, 368
  low-density lipoprotein (LDL), 370
  micelles, 138, 150–151, 154, 260, 365–366, 386
  mobilization of lipids, 367–368
  very low-density lipoproteins (VLDL), 417, 260
Lipid rafts, 258
Lipid structure and function
  energy storage, 148–151, 154, 400
  glycerophospholipids (phosphoglycerides), 139–140, 153, 260, 261*f*
  glycolipids, 140–141

in biological membranes, 259–262, 276
phospholipid bilayers, 138, 139, 145, 257–258, 259, 262
phospholipids, 137, 138–140, 153, 260
prostaglandins, 56, 146, 154
signaling lipids, 143–148, 153–154
sphingolipids, 139, 140–141, 153, 261
steroid hormones, 145, 412–413
steroids, 144–145, 145*f*, 153, 262
sterols, 137
structural lipids, 138–143, 153
terpenes, 137, 143–144, 153
terpenoids, 144
waxes, 142*f*, 262
Lipoprotein lipase (LPL), 367, 371, 410, 417
Lipoproteins
apolipoproteins (apoproteins), 368, 369, 370, 371
chylomicrons, 260, 366, 367, 368–369, 386, 417
functions of, 368–369
glycerophospholipids on, 260
high-density lipoprotein (HDL), 368, 370
intermediate-density lipoprotein (IDL), 369
low-density lipoprotein (LDL), 370
structure, 368
very low-density lipoproteins (VLDL), 417, 260
Liposomes, 138
Liver
gluconeogenesis, 307–308, 309–310, 382
glucose regulation, 290, 417
glycogen storage and metabolism, 302, 304, 306, 407
ketogenesis and ketolysis, 380–381
lipid storage and metabolism, 367
lipid synthesis, 373
metabolic role overview, 416
urea cycle, 383, 384*f*
Liver, metabolic role, 417
Lock and Key Theory, 44–45, 59
Lowry reagent assay, 91
Lyases, 41, 59
Lysine, 4, 8, 9, 15, 18, 411

M

Malate-aspartate shuttle, 347, 353
Malate dehydrogenase, 337, 346, 352
Maltose, 119, 120, 122
Maximum velocity (v_{max}), 47–48, 54–55, 60, 81, 290
Membrane-associated (peripheral) proteins, 262
Membrane potential (V_m), 80, 270, 272–273, 278–279
Membrane receptors, 81, 264
Membrane-spanning domain (enzyme-linked receptors), 81
Membrane transport
active transport, 267, 270
antiports, 270
concentration gradients, 80, 267, 277
endocytosis, 271, 277
exocytosis, 271, 277
paracellular transport and, 265, 277
passive transport, 267–270, 277
phagocytosis, 271
pinocytosis, 271
primary active transport, 270
secondary active transport, 270
symports, 270
thermodynamics, 267
Menaquinones (vitamin K_2), 147, 154
Messenger RNA (mRNA)
3´ polyadenosyl (poly-A) tail, 227
5´ Cap, 227
base pairing of aminoacyl tRNA with mRNA, 220, 227–228
mRNA translation and protein synthesis, 216, 217, 227, 228
post-transcriptional processing, 243–244
ribosome recognition of mRNA binding site, 227
Shine-Dalgarno sequence, 230
splicing, 226
structure, 218
synthesis, 224–225
Metabolic states
homeostasis, 53, 364, 405, 408, 412
postabsorptive (fasting) state, 406–407, 412, 425
postprandial (absorptive or well-fed) state, 405–406, 425
preferred fuels in well-fed and fasting states, 417
prolonged fasting (starvation), 407–408
Metastasis, 185, 202
Methanol poisoning, 54
Methionine, 5*f*, 221, 230–231, 244
Methylmalonyl-CoA mutase, 378
Micelles, 138, 150–151, 154, 260, 365–366, 386
Michaelis constant (K_m), 48–49
Michaelis–Menten equation, 48–49, 60
Microtubules, 74, 75, 177
Mismatch repair, 187, 202
Missense mutations, 221
Mitochondria
absence from red blood cells, 310
cristae, 274, 342
fatty acid transport into, 376–377
fatty acid β-oxidation in, 377–380, 387
mitochondrial DNA, 183
mitochondrial membranes, 273–274, 278, 342
structure, 342*f*
Mixed inhibition, 55, 60
Modified standard state, 399
Molten globules, 22
Monocistronic RNA, 217
Monosaccharides
classification, 107, 124
common names, 108–109
definition, 107
nomenclature, 108–109
reactions of, 115–118, 124
Monoterpenes, 144
Motifs, 74
Motor proteins, 74, 75, 94
Muscle
active muscle metabolism, 418
cardiac muscle, 416
glucose transport, 290–291
glycogen storage and metabolism, 302, 304, 306, 310
ketone metabolism, 380
motor proteins, 75, 94
protein catabolism, 382
resting muscle metabolism, 418
skeletal muscle metabolism, 418
Mutarotation, 113–114
Mutations
and cancer, 185
frameshift mutations, 221–222
in mRNA splice sites, 228
missense mutations, 221
nonsense mutations (truncation mutations), 221
on the lagging strand, 186
point mutations, 221, 243
severe combined immunodeficiency (SCID), 195
sickle cell hemoglobin mutation, 3
silent or degenerate mutations, 221
wobble position in codons, 221
Myoglobin, 21, 24
Myosin, 75

N

N-acetylneuraminic acid (NANA; sialic acid), 141
NADH
as energy carrier, 312
citric acid cycle, 334, 335–338, 340–341
electron transport chain, 342, 343–344, 377
from glycolysis, 290, 294, 339
lactate dehydrogenase oxidation, 294
pyruvate dehydrogenase complex and, 330, 331, 338
NADH-CoQ oxidoreductase, 343–344, 352
NADH shuttles, 345–346
NADPH
electron donor functions, 312–313
from pentose phosphate pathway, 310
glutathione reduction, 312–313
Negative feedback (feedback inhibition), 53, 59, 236, 339
Nernst equation, 273
NMR spectroscopy, 95
Noncompetitive inhibition, 54–55, 60
Nonsense mutations, 221
Nontemplate synthesis, 373
Norepinephrine (noradrenaline), 406, 414
Nuclear pores, 228
Nucleases, 180, 187, 191–192

Nucleic acids
complementary base pairing, 171–172
nomenclature for bases, nucleosides, and nucleotides, 168*f*
nucleosides, 166, 168*t*, 200
nucleotides, 166, 168, 200
purines, 170–171
pyrimidines, 170–171
ribose and deoxyribose in, 167, 168*f*
strand polarity, 169–170
Nucleoproteins, 24, 176
Nucleosides, 166, 168*t*, 200
Nucleosomes, 175*f*
Nucleotide excision repair (NER), 187*f*, 202
Nucleotides, 166, 168*t*, 200

O

Occluded state, 269
Okazaki fragments, 182, 186
Oligopeptides, 16
Oncogenes, 185, 202
Open systems, 398
Operator sites, 234, 236
Operons
catabolite activator protein (CAP), 235
corepressors, 236
inducible systems, 235, 245
Jacob-Monod model, 234
lac operon, 235, 236*f*
operator sites, 234, 236
promoter sites, 224, 234, 238–239
regulator genes, 234, 236
repressible systems, 236, 237*f*, 245
repressor proteins, 234, 235
structural genes, 234
structure, 234
trp operon, 234, 236
Opsonization, 78
Orexin, 421
Origins of DNA replication, 178–180
Ornithine, 4
Osmolarity, 52, 268
Osmosis, 267–269, 277
Osmotic pressure, 268–269, 277
Outer mitochondrial membrane, 273–274
Oxaloacetate formation, 337*f*
Oxidants, 41
Oxidative phosphorylation
ATP production, 295, 338, 353, 401, 404
ATP synthase, 345, 348–349, 350, 353, 401
chemiosmotic coupling, 348–349, 353
conformational coupling, 348
regulation, 349
Oxidoreductases
biological oxidation and reduction, 403–405
complex III ($CoQH_2$-cytochrome *c* oxidoreductase), 344–345, 352
complex II (succinate-CoQ oxidoreductase), 344, 352
complex I (NADH-CoQ oxidoreductase), 343–344, 352
general, 41, 58

P

Pancreatic lipase, 364, 386
Paracellular transport, 265, 277
Partitioning (chromatography), 86, 87*f*
Passive transport
carriers, 258, 269
concentration gradients, 80, 267, 277
facilitated diffusion, 80, 269–270, 277
osmosis, 267–269, 277
simple diffusion, 267, 277
Pentose phosphate pathway, 311–313, 316
Pepsin, 52, 382
Peptide bond formation in translation, 231
Peptide bonds
chymotrypsin and, 18, 40, 91, 382
C-terminus, 17
formation during translation, 231
formation in dehydration reaction, 17, 27
hydrolysis, 17–18, 27
N-terminus, 17
peptide residues, 16
resonance in, 17
trypsin and, 18, 91, 382
Peptide residues, 16
peptides, structure and classification, 16
Peptides, structure and classification, 16
Peptidyl transferase, 231, 232
Phagocytosis, 271
pH, effects on enzyme activity, 52, 60
Phenylalanine, 6, 9*f*, 18, 40
Phosphatidylcholine, 139, 140, 260
Phosphatidylethanolamine, 139
Phosphatidylinositol, 260, 261*f*
Phosphoenolpyruvate carboxykinase (PEPCK), 309, 315, 411
Phosphoenolpyruvate (PEP), 294, 295, 309, 411
Phosphofructokinase-1 (PFK-1), 309, 310, 314
Phosphofructokinase-2 (PFK-2), 314
Phospholipase C, 82
3-Phosphoglycerate kinase, 294, 314
Phospholipid bilayers, 138, 139, 145, 257–258, 259, 262
Phospholipids, 137, 138–140, 153, 260
phosphorylation of proteins, 233
Phylloquinone (vitamin K_1), 147, 154
Pinocytosis, 271
Plasmids, 191, 192
β-pleated sheets, 19, 20, 27
Point mutations, 221, 243
Polyacrylamide gel, 84
Polyacrylamide gel electrophoresis (PAGE), 85
Polycistronic RNA, 217
Polymerase chain reactions (PCR), 174, 190, 194, 203
Polypeptides, 16
Polysaccharides, 120–122, 125
Postabsorptive (fasting) state, 406–407, 412, 425
Postprandial (absorptive or well-fed) state, 405–406, 425
Post-translational modifications, 232–233
Prenylation of proteins, 233
primary structure, 27
Probe DNA, 174
Proline, 5, 20, 27, 246
Prolonged fasting (starvation), 407–408
Promoter sites, 224, 234, 238–239
Propionic acid pathway, 378
Propionyl-CoA carboxylase, 378
Prostaglandins, 56, 146, 154
Prosthetic groups, 24, 28, 46, 404
Proteases, 382
Protein analysis
activity analysis, 91
bicinchoninic acid (BCA) assay, 91
Bradford protein assay, 91–92
concentration determination, 91–92, 96
digestion, 91
Edman degradation, 91
Lowry reagent assay, 91
NMR spectroscopy, 95
protein structure determination, 90–91
sequencing, 19, 91, 96
UV spectroscopy, 91
X-ray crystallography, 90–91, 95
Protein catabolism, 382–385, 387
Protein folding, 21, 22
Protein function (nonenzymatic)
binding proteins, 76, 94, 180
cell adhesion molecules (CAMs), 76–77, 94, 264
cellular functions, overview, 94
embedded proteins, 74, 262
immunoglobulins (Ig), 22, 77–78, 94
integral proteins, 262
membrane-associated (peripheral) proteins, 262
membrane proteins, 262, 276
motor proteins, 74, 75, 94
structural proteins, 74, 94
transmembrane proteins, 262, 264, 265
Protein isolation, 83–89
Protein structure, 3–34
hydrophobic interactions, 9, 21–22, 25, 27
Proto-oncogenes, 185
Purines, 170–171
Pyranose rings, 112
Pyrimidines, 170–171
Pyruvate
conversion to acetyl-CoA, 299–300, 330–331
fermentation to ethanol, 294
reduction by lactate dehydrogenase, 294

Pyruvate carboxylase, 301, 309–310, 315, 330, 377, 385
Pyruvate dehydrogenase complex
dihydrolipoyl dehydrogenase, 330, 331
dihydropropyl transacetylase, 331
energy yield, 353
pyruvate conversion to acetyl-CoA, 300–301, 330–331, 351
pyruvate dehydrogenase kinase, 330, 339
pyruvate dehydrogenase (PDH), 300–302, 308, 309, 315, 330–331
pyruvate dehydrogenase phosphatase, 330, 339
reaction mechanism, 301, 309, 330–331, 351
regulation, 329, 339
Pyruvate dehydrogenase kinase, 330, 339
Pyruvate dehydrogenase (PDH), 300–302, 308, 309, 315, 330–331
Pyruvate dehydrogenase phosphatase, 330, 339
Pyruvate kinase, 294, 295, 309, 314

Q

Q cycle, 345
Quaternary structure, 22–24, 27–28

R

Receptor tyrosine kinases (RTK), 81
Recombinant DNA, 190, 202
Recombinant proteins, 190, 192
Recombinant vectors, 191–192
Red blood cells (erythrocytes)
ABO blood typing system, 140, 263
cell lysis, 311, 313
Cori cycle, 310
glycolysis, 291, 295–296
lack of mitochondria, 291
osmolarity, 268
oxidative stress, 311
sickle cell anemia, 3
Reducing sugars, 115–116
Reductants, 41
Regulation of body mass, 420–421
Regulator genes, 234, 236
Replisome or replication complex, 178
Repressible systems, 236, 237*f*, 245
Repressor proteins, 234, 235
Respiratory quotient (RQ), 419–420
Respirometry, 419–420
Resting membrane potential, 273, 278
Restriction enzymes (restriction endonucleases), 191–192, 202
Retinal, 137, 144, 146, 154
Retinoic acid, 147
Retinol, 146–147
Retroviral gene therapy, 196*f*
Reversible inhibition, 54–56, 60
Riboflavin (vitamin B_2), 46, 404
Ribose, 111, 167, 168*f*
Ribosomal RNA (rRNA), 219, 223, 229–230
Ribosomes
A site, 231
E site, 231
mRNA translation and protein synthesis, 216, 217, 227, 228
P site, 231
tRNA interaction, 218
Ribozymes, 219
Rickets, 147
RNA polymerases, 217, 224–225, 229, 234–235
RNA primase, 182
RNA primers, 183, 193, 201
RNA (ribonucleic acid)
3′ polyadenosyl (poly-A) tail, 227
5′ Cap, 227
alternative splicing of hnRNA, 227
anticodons in tRNA, 218, 220, 228, 230
base pairing of aminoacyl tRNA with mRNA, 220, 227–228
charged or activated transfer RNA, 218
codons, 217, 219–221
exons, 192, 226, 227
heterogeneous nuclear RNA (hnRNA), 225, 225–227
initiator tRNA, 230
introns, 219, 226, 239
lariat structures, 226
messenger RNA (mRNA) structure, 217
monocistronic RNA, 217
mutations in splice sites, 227
nomenclature for bases, nucleosides, and nucleotides, 168
nucleosides, 166*f*
nucleotides, 166*f*
polycistronic RNA, 217
post-transcriptional processing, 225–227, 243–244
purines, 170–171
pyrimidines, 170–171
ribose in, 167, 168
ribosomal RNA (rRNA), 219, 223, 229–230
ribozymes, 219
Shine-Dalgarno sequence in mRNA, 230
small nuclear ribonucleoproteins (snRNPs or snurps), 226
small nuclear RNA (snRNA), 224, 226
splicing, 226
start codon, 221, 227, 230
transcription, 216–217, 223–225, 243–244
transfer RNA (tRNA), overview, 218–219
transfer RNA (tRNA), role in translation, 231–235
transfer RNA (tRNA), synthesis, 223
Rocky Balboa, 73

S

Salinity, effects on enzyme activity, 52, 60
Saponification, 149, 150, 154
Sarcolemma, 272
Saturated fatty acids, 139, 260, 373, 386
Saturation kinetics, 47, 60
SDS-PAGE (sodium dodecyl sulfate-polyacrylamide gel electrophoresis), 85, 95
SDS (sodium dodecyl sulfate, sodium lauryl sulfate), 25
Secondary structure, 19–20
Second messenger cascades, 81, 260, 408, 411
Selectins, 76–77, 94
Sequencing of DNA, 19, 194–195
Sequencing of primary structure of proteins, 19, 91, 96
Serine, 7, 22
Sesquiterpenes, 144
Severe combined immunodeficiency (SCID), 195
Shine–Dalgarno sequence, 230
Shuttle mechanisms
acetyl-CoA shuttle, 374
carnitine shuttle, 376, 387
citrate shuttle, 372
glycerol 3-phosphate shuttle, 346, 353
malate-aspartate shuttle, 347, 353
NADH shuttles, 345–346
Q cycle, 345
Sickle cell anemia, 3
Signaling lipids, 143–148, 153–154
Silent mutations, 221
Single-stranded DNA binding protein, 180, 201
Size-exclusion chromatography, 88–89, 95
Skeletal muscle, metabolic role overview, 418
Small nuclear ribonucleoproteins (snRNPs, or “snurps”), 226
Small nuclear RNA (snRNA), 224, 226
Soaps, 149–151, 154
Sodium-potassium pump (Na^+/K^+ ATPase), 272–273
Solvation layer, 22
Southern blotting, 194, 203
Specificity of enzymes, 40, 44, 59, 121
Spermaceti, 137
Sphingoid compounds, 140
Sphingolipids, 139, 140–141, 153, 261
Sphingomyelins, 140, 153, 141
Sphingosine, 139, 140
Spliceosome, 226
Standard-state conditions, 398
Starches, 121–122, 302, 303*f*
Start codon, 221, 227, 230
Steroid hormones, 145, 412–413
Steroids, 144–145, 145*f*, 153, 262
Sterols, 137
Stop codons, 221, 227, 232
Structural genes, 234
Structural lipids, 138–143, 153
Structural proteins, 74, 94
Substrate-level phosphorylation, 294, 295, 314

Substrates, 44
Succinate-CoQ oxidoreductase, 344, 352
Succinate dehydrogenase, 337, 344, 352
Succinyl-CoA synthetase, 336–337, 352
Sucrose, 119, 120, 299
Supercoiling of DNA, 175, 180, 201
Surfactants, 150
Symports, 270

T

TATA box, 224, 225
Tautomerization, 116
Telomerase, 177
Telomeres, 177, 184, 201
Temperature, effects on enzyme activity, 51–52, 60, 194
Template strands
  DNA repair, 185, 187
  DNA transcription, 216, 217, 223–224
Terpenes, 137, 143–144, 153
Terpenoids, 144
Tertiary structure, 21–22, 27
Tetraterpenes, 144
Thermodynamics
  bioenergetics, overview, 398–400, 424
  closed systems, 398
  enthalpy changes (ΔH), 22, 267, 399
  entropy changes (ΔS), 22, 267, 268, 399
  First Law of Thermodynamics, 398
  internal energy changes (ΔU), 398
  modified standard state, 399
  open systems, 398
  standard-state conditions, 398
Thiol group, 7, 330
Thoracic duct, 366
Threonine, 7
Threose structure, 111
Thymine, 170
Thyroid hormones, 408, 414–415
Thyroxine (T_4), 414–415
Tight junctions, 265, 277
Tocopherols and tocotrienols, 147
Tollen's reagent, 115–116
Transcription, 216–217, 223–225, 243–244
Transcription factors, 224, 238, 239–240, 245
Transferases, 41, 59
Transfer RNA (tRNA)
  anticodons in, 218, 220, 228, 230
  base pairing of aminoacyl tRNA with mRNA, 220, 227–228
  charged or activated transfer RNA, 218
  initiator tRNA, 230
  synthesis, 224
Transgenes, 196–197
Transgenic mice, 196–198
Translation
  elongation, 231
  elongation factors (EFs), 231
  initiation, 230
  initiation factors (IFs), 230
  mechanism, 229–232
  post-translational processing, 232–233
  release factor (RF), 232
  Shine-Dalgarno sequence in mRNA, 230
  start codon, 221, 227, 230
  synthesis of secretory, membrane, and lysosomal proteins, 232*f*
  termination, 232
Transmembrane proteins, 262, 264, 265
Trehalose, 119*f*
Triacylglycerols (triglycerides)
  digestion and absorption, 364, 366
  energy storage, 148–149, 154
  fatty acids in, 148–149, 260*f*
  mobilization, 367
  saponification, 150*f*, 154
  structure, 149–150, 155
  synthesis, 375
  transport in lipoproteins, 368–370
Triiodothyronine (T_3), 414–415
Tripeptides, 16
Triterpenes, 144
Trp operon, 234, 236
Truncation mutations, 221
Trypsin, 18, 57, 91, 382
Tryptophan, 6*f*, 18, 40, 234, 236
Tubulin, 74, 75
Tumor suppressor genes, 185, 202
Tyrosine, 6, 9, 18, 40

U

Uncompetitive inhibition, 55, 60
Uncouplers, 349
Unsaturated fatty acids, 139, 260, 373, 379, 386
Uracil, 170
Urea and denaturation of proteins, 25
Urea cycle, 4, 383–384
UV spectroscopy, 91

V

Valine, 3, 5, 9, 16
Van't Hoff factor, 269
Very-low-density lipoprotein (VLDL), 260, 417
Viruses, structure, 23
Vitamins
  as cofactors, 46
  ascorbic acid (vitamin C), 46
  B complex vitamins, 46
  fat-soluble vitamins, 46, 146–147, 151
  vitamin A (carotene), 144, 146, 154
  vitamin B2 (riboflavin), 46, 404
  vitamin D (cholecalciferol), 147, 154
  vitamin E, 144, 154
  vitamin K, 147, 154, 233
  water-soluble vitamins, 46, 146
Von Gierke's Disease, 306

W

Watson-Crick model of DNA structure, 171–173, 200
Waxes, 142*f*, 262
Wobble position in codons, 221

X

X-ray crystallography, 90–91, 95

Z

Z-DNA, 173
Zwitterions, 12–13, 13–14, 26, 85–86
Zymogens, 40–41, 57, 61, 383

Preface

And now it starts: your long, yet fruitful journey toward wearing a white coat. Proudly wearing that white coat, though, is hopefully only part of your motivation. You are reading this book because you want to be a healer.

If you're serious about going to medical school, then you are likely already familiar with the importance of the MCAT in medical school admissions. While the holistic review process puts additional weight on your experiences, extracurricular activities, and personal attributes, the fact remains: along with your GPA, your MCAT score remains one of the two most important components of your application portfolio—at least early in the admissions process. Each additional point you score on the MCAT pushes you in front of thousands of other students and makes you an even more attractive applicant. But the MCAT is not simply an obstacle to overcome; it is an opportunity to show schools that you will be a strong student and a future leader in medicine.

We at Kaplan take our jobs very seriously and aim to help students see success not only on the MCAT, but as future physicians. We work with our Learning Science experts to ensure that we're using the most up-to-date teaching techniques in our resources. Multiple members of our team hold advanced degrees in medicine or associated biomedical sciences, and are committed to the highest level of medical education. Kaplan has been working with the MCAT for over 50 years and our commitment to premed students is unflagging; in fact, Stanley Kaplan created this company when he had difficulty being accepted to medical school due to unfair quota systems that existed at the time.

We stand now at the beginning of a new era in medical education. As citizens of this 21st-century world of healthcare, we are charged with creating a patient-oriented, culturally competent, cost-conscious, universally available, technically advanced and research-focused healthcare system, run by compassionate providers. Suffice it to say, this is no easy task. Problem-based learning, integrated curricula, and classes in interpersonal skills are some of the responses to this demand for an excellent workforce—a workforce of which you'll soon be a part.

We're thrilled that you've chosen us to help you on this journey. Please reach out to us to share your challenges, concerns, and successes. Together, we will shape the future of medicine in the United States and abroad; we look forward to helping you become the doctor you deserve to be.

Good luck!

How This Book Was Created xix

Using This Book xx

Chapter 1: The Cell ★★★★ **1**

1.1 Cell Theory 3

1.2 Eukaryotic Cells 4

1.3 Classification and Structure of Prokaryotic Cells 14

1.4 Genetics and Growth of Prokaryotic Cells 21

1.5 Viruses and Subviral Particles 26

Chapter 2: Reproduction ★★★ **49**

2.1 The Cell Cycle and Mitosis 52

2.2 Meiosis 58

2.3 The Reproductive System 62

Chapter 3: Embryogenesis and Development ★★ **85**

3.1 Early Developmental Stages 88

3.2 Mechanisms of Development 96

3.3 Fetal Circulation 103

3.4 Gestation and Birth 106

Chapter 4: The Nervous System ★★★★ **121**

4.1 Cells of the Nervous System 124

4.2 Transmission of Neural Impulses 128

4.3 Organization of the Human Nervous System 137

Chapter 5: The Endocrine System ★★★ **157**

5.1 Mechanisms of Hormone Action 160

5.2 Endocrine Organs and Hormones 164

Chapter 6: The Respiratory System ★ **197**

6.1 Anatomy and Mechanism of Breathing 200

6.2 Functions of the Respiratory System 206

Chapter 7: The Cardiovascular System ☆☆ **223**

7.1 Anatomy of the Cardiovascular System 226

7.2 Blood 237

7.3 Physiology of the Cardiovascular System 245

Chapter 8: The Immune System ☆☆ **269**

8.1 Structure of the Immune System 272

8.2 The Innate Immune System 277

8.3 The Adaptive Immune System 283

8.4 The Lymphatic System 291

Chapter 9: The Digestive System ☆☆ **305**

9.1 Anatomy of the Digestive System 307

9.2 Ingestion and Digestion 310

9.3 Accessory Organs of Digestion 316

9.4 Absorption and Defecation 322

Chapter 10: Homeostasis ☆☆☆ **339**

10.1 The Excretory System 342

10.2 Skin 353

Chapter 11: Musculoskeletal System ☆☆ **369**

11.1 The Muscular System 372

11.2 The Skeletal System 381

Chapter 12: Genetics and Evolution ☆☆☆☆ **399**

12.1 Fundamental Concepts of Genetics 402

12.2 Changes in the Gene Pool 408

12.3 Analytical Approaches in Genetics 413

12.4 Evolution 422

About *Scientific American*

Founded in 1845, *Scientific American* is the award-winning authoritative source for the science discoveries and technology innovations that matter. The longest continuously published magazine in the United States, it is translated into 14 languages and reaches a global audience of more than 6 million. Other titles include *Scientific American Mind* and *Spektrum der Wissenschaft* in Germany. In its history, 152 Nobel Prize scientists have contributed 246 articles to *Scientific American*, including Albert Einstein, Francis Crick, Stanley Prusiner, and Richard Axel.

Scientific American is at the heart of Nature Publishing Group's consumer media division, meeting the needs of the general public. For more information, please visit www.scientificamerican.com.

About the MCAT

ANATOMY OF THE MCAT

Here is a general overview of the structure of Test Day:

Section	Number of Questions	Time Allotted
Examinee Agreement		8 minutes
Tutorial (optional)		10 minutes
Chemical and Physical Foundations of Biological Systems	59	95 minutes
Break (optional)		10 minutes
Critical Analysis and Reasoning Skills (CARS)	53	90 minutes
Lunch Break (optional)		30 minutes
Biological and Biochemical Foundations of Living Systems	59	95 minutes
Break (optional)		10 minutes
Psychological, Social, and Biological Foundations of Behavior	59	95 minutes
Void Question		5 minutes
Satisfaction Survey (optional)		5 minutes

The structure of the four sections of the MCAT is further detailed below.

Chemical and Physical Foundations of Biological Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 5% • General Chemistry: 30% • Organic Chemistry: 15% • Physics: 25%
Critical Analysis and Reasoning Skills (CARS)	
Time	90 minutes
Format	• 53 questions • 9 passages • All questions are passage-based. There are no discrete (stand-alone) questions. • Score between 118 and 132

What It Tests	Disciplines: • Humanities: 50% • Social Sciences: 50% Skills: • *Foundations of Comprehension*: 30% • *Reasoning Within the Text*: 30% • *Reasoning Beyond the Text*: 40%
Biological and Biochemical Foundations of Living Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 65% • General Chemistry: 5% • Organic Chemistry: 5%
Psychological, Social, and Biological Foundations of Behavior	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biology: 5% • Psychology: 65% • Sociology: 30%
Total	
Testing Time	375 minutes (6 hours, 15 minutes)
Total Seat Time	453 minutes (7 hours, 33 minutes)
Questions	230
Score	472 to 528

SCIENTIFIC INQUIRY AND REASONING SKILLS (SIRS)

The AAMC has defined four *Scientific Inquiry and Reasoning Skills* (SIRS) that will be tested in the three science sections of the MCAT:

1. *Knowledge of Scientific Concepts and Principles* (35% of questions)
2. *Scientific Reasoning and Problem-Solving* (45% of questions)
3. *Reasoning About the Design and Execution of Research* (10% of questions)
4. *Data-Based and Statistical Reasoning* (10% of questions)

Let's see how each one breaks down into more specific Test Day behaviors. Note that the bullet points of specific objectives for each of the SIRS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Skill 1: *Knowledge of Scientific Concepts and Principles*

This is probably the least surprising of the four SIRS; the testing of science knowledge is, after all, one of the signature qualities of the MCAT. Skill 1 questions will require you to do the following:

- Recognize correct scientific principles
- Identify the relationships among closely-related concepts
- Identify the relationships between different representations of concepts (verbal, symbolic, graphic)
- Identify examples of observations that illustrate scientific principles
- Use mathematical equations to solve problems

At Kaplan, we simply call these Science Knowledge or Skill 1 questions. Another way to think of Skill 1 questions is as "one-step" problems. The single step is either to realize which scientific concept the question stem is suggesting or to take the concept stated in the question stem and identify which answer choice is an accurate application of it. Skill 1 questions are particularly prominent among discrete questions (those not associated with a passage). These questions are an opportunity to gain quick points on Test Day—if you know the science concept attached to the question, then that's it! On Test Day, 35% of the questions in each science section will be Skill 1 questions.

Here are some sample Skill 1 question stems:

- How would a proponent of the James–Lange theory of emotion interpret the findings of the study cited the passage?
- Which of the following most accurately describes the function of FSH in the human female menstrual cycle?
- If the products of Reaction 1 and Reaction 2 were combined in solution, the resulting reaction would form:
- Ionic bonds are maintained by which of the following forces?

Skill 2: *Scientific Reasoning and Problem-Solving*

The MCAT science sections do, of course, move beyond testing straightforward science knowledge; Skill 2 questions are the most common way in which it does so. At Kaplan, we also call these Critical Thinking questions. Skill 2 questions will require you to do the following:

- Reason about scientific principles, theories, and models
- Analyze and evaluate scientific explanations and predictions
- Evaluate arguments about causes and consequences
- Bring together theory, observations, and evidence to draw conclusions
- Recognize scientific findings that challenge or invalidate a scientific theory or model
- Determine and use scientific formulas to solve problems

Just as Skill 1 questions can be thought of as "one-step" problems, many Skill 2 questions are "two-step" problems, and more difficult Skill 2 questions may require three or more steps. These questions can require a wide spectrum of reasoning skills, including integration of multiple facts from a passage, combination of multiple science content areas, and prediction of an experiment's results. Skill 2 questions also tend to ask about science content without actually mentioning it by name. For example, a question might describe the results of one experiment and ask you to predict the results of a second experiment without actually telling you what underlying scientific principles are at work—part of the question's difficulty will be figuring out which principles to apply in order to get the correct answer. On Test Day, 45% of the questions in each science section will be Skill 2 questions.

Here are some sample Skill 2 question stems:

- Which of the following experimental conditions would most likely yield results similar to those in Figure 2?
- All of the following conclusions are supported by the information in the passage EXCEPT:
- The most likely cause of the anomalous results found by the experimenter is:
- An impact to a man's chest quickly reduces the volume of one of his lungs to 70% of its initial value while not allowing any air to escape from the man's mouth. By what percentage is the force of outward air pressure increased on a 2 cm^2 portion of the inner surface of the compressed lung?

Skill 3: *Reasoning About the Design and Execution of Research*

The MCAT is interested in your ability to critically appraise and analyze research, as this is an important day-to-day task of a physician. We call these questions Skill 3 or Experimental and Research Design questions for short. Skill 3 questions will require you to do the following:

- Identify the role of theory, past findings, and observations in scientific questioning
- Identify testable research questions and hypotheses
- Distinguish between samples and populations and distinguish results that support generalizations about populations
- Identify independent and dependent variables
- Reason about the features of research studies that suggest associations between variables or causal relationships between them (such as temporality and random assignment)
- Identify conclusions that are supported by research results
- Determine the implications of results for real-world situations
- Reason about ethical issues in scientific research

Over the years, the AAMC has received input from medical schools to require more practical research skills of MCAT test-takers, and Skill 3 questions are the response to these demands. This skill is unique in that the outside knowledge you need to answer Skill 3 questions is not taught in any one undergraduate course; instead, the research design principles needed to answer these questions are learned gradually throughout your science classes and especially through any laboratory work you have completed. It should be noted that Skill 3 comprises 10% of the questions in each science section on Test Day.

Here are some sample Skill 3 question stems:

- What is the dependent variable in the study described in the passage?
- The major flaw in the method used to measure disease susceptibility in Experiment 1 is:
- Which of the following procedures is most important for the experimenters to follow in order for their study to maintain a proper, randomized sample of research subjects?
- A researcher would like to test the hypothesis that individuals who move to an urban area during adulthood are more likely to own a car than are those who have lived in an urban area since birth. Which of the following studies would best test this hypothesis?

Skill 4: *Data-Based and Statistical Reasoning*

Lastly, the science sections of the MCAT test your ability to analyze the visual and numerical results of experiments and studies. We call these Data and Statistical Analysis questions. Skill 4 questions will require you to do the following:

- Use, analyze, and interpret data in figures, graphs, and tables
- Evaluate whether representations make sense for particular scientific observations and data

- Use measures of central tendency (mean, median, and mode) and measures of dispersion (range, interquartile range, and standard deviation) to describe data
- Reason about random and systematic error
- Reason about statistical significance and uncertainty (interpreting statistical significance levels and interpreting a confidence interval)
- Use data to explain relationships between variables or make predictions
- Use data to answer research questions and draw conclusions

Skill 4 is included in the MCAT because physicians and researchers spend much of their time examining the results of their own studies and the studies of others, and it's very important for them to make legitimate conclusions and sound judgments based on that data. The MCAT tests Skill 4 on all three science sections with graphical representations of data (charts and bar graphs) as well as numerical ones (tables, lists, and results summarized in sentence or paragraph form). On Test Day, 10% of the questions in each science section will be Skill 4 questions.

Here are some sample Skill 4 question stems:

- According to the information in the passage, there is an inverse correlation between:
- What conclusion is best supported by the findings displayed in Figure 2?
- A medical test for a rare type of heavy metal poisoning returns a positive result for 98% of affected individuals and 13% of unaffected individuals. Which of the following types of error is most prevalent in this test?
- If a fourth trial of Experiment 1 was run and yielded a result of 54% compliance, which of the following would be true?

SIRS Summary

Discussing the SIRS tested on the MCAT is a daunting prospect given that the very nature of the skills tends to make the conversation rather abstract. Nevertheless, with enough practice, you'll be able to identify each of the four skills quickly, and you'll also be able to apply the proper strategies to solve those problems on Test Day. If you need a quick reference to remind you of the four SIRS, these guidelines may help:

Skill 1 (**Science Knowledge**) questions ask:

- Do you remember this science content?

Skill 2 (**Critical Thinking**) questions ask:

- Do you remember this science content? And if you do, could you please apply it to this novel situation?
- Could you answer this question that cleverly combines multiple content areas at the same time?

Skill 3 (**Experimental and Research Design**) questions ask:

- Let's forget about the science content for a while. Could you give some insight into the experimental or research methods involved in this situation?

Skill 4 (**Data and Statistical Analysis**) questions ask:

- Let's forget about the science content for a while. Could you accurately read some graphs and tables for a moment? Could you make some conclusions or extrapolations based on the information presented?

CRITICAL ANALYSIS AND REASONING SKILLS (CARS)

The *Critical Analysis and Reasoning Skills* (CARS) section of the MCAT tests three discrete families of textual reasoning skills; each of these families requires a higher level of reasoning than the last. Those three skills are as follows:

1. *Foundations of Comprehension* (30% of questions)
2. *Reasoning Within the Text* (30% of questions)
3. *Reasoning Beyond the Text* (40% of questions)

These three skills are tested through nine humanities- and social sciences-themed passages, with approximately 5 to 7 questions per passage. Let's take a more in-depth look into these three skills. Again, the bullet points of specific objectives for each of the CARS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Foundations of Comprehension

Questions in this skill will ask for basic facts and simple inferences about the passage; the questions themselves will be similar to those seen on reading comprehension sections of other standardized exams like the SAT® and ACT®. *Foundations of Comprehension* questions will require you to do the following:

- Understand the basic components of the text
- Infer meaning from rhetorical devices, word choice, and text structure

This admittedly covers a wide range of potential question types including Main Idea, Detail, Function, and Definition-in-Context questions, but finding the correct answer to all *Foundations of Comprehension* questions will follow from a basic understanding of the passage and the point of view of its author (and occasionally that of other voices in the passage).

Here are some sample *Foundations of Comprehension* question stems:

- **Main Idea**—The author's primary purpose in this passage is:
- **Detail**—Based on the information in the second paragraph, which of the following is the most accurate summary of the opinion held by Schubert's critics?
- **(Scattered) Detail**—According to the passage, which of the following is FALSE about literary reviews in the 1920s?
- **Function**—The author's discussion of the effect of socioeconomic status on social mobility primarily serves which of the following functions?
- **Definition-in-Context**—The word "obscure" (paragraph 3), when used in reference to the historian's actions, most nearly means:

Reasoning Within the Text

While *Foundations of Comprehension* questions will usually depend on interpreting a single piece of information in the passage or understanding the passage as a whole, *Reasoning Within the Text* questions will typically require you to infer unstated parts of arguments or bring together two disparate pieces of the passage. *Reasoning Within the Text* questions will require you to:

- Integrate different components of the text to increase comprehension

In other words, questions in this skill often ask either *How do these two details relate to one another?* or *What else must be true that the author didn't say?* The CARS section will also ask you to judge certain parts of the passage or even judge the author. These questions, which fall under the *Reasoning Within the Text* skill, can ask you to identify authorial bias, evaluate the credibility of cited sources, determine the logical soundness of an argument, or search for relevant evidence in the passage to support a given conclusion. In all, this category includes Inference and Strengthen–Weaken (Within the Passage) questions, as well as a smattering of related—but rare—question types.

Here are some sample *Reasoning Within the Text* question stems:

- **Inference (Implication)**—Which of the following phrases, as used in the passage, is most suggestive that the author has a personal bias toward narrative records of history?
- **Inference (Assumption)**—In putting together her argument in the passage, the author most likely assumes:
- **Strengthen–Weaken (Within the Passage)**—Which of the following facts is used in the passage as the most prominent piece of evidence in favor of the author's conclusions?
- **Strengthen–Weaken (Within the Passage)**—Based on the role it plays in the author's argument, *The Possessed* can be considered:

Reasoning Beyond the Text

The distinguishing factor of *Reasoning Beyond the Text* questions is in the title of the skill: the word *Beyond*. Questions that test this skill, which make up a larger share of the CARS section than questions from either of the other two skills, will always introduce a completely new situation that was not present in the passage itself; these questions will ask you to determine how one influences the other. *Reasoning Beyond the Text* questions will require you to:

- Apply or extrapolate ideas from the passage to new contexts
- Assess the impact of introducing new factors, information, or conditions to ideas from the passage

The *Reasoning Beyond the Text* skill is further divided into Apply and Strengthen–Weaken (Beyond the Passage) questions, and a few other rarely appearing question types.

Here are some sample *Reasoning Beyond the Text* question stems:

- **Apply**—If a document were located that demonstrated Berlioz intended to include a chorus of at least 700 in his *Grande Messe des Mortes*, how would the author likely respond?
- **Apply**—Which of the following is the best example of a "virtuous rebellion," as it is defined in the passage?
- **Strengthen–Weaken (Beyond the Text)**—Suppose Jane Austen had written in a letter to her sister, "My strongest characters were those forced by circumstance to confront basic questions about the society in which they lived." What relevance would this have to the passage?
- **Strengthen–Weaken (Beyond the Text)**—Which of the following sentences, if added to the end of the passage, would most WEAKEN the author's conclusions in the last paragraph?

CARS Summary

Through the *Foundations of Comprehension* skill, the CARS section tests many of the reading skills you have been building on since grade school, albeit in the context of very challenging doctorate-level passages. But through the two other skills (*Reasoning Within the Text* and *Reasoning Beyond the Text*), the MCAT demands that you understand the deep structure of passages and the arguments within them at a very advanced level. And, of course, all of this is tested under very tight timing restrictions: only 102 seconds per question—and that doesn't even include the time spent reading the passages.

Here's a quick reference guide to the three CARS skills:

Foundations of Comprehension questions ask:

- Did you understand the passage and its main ideas?
- What does the passage have to say about this particular detail?

Reasoning Within the Text questions ask:

- What must be true that the author did not say?
- What's the logical relationship between these two ideas from the passage?
- How well argued is the author's thesis?

Reasoning Beyond the Text questions ask:

- How does this principle from the passage apply to this new situation?
- How does this new piece of information influence the arguments in the passage?

SCORING

Each of the four sections of the MCAT is scored between 118 and 132, with the median at 125. This means the total score ranges from 472 to 528, with the median at 500. Why such peculiar numbers? The AAMC stresses that this scale emphasizes the importance of the central portion of the score distribution, where most students score (around 125 per section, or 500 total), rather than putting undue focus on the high end of the scale.

Note that there is no wrong answer penalty on the MCAT, so you should select an answer for every question—even if it is only a guess.

The AAMC has released the official correlation between scaled score and percentile, as shown here. It should be noted that the percentile scale is adjusted and renormalized over time and thus should not be overinterpreted.

Total Score	Percentile	Total Score	Percentile
528	100	499	47
527	100	498	43
526	100	497	40
525	100	496	37
524	100	495	34
523	100	494	31
522	99	493	28
521	99	492	25
520	98	491	22
519	98	490	20
518	97	489	18
517	96	488	15
516	95	487	13

Total Score	Percentile	Total Score	Percentile
515	93	486	11
514	91	485	10
513	89	484	8
512	87	483	7
511	85	482	6
510	83	481	5
509	80	480	4
508	77	479	3
507	74	478	2
506	71	477	1
505	68	476	1
504	64	475	1
503	61	474	0
502	57	473	0
501	54	472	0
500	51		

Source: AAMC. 2015. *Summary of Total and Section Scores from the MCAT Exam Based on Results for Tests Administered in April and May 2015.* Accessed February 2016. https://students-residents.aamc.org/search/?q=percentilenewmcat.pdf.

Further information on score reporting is included at the end of the next section (see *After Your Test*).

MCAT POLICIES AND PROCEDURES

We strongly encourage you to download the latest copy of *MCAT® Essentials*, available on the AAMC's website, to ensure that you have the latest information about registration and Test Day policies and procedures; this document is updated annually. A brief summary of some of the most important rules is provided here.

MCAT Registration

The only way to register for the MCAT is online. You can access AAMC's registration system at: www.aamc.org/mcat.

You will be able to access the site approximately six months before Test Day. The AAMC designates three registration "Zones"—Gold, Silver, and Bronze. Registering during the Gold Zone (from the opening of registration until approximately one month before Test Day) provides the most flexibility and lowest test fees. The Silver Zone runs until approximately two to three weeks before Test Day and has less flexibility and higher fees; the Bronze Zone runs until approximately one to two weeks before Test Day and has the least flexibility and highest fees.

Fees and the Fee Assistance Program (FAP)

Payment for test registration must be made by MasterCard or VISA. As described earlier, the fees for registering for the MCAT—as well as rescheduling the exam or changing your testing center—increase as one approaches Test Day. In addition, it is not uncommon for test centers to fill up well in advance of the registration deadline. For these reasons, we recommend identifying your preferred Test Day as soon as possible and registering. There are ancillary benefits to having a set Test Day, as well: when you know the date you're working toward, you'll study harder and are less likely to keep pushing back the exam. The AAMC offers a Fee Assistance Program (FAP) for students with financial hardship to help reduce the cost of taking the MCAT, as well as for the American Medical College Application Service (AMCAS®) application. Further information on the FAP can be found at: www.aamc.org/students/applying/fap.

Testing Security

On Test Day, you will be required to present a government-issued ID. When registering, take care to spell your name precisely the same as it appears on this ID; failure to provide this ID at the test center or differences in spelling between your registration and ID will be considered a "no-show," and you will not receive a refund for the exam.

You will also be required to provide an electronic thumbprint and electronic signature verification to take the exam. Some testing centers may use a metal detection wand to ensure that no prohibited items are brought into the testing room. Prohibited items include all electronic devices, including watches and timers, calculators, cell phones, and any and all forms of recording equipment; food, drinks (including water), and cigarettes or other smoking paraphernalia; hats and scarves (except for religious purposes); and books, notes, or other study materials. If you require a medical device, such as an insulin pump or pacemaker, you must apply for accommodated testing. During breaks, you are allowed to access food and drink, but not electronic devices, including cell phones.

Testing centers are under video surveillance and the AAMC does not take potential violations of testing security lightly. The bottom line: *know the rules and don't break them*.

Accommodations

Students with disabilities or medical conditions can apply for accommodated testing. Documentation of the disability or condition is required, and requests may take two months—or more—to be approved. For this reason, it is recommended that you begin the process of applying for accommodated testing as early as possible. More information on applying for accommodated testing can be found at: www.aamc.org/students/applying/mcat/accommodations

After Your Test

When your MCAT is all over, no matter how you feel you did, be good to yourself when you leave the test center. Celebrate! Take a nap. Watch a movie. Ride your bike. Plan a trip. Call up all of your neglected friends or stalk them on Facebook. Totally consume a cheesesteak and drink dirty martinis at night (assuming you're over 21). Whatever you do, make sure that it has absolutely nothing to do with thinking too hard—you deserve some rest and relaxation.

Perhaps most importantly, do not discuss specific details about the test with anyone. For one, it is important to let go of the stress of Test Day, and reliving your exam only inhibits you from being able to do so. But more significantly, the Examinee Agreement you sign at the beginning of your exam specifically prohibits you from discussing or disclosing exam content. The AAMC is known to seek out individuals who violate this agreement and retains the right to prosecute these individuals at their discretion. This means that you should not, under any circumstances, discuss the exam in person or over the phone with other individuals—including us at Kaplan—or post information or questions about exam content to Facebook, Student Doctor Network, or other online social media. You are permitted to comment on your "general exam experience," including how you felt about the exam overall or an individual section, but this is a fine line. In summary: *if you're not certain whether you can discuss an aspect of the test or not, just don't do it!* Do not let a silly Facebook post stop you from becoming the doctor you deserve to be.

Scores are released approximately one month after Test Day. The release is staggered during the afternoon and evening, starting at 5 p.m. Eastern. This means that not all examinees receive their scores at exactly the same time. Your score report will include a scaled score for each section between 118 and 132, as well as your total combined score between 472 and 528. These scores are given as confidence intervals. For each section, the confidence interval is approximately the given score ±1; for the total score, it is approximately the given score ±2. You will also be given the corresponding percentile rank for each of these section scores and the total score.

How This Book Was Created

The *Kaplan MCAT Review* project began shortly after the release of the *Preview Guide for the MCAT 2015 Exam*, 2nd edition. Through thorough analysis by our staff psychometricians, we were able to analyze the relative yield of the different topics on the MCAT, and we began constructing tables of contents for the books of the *Kaplan MCAT Review* series. A dedicated staff of 30 writers, 7 editors, and 32 proofreaders worked over 5,000 combined hours to produce these books. The format of the books was heavily influenced by weekly meetings with Kaplan's learning-science team.

These books were submitted for publication in February 2016. For any updates after this date, please visit www.kaplanmcat.com/pages/retail-book-corrections-and-updates.

If you have any questions about the content presented here, email KaplanMCATfeedback@kaplan.com. For other questions not related to content, email booksupport@kaplan.com.

Each book has been vetted through at least eight rounds of review. To that end, the information presented is these books is true and accurate to the best of our knowledge. Still, your feedback helps us improve our prep materials. Please notify us of any inaccuracies or errors in the books by sending an email to KaplanMCATfeedback@kaplan.com.

Using This Book

Kaplan MCAT Biology Review, along with the other seven books in your student kit, is the cornerstone of your prep for the MCAT. This book offers the content review, strategies, and practice that make Kaplan the #1 choice for MCAT prep.

This book is designed to help you review the biology topics covered on the MCAT. Please understand that content review—no matter how thorough—is not sufficient preparation for the MCAT! The MCAT tests not only your science knowledge but also your critical reading, reasoning, and problem-solving skills. Do not assume that simply memorizing the contents of this book will earn you high scores on Test Day; to maximize your scores, you must also improve your reading and test-taking skills through MCAT-style questions and practice tests.

MCAT CONCEPT CHECKS

At the end of each section, you'll find a few open-ended questions that you can use to assess your mastery of the material. These MCAT Concept Checks were introduced after multiple conversations with Kaplan's learning-science team. Research has demonstrated repeatedly that introspection and self-analysis improve mastery, retention, and recall of material. Complete these MCAT Concept Checks to ensure that you've got the key points from each section before moving on!

PRACTICE QUESTIONS

At the end of each chapter, you'll find 15 MCAT-style practice questions. These are designed to help you assess your understanding of the chapter you just read. Most of these questions focus on the first of the *Scientific Inquiry and Reasoning Skills* (*Knowledge of Scientific Concepts and Principles*), although there are occasional questions that fall into the second or fourth SIRS (*Scientific Reasoning and Problem-Solving*, and *Data-Based and Statistical Reasoning*, respectively).

SIDEBARS

The following is a guide to the five types of sidebars you'll find in *Kaplan MCAT Biology Review*:

- **Bridge:** These sidebars create connections between science topics that appear in multiple chapters throughout the *Kaplan MCAT Review* series.
- **Key Concept:** These sidebars draw attention to the most important takeaways in a given topic, and they sometimes offer synopses or overviews of complex information. If you understand nothing else, make sure you grasp the Key Concepts for any given subject.
- **MCAT Expertise:** These sidebars point out how information may be tested on the MCAT or offer key strategy points and test-taking tips that you should apply on Test Day.
- **Mnemonic:** These sidebars present memory devices to help recall certain facts.
- **Real World:** These sidebars illustrate how a concept in the text relates to the practice of medicine or the world at large. While this is not information you need to know for Test Day, many of the topics in Real World sidebars are excellent examples of how a concept may appear in a passage or discrete (stand-alone) question on the MCAT.

WHAT THIS BOOK COVERS

The information presented in the *Kaplan MCAT Review* series covers everything listed on the official MCAT content lists. Every topic in these lists is covered in the same level of detail as is common to the undergraduate and postbaccalaureate classes that are considered prerequisites for the MCAT. Note that your premedical classes may include topics not discussed in these books, or they may go into more depth than these books do. Additional exposure to science content is never a bad thing, but recognize that all of the content knowledge you are expected to have walking in on Test Day is covered in these books.

New to the Third Edition of the *Kaplan MCAT Review* series are **Star Ratings**. You'll see these stars throughout the book, and they are meant as a guide to the number and density of test-worthy facts in each chapter and sub-chapter.

★★★★ Four-star chapters and topics are packed with testable facts. Make sure you have all of these down before Test Day. Even if you find these topics difficult to grasp, you should put in the extra effort to fully understand them.

★★★ Three-star chapters and topics contain content that is tested an above-average amount. If you plan to score above average–and you probably do!–then you should master all or nearly all of these before Test Day.

★★ Two-star sections will demand varied focus, depending on your personal studying needs. These topics have been proven to be MCAT-worthy, but if you have limited study time or already feel confident with these topics, you can move more quickly through this material.

★ One-star chapters and topics are unlikely to be directly tested, but many of these topics provide foundations for, and connections between, higher-yield material.

These Star Ratings were created based on material released by the AAMC. In other words, according to the testmaker and all our experience with their resources, more stars means more questions on Test Day.

This book also contains a thorough glossary and index for easy navigation of the text.

In the end, this is your book, so write in the margins, draw diagrams, highlight the key points—do whatever is necessary to help you get that higher score. We look forward to working with you as you achieve your dreams and become the doctor you deserve to be!

1.5 Viruses and Subviral Particles ☆☆☆
- Viral Structure 26
- Viral Genomes 27
- Viral Life Cycle 28
- Prions and Viroids 31

Concept Summary 34

Introduction

The human body contains approximately 37 trillion cells. These cells create tissues from which organs form. Each cell serves a purpose, communicating and carrying out the reactions that make life possible. Interestingly, bacteria outnumber the eukaryotic cells in our bodies about ten to one. But the sheer number of cells from which the human body is created is not nearly as impressive as the numerous functions these cells can perform, from conduction of impulses through the nervous system, allowing for memory and learning, to the simultaneous contraction of cardiac myocytes to allow for the pumping of blood through the entire human body. In order to understand the human organism as a whole, and how the human body reacts to various pathogens, a thorough understanding of cell biology is required. It is not enough to simply memorize each part of the cell; the MCAT requires an understanding of how each cell structure carries out its functions and affects the entire organism.

1.1 Cell Theory ☆

Prior to the 1600s, organisms were perceived as being complete and inseparable into smaller parts. This was due in part to the inability to see smaller structures through optical instruments like the microscope. In 1665, Robert Hooke assembled a crude compound microscope and tested its properties on a piece of cork. He noticed a honeycomb-like structure and compared the spaces within the cork to the small rooms of a monastery,

Bridge

Robert Hooke, who invented the first crude microscopes to look at cork, is also known for his characterization of springs. Hooke's Law, $F = -kx$, describes the relationship between elastic force, the spring constant, and the displacement of a spring from equilibrium. While Hooke's law does not appear on the official MCAT content lists, the related topic of elastic potential energy, $U = \frac{1}{2}kx^2$, is testable content. This equation, as well as other forms of energy, is discussed in Chapter 2 of *MCAT Physics and Math Review*.

known as cells. Because cork consists of desiccated nonliving cells, Hooke was not able to see nuclei, organelles, or cell membranes. In 1674, Anton van Leeuwenhoek was the first to view a living cell under a microscope. Later researchers noted that cells could be separated, and that each cell was a distinct structure. Further research indicated that tissues were made of cells, and the function of a tissue was dependent upon the function of the cells from which it is formed. Two centuries later, in 1850, Rudolph Virchow demonstrated that diseased cells could arise from normal cells in normal tissues.

The original form of the **cell theory** consisted of three basic tenets:

- All living things are composed of cells.
- The cell is the basic functional unit of life.
- Cells arise only from preexisting cells.

Through advances of molecular biology, a fourth tenet has been added to the theory:

- Cells carry genetic information in the form of deoxyribonucleic acid (DNA). This genetic material is passed on from parent to daughter cell.

Cell theory has created an interesting dilemma with respect to viruses. Viruses are small structures that contain genetic material, but are unable to reproduce on their own. This violates the third and fourth tenets of the cell theory because virions can only replicate by invading other organisms and because they may contain ribonucleic acid (RNA) as their genetic information. Therefore, viruses, discussed later in this chapter, are not considered living organisms.

MCAT Concept Check 1.1:

Before you move on, assess your understanding of the material with this question.

1. What are the four fundamental tenets of the cell theory?
   - _____
   - _____
   - _____
   - _____

1.2 Eukaryotic Cells ★★★★

The first major distinction we can make between living organisms is whether they are composed of prokaryotic or eukaryotic cells. Eukaryotic organisms can be unicellular or multicellular. Whereas **eukaryotic cells** contain a true nucleus

enclosed in a membrane, **prokaryotic cells** do not contain a nucleus. The major organelles are identified in the eukaryotic cell in Figure 1.1.

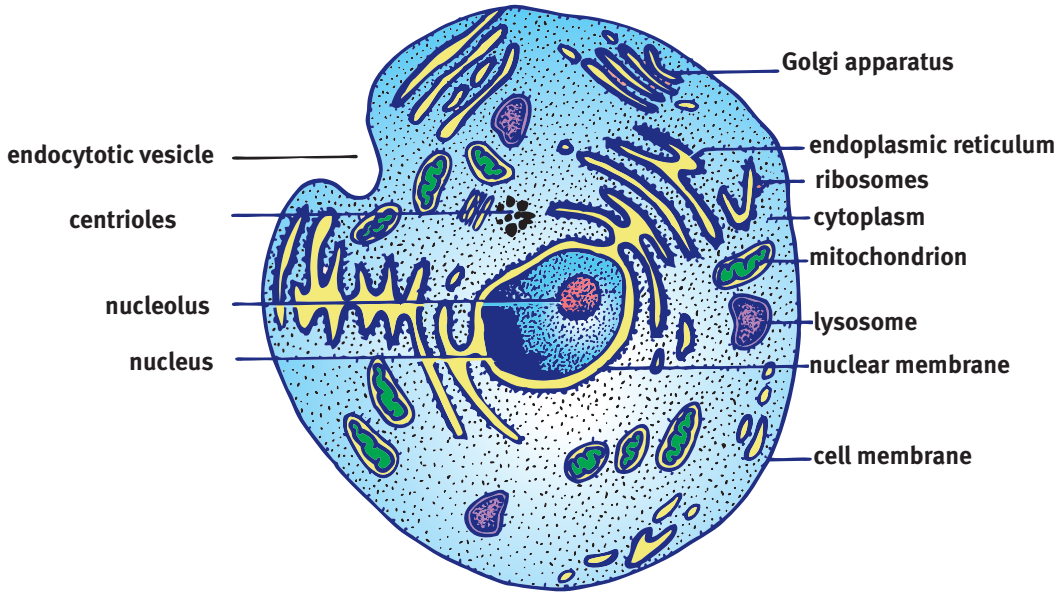

Figure 1.1. Eukaryotic Cell
Numerous membrane-bound organelles are found in the cytoplasm of a eukaryotic cell.

MEMBRANE-BOUND ORGANELLES

Each cell has a cell membrane enclosing a semifluid cytosol in which the **organelles** are suspended. In eukaryotic cells, most organelles are membrane bound, allowing for compartmentalization of functions. Membranes of eukaryotic cells consist of a phospholipid bilayer. This membrane is unique in that its surfaces are hydrophilic, electrostatically interacting with the aqueous environments inside and outside of the cell, while its inner portion is hydrophobic, which helps to provide a highly selective barrier between the interior of the cell and the external environment. The cell membrane is such an important topic on the MCAT that an entire chapter—Chapter 8 of *MCAT Biochemistry Review*—is devoted solely to discussing the structure and physiology of biological membranes. The **cytosol** allows for the diffusion of molecules throughout the cell. Within the **nucleus**, genetic material is encoded in **deoxyribonucleic acid** (**DNA**), which is organized into **chromosomes**. Eukaryotic cells reproduce by **mitosis**, allowing for the formation of two identical daughter cells.

The Nucleus

As the control center of the cell, the **nucleus** is the most heavily tested organelle on the MCAT. It contains all of the genetic material necessary for replication of the cell. The nucleus is surrounded by the **nuclear membrane** or **envelope**,

Bridge

The nuclear envelope creates two distinct environments within the cell because it separates the nucleus from the cytoplasm. This allows for compartmentalization of transcription (the formation of hnRNA from DNA, which is subsequently processed to form mRNA) and translation (the formation of a peptide from mRNA). These processes are discussed in Chapter 7 of *MCAT Biochemistry Review*.

Real World

The *serial endosymbiosis theory* attempts to explain the formation of some of the membrane-bound organelles; it posits that these organelles formed by the engulfing of one prokaryote by another and the establishment of a symbiotic relationship between the two. In addition to mitochondria, chloroplasts in plant cells and organelles of motility (such as flagella) are believed to have evolved through this process.

a double membrane that maintains a nuclear environment separate and distinct from the cytoplasm. **Nuclear pores** in the nuclear membrane allow for selective two-way exchange of material between the cytoplasm and the nucleus.

The genetic material (DNA) contains coding regions called **genes**. Linear DNA is wound around organizing proteins known as **histones**, and is then further wound into linear strands called **chromosomes**. The location of DNA in the nucleus allows for the compartmentalization of DNA transcription separate from RNA translation. Finally, there is a subsection of the nucleus known as the **nucleolus**, where the **ribosomal RNA** (**rRNA**) is synthesized. The nucleolus actually takes up approximately 25 percent of the volume of the entire nucleus and can often be identified as a darker spot in the nucleus.

Mitochondria

Mitochondria, shown in Figure 1.2, are often called *the power plants of the cell*, in reference to their important metabolic functions. The mitochondrion contains two layers: the outer and inner membranes. The **outer membrane** serves as a barrier between the cytosol and the inner environment of the mitochondrion. The inner membrane, which is thrown into numerous infoldings called **cristae**, contains the molecules and enzymes necessary for the electron transport chain. The cristae are highly convoluted structures that increase the surface area available for electron transport chain enzymes. The space between the inner and outer membranes is called the **intermembrane space**; the space inside the inner membrane is called the mitochondrial **matrix**. As described in Chapter 10 of *MCAT Biochemistry Review*, the pumping of protons from the mitochondrial matrix to the intermembrane space establishes the proton-motive force; ultimately, these protons flow through *ATP synthase* to generate ATP during oxidative phosphorylation.

Mitochondria are different from other parts of the cell in that they are semi-autonomous. They contain some of their own genes and replicate independently of the nucleus via binary fission. As such, they are paradigmatic examples of **cytoplasmic** or **extranuclear inheritance**—the transmission of genetic material independent of the nucleus. Mitochondria are thought to have evolved from an anaerobic prokaryote engulfing an aerobic prokaryote and establishing a symbiotic relationship.

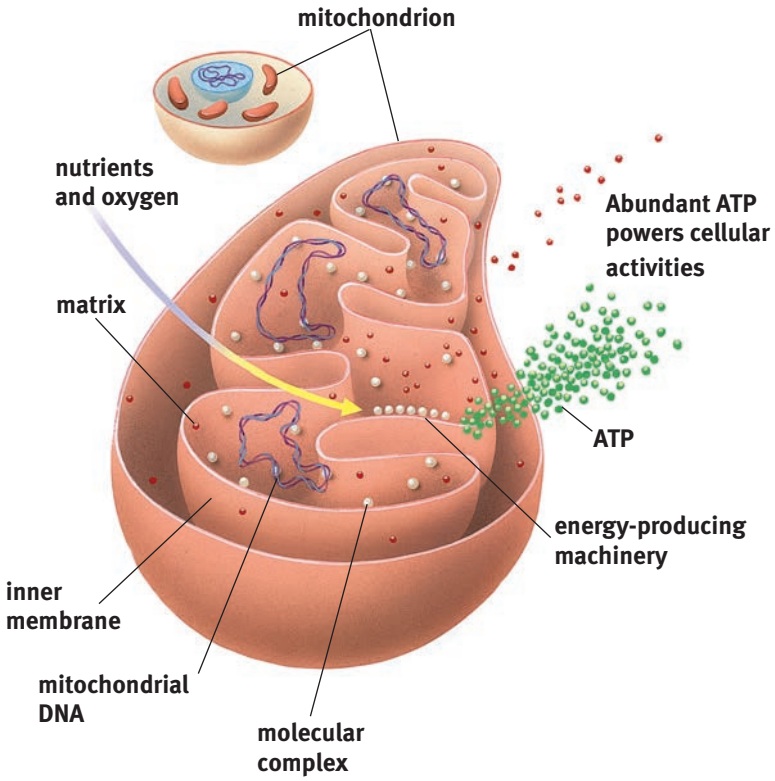

Figure 1.2. Mitochondrial Structure

In addition to keeping the cell alive by providing energy, the mitochondria are also capable of killing the cell by release of enzymes from the electron transport chain. This release kick-starts a process known as **apoptosis**, or programmed cell death.

Lysosomes

Lysosomes are membrane-bound structures containing hydrolytic enzymes that are capable of breaking down many different substrates, including substances ingested by endocytosis and cellular waste products. The lysosomal membrane sequesters these enzymes to prevent damage to the cell. However, release of these enzymes can occur in a process known as **autolysis**. Like mitochondria, when lysosomes release their hydrolytic enzymes, it results in apoptosis. In this case, the released enzymes directly lead to the degradation of cellular components.

Endoplasmic Reticulum

The **endoplasmic reticulum** (**ER**) is a series of interconnected membranes that are actually contiguous with the nuclear envelope. The double membrane of the endoplasmic reticulum is folded into numerous invaginations, creating complex structures with a central lumen. There are two varieties of ER: smooth and rough. The **rough ER** (**RER**) is studded with **ribosomes**, which permit the

translation of proteins destined for secretion directly into its lumen. On the other hand, the **smooth ER** (**SER**) lacks ribosomes and is utilized primarily for lipid synthesis (such as the phospholipids in the cell membrane) and the detoxification of certain drugs and poisons. The SER also transports proteins from the RER to the Golgi apparatus.

Golgi Apparatus

The **Golgi apparatus** consists of stacked membrane-bound sacs. Materials from the ER are transferred to the Golgi apparatus in vesicles. Once in the Golgi apparatus, these cellular products may be modified by the addition of various groups, including carbohydrates, phosphates, and sulfates. The Golgi apparatus may also modify cellular products through the introduction of signal sequences, which direct the delivery of the product to a specific cellular location. After modification and sorting in the Golgi apparatus, cellular products are repackaged in vesicles, which are subsequently transferred to the correct cellular location. If the product is destined for secretion, then the secretory vesicle merges with the cell membrane and its contents are released via **exocytosis**. The relationships between lysosomes, the ER, and the Golgi apparatus are shown in Figure 1.3.

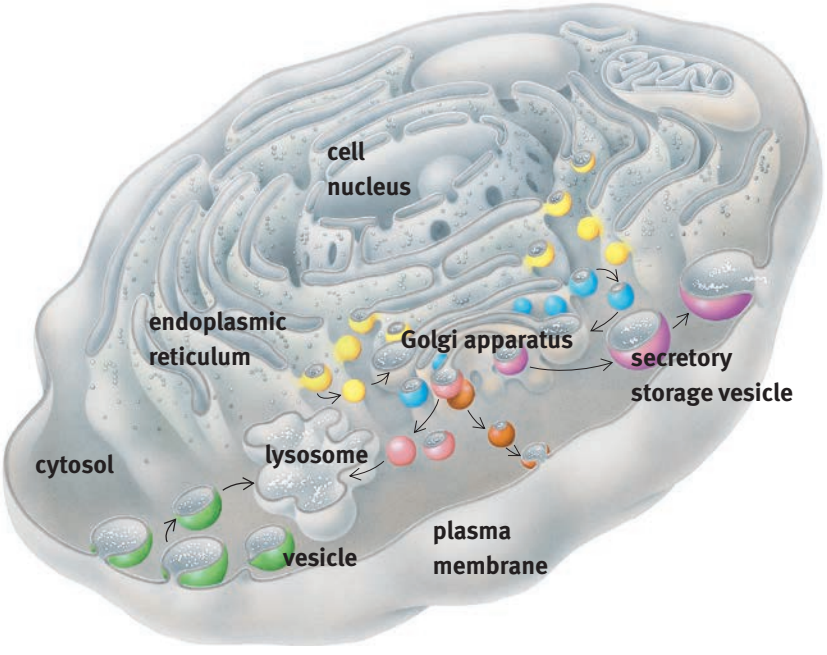

Figure 1.3. Lysosomes, the Endoplasmic Reticulum, and the Golgi Apparatus

Peroxisomes

Peroxisomes contain hydrogen peroxide. One of the primary functions of peroxisomes is the breakdown of very long chain fatty acids via β-oxidation. Peroxisomes participate in the synthesis of phospholipids and contain some of the enzymes involved in the pentose phosphate pathway, discussed in Chapter 9 of *MCAT Biochemistry Review*.

Key Concept

Not all cells have the same relative distribution of organelles. Form will follow function. Cells that require a lot of energy for locomotion (such as sperm cells) have high concentrations of mitochondria. Cells involved in secretion (such as pancreatic islet cells and other endocrine tissues) have high concentrations of RER and Golgi apparatus. Other cells, such as red blood cells, which primarily serve a transport function, have no organelles at all.

THE CYTOSKELETON

The **cytoskeleton**, shown in Figure 1.4, provides structure to the cell and helps it to maintain its shape. In addition, the cytoskeleton provides a conduit for the transport of materials around the cell. There are three components of the cytoskeleton: microfilaments, microtubules, and intermediate filaments.

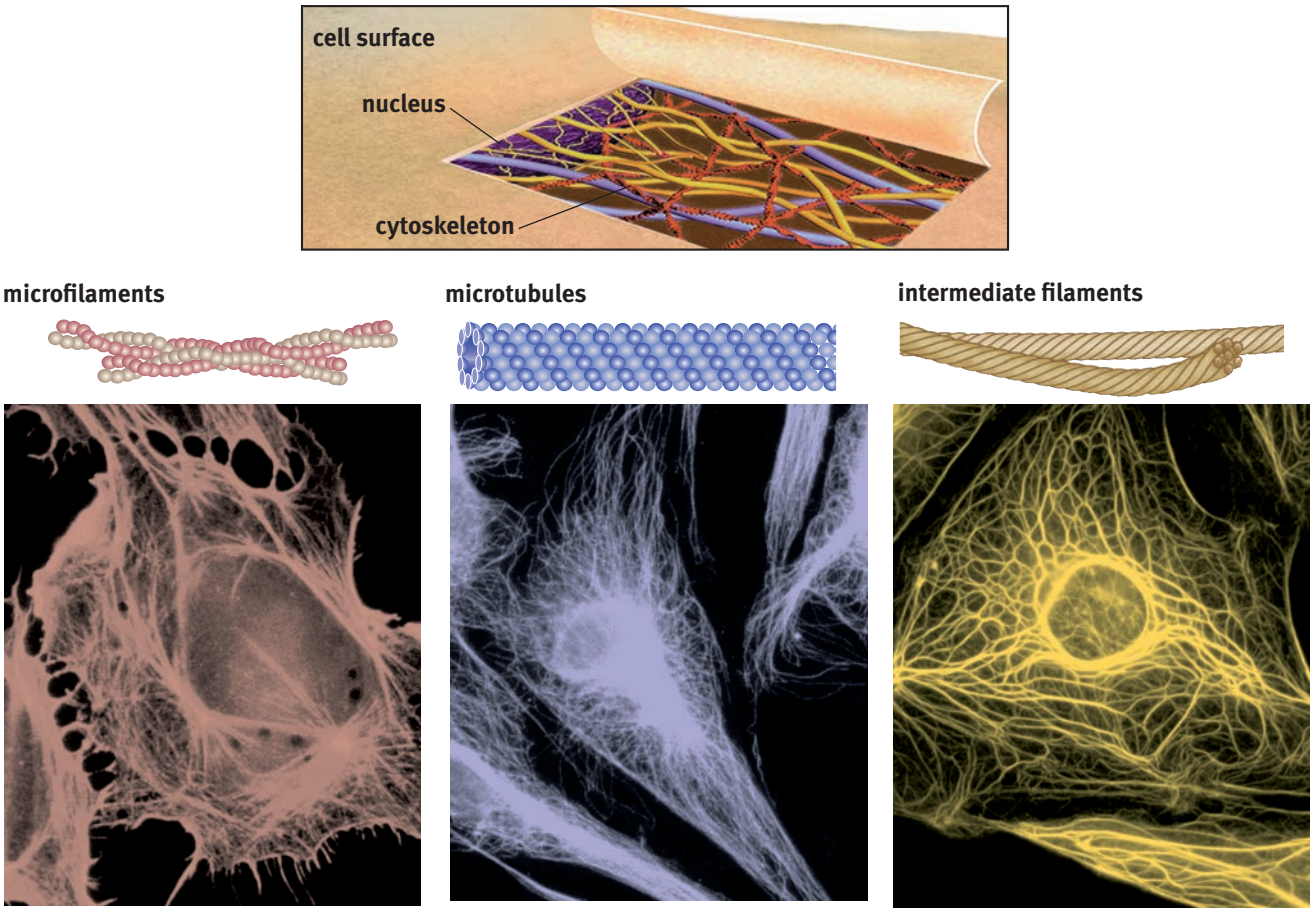

Figure 1.4. Cytoskeletal Elements
The rounded shape near the center in each of these photographs is the nucleus.

Microfilaments

Microfilaments are made up of solid polymerized rods of **actin**. The actin filaments are organized into bundles and networks and are resistant to both compression and fracture, providing protection for the cell. Actin filaments can also use ATP to generate force for movement by interacting with **myosin**, such as in muscle contraction.

Microfilaments also play a role in **cytokinesis**, or the division of materials between daughter cells. During mitosis, the **cleavage furrow** is formed from microfilaments, which organize as a ring at the site of division between the two new daughter cells. As the actin filaments within this ring contract, the ring becomes smaller, eventually pinching off the connection between the two daughter cells.

Bridge

Motor proteins like kinesin and dynein are classic examples of nonenzymatic protein function, along with binding proteins, cell adhesion molecules, immunoglobulins, and ion channels. Motor proteins often travel along cytoskeletal structures to accomplish their functions. Nonenzymatic protein functions are discussed in Chapter 3 of *MCAT Biochemistry Review*.

Microtubules

Unlike microfilaments, **microtubules** are hollow polymers of **tubulin** proteins. Microtubules radiate throughout the cell, providing the primary pathways along which motor proteins like **kinesin** and **dynein** carry vesicles.

Cilia and flagella are motile structures composed of microtubules. **Cilia** are projections from a cell that are primarily involved in movement of materials along the surface of the cell; for example, cilia line the respiratory tract and are involved in movement of mucus. **Flagella** are structures involved in movement of the cell itself, such as the movement of sperm cells through the reproductive tract. Cilia and flagella share the same structure, composed of nine pairs of microtubules forming an outer ring, with two microtubules in the center, as shown in Figure 1.5. This is known as a **9 + 2 structure** and is seen only in eukaryotic organelles of motility. Bacterial flagella have a different structure with a different chemical composition, as discussed later in this chapter.

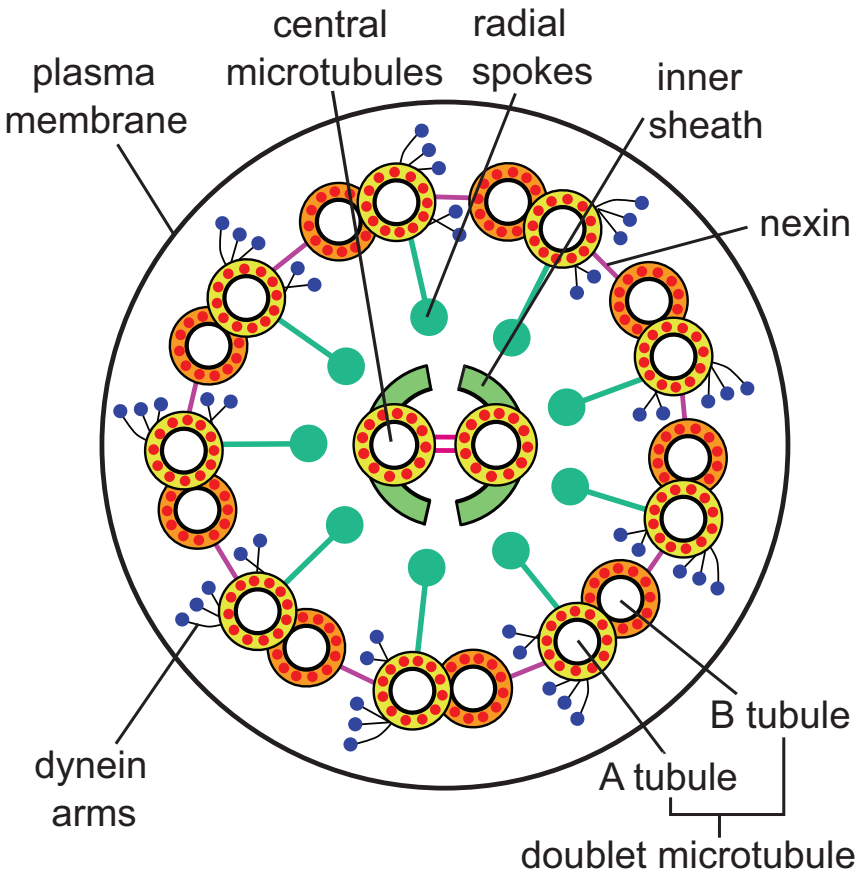

Figure 1.5. Cilium and Flagellum Structure
Microtubules are organized into a ring of 9 doublets with 2 central microtubules.

Centrioles are found in a region of the cell called the **centrosome**. They are the organizing centers for microtubules and are structured as nine triplets of microtubules with a hollow center. During mitosis, the centrioles migrate to opposite poles of the dividing cell and organize the mitotic spindle. The microtubules emanating from the centrioles attach to the chromosomes via complexes called **kinetochores** and can exert force on the sister chromatids, pulling them apart.

Intermediate Filaments

Intermediate filaments are a diverse group of filamentous proteins, including keratin, desmin, vimentin, and lamins. Many intermediate filaments are involved in cell–cell adhesion or maintenance of the overall integrity of the cytoskeleton. Intermediate filaments are able to withstand a tremendous amount of tension, making the cell structure more rigid. In addition, intermediate filaments help anchor other organelles, including the nucleus. The identity of the intermediate filament proteins within a cell is specific to the cell and tissue type.

TISSUE FORMATION

One of the unique characteristics of eukaryotic cells is the formation of tissues with division of labor, as different cells in a tissue may carry out different functions. For example, in the heart, some cells participate in the conduction pathways while others cause contraction; still others serve a supportive role, maintaining structural integrity of the organ. There are four tissue types: epithelial tissue, connective tissue, muscle, and nervous tissue. While muscle and nervous tissue are considered more extensively in subsequent chapters, we explore epithelial and connective tissues below.

Epithelial Tissue

Epithelial tissues cover the body and line its cavities, providing a means for protection against pathogen invasion and desiccation. In certain organs, epithelial cells are involved in absorption, secretion, and sensation. To remain one cohesive unit, epithelial cells are tightly joined to each other and to an underlying layer of connective tissue known as the **basement membrane**. Epithelial cells are highly diverse and serve numerous functions depending on the identity of the organ in which they are found; in most organs, epithelial cells constitute the **parenchyma**, or the functional parts of the organ. For example, nephrons in the kidney, hepatocytes in the liver, and acid-producing cells of the stomach are all composed of epithelial cells.

Epithelial cells are often polarized, meaning that one side faces a lumen (the hollow inside of an organ or tube) or the outside world, while the other side interacts with underlying blood vessels and structural cells. For example, in the small intestine, one side of the cell will be involved in absorption of nutrients from the lumen, while the other side will be involved in releasing those nutrients into circulation for use in the rest of the body.

We can classify different epithelia according to the number of layers they have and the shape of their cells. **Simple epithelia** have one layer of cells; **stratified epithelia** have multiple layers; and **pseudostratified epithelia** appear to have multiple layers due to differences in cell height, but are, in reality, only one layer. Turning to shape, cells may be classified as cuboidal, columnar, or squamous. As their names imply, **cuboidal** cells are cube-shaped and **columnar** cells are long and thin. **Squamous** cells are flat and scalelike.

Connective Tissue

Connective tissue supports the body and provides a framework for the epithelial cells to carry out their functions. Whereas epithelial cells contribute to the parenchyma of an organ, connective tissues are the main contributors to the **stroma** or support structure. Bone, cartilage, tendons, ligaments, adipose tissue, and blood are all examples of connective tissues. Most cells in connective tissues produce and secrete materials such as collagen and elastin to form the **extracellular matrix**.

MCAT Concept Check 1.2:

Before you move on, assess your understanding of the material with these questions.

1. Briefly describe the functions of each of the organelles listed below:
   - Nucleus:

     _____

     _____
   - Mitochondrion:

     _____

     _____
   - Lysosome:

     _____

     _____
   - Rough endoplasmic reticulum:

     _____

     _____
   - Smooth endoplasmic reticulum:

     _____

     _____
   - Golgi apparatus:

     _____

     _____

- Peroxisome:

_____

_____

2. A child is diagnosed with an enzyme deficiency that prevents the production of hydrogen peroxide. What would the likely outcome be of such a deficiency?

_____

_____

3. What are the predominant proteins in each cytoskeletal element?
   - Microfilaments:

     _____
   - Microtubules:

     _____
   - Intermediate filaments:

     _____

4. How do the cytoskeletal structures of centrioles and flagella differ?

_____

_____

5. Classify each of the following cells as epithelial cells or connective tissue:
   - Fibroblasts, which produce collagen in a number of organs:

     _____
   - Endothelial cells, which line blood vessels:

     _____
   - α-cells, which produce glucagon in the pancreas:

     _____
   - Osteoblasts, which produce osteoid, the material that hardens into bone:

     _____
   - Chondroblasts, which produce cartilage:

     _____

1.3 Classification and Structure of Prokaryotic Cells

Prokaryotes are the simplest of all organisms and include all bacteria. Prokaryotes do not contain any membrane-bound organelles, and their genetic material is organized into a single circular molecule of DNA concentrated in an area of the cell called the **nucleoid region**. Despite the simplicity of prokaryotes, they are incredibly diverse, and knowledge of this diversity is essential for the study of medicine because many prokaryotes can cause infection. In fact, choosing the appropriate antibiotic to fight an infection requires knowledge about the basic structure of the bacteria causing the infection.

PROKARYOTIC DOMAINS

There are three overarching domains into which all life is classified: Archaea, Bacteria, and Eukarya. Two of these—Archaea and Bacteria—contain prokaryotes. Initially, Archaea and Bacteria were classified together into the kingdom of Monera. However, modern genetics and biochemical techniques have indicated that the differences in the evolutionary pathways between Archaea and Bacteria are at least as significant as between either of these domains and Eukarya.

Archaea

Archaea are single-celled organisms that are visually similar to bacteria, but contain genes and several metabolic pathways that are more similar to eukaryotes than to bacteria. Historically, Archaea were considered ***extremophiles***, in that they were most commonly isolated from harsh environments with extremely high temperatures, high salinity, or no light. More recent research has demonstrated a greater variety of habitats for these organisms, including the human body. Archaea are notable for their ability to use alternative sources of energy. While some are photosynthetic, many are chemosynthetic and are able to generate energy from inorganic compounds, including sulfur- and nitrogen-based compounds, such as ammonia.

Due to the similarities of this domain to eukaryotes, it is hypothesized that eukaryotes and the domain Archaea share a common origin. Both eukaryotes and Archaea start translation with methionine, contain similar *RNA polymerases*, and associate their DNA with histones. However, Archaea contain a single circular chromosome, divide by binary fission or budding, and overall share a similar structure to bacteria. Interestingly, Archaea are resistant to many antibiotics.

Bacteria

All bacteria contain a **cell membrane** and **cytoplasm**, and some have **flagella** or **fimbriae** (similar to cilia), as shown in Figure 1.6. Because bacteria and eukaryotes often share analogous structures, it can be difficult to develop medicines that target only bacteria. However, in some cases, even seemingly similar structures have enough biochemical differences to allow the targeting of one organism over the other. For example, bacterial flagella and eukaryotic flagella are distinct enough that scientists are able to develop antibacterial vaccines that specifically target the bacterial flagellum. Also, many antibiotics target the bacterial ribosome, which is significantly smaller than the eukaryotic ribosome.

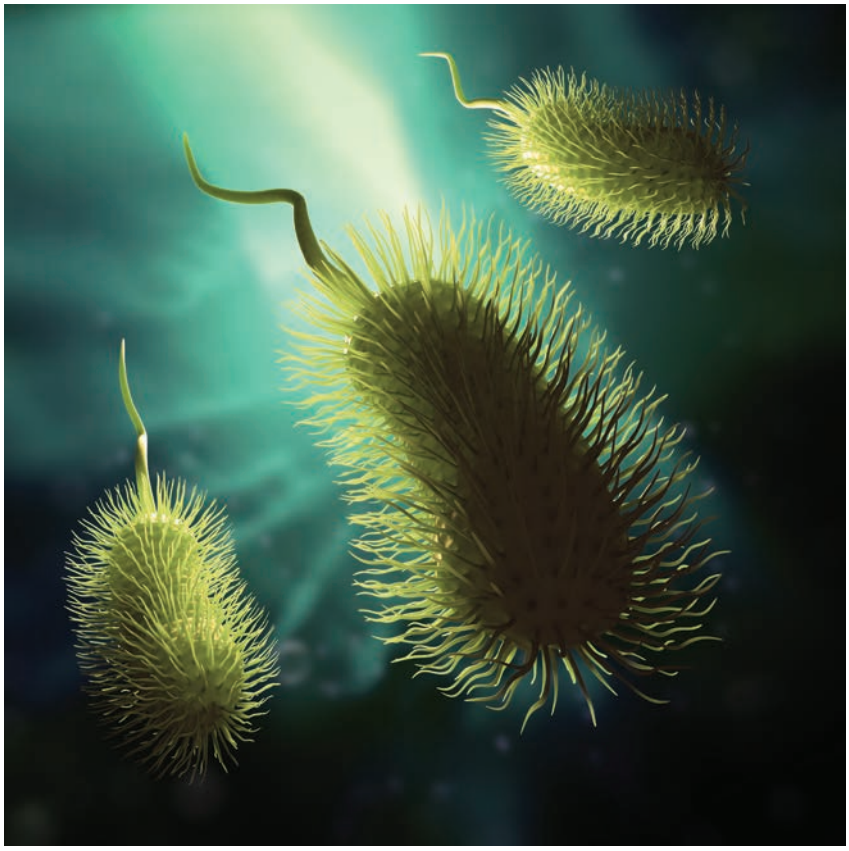

Figure 1.6. Prokaryotic Cell Specializations: Flagella and Fimbriae

There are approximately 5×10^{30} bacteria on earth, outnumbering all of the plants and animals combined. As mentioned in the introduction to this chapter, bacteria outnumber human cells in the body by 10:1. The relationship between the human body and bacteria is complex. Some bacteria are **mutualistic symbiotes**, meaning that both humans and the bacteria benefit from the relationship. Examples include the bacteria in the human gut that produce vitamin K and biotin (vitamin B_7), and which also prevent the overgrowth of harmful bacteria. Other bacteria are **pathogens** or **parasites**, meaning that they provide no advantage or benefit to the host, but

Real World

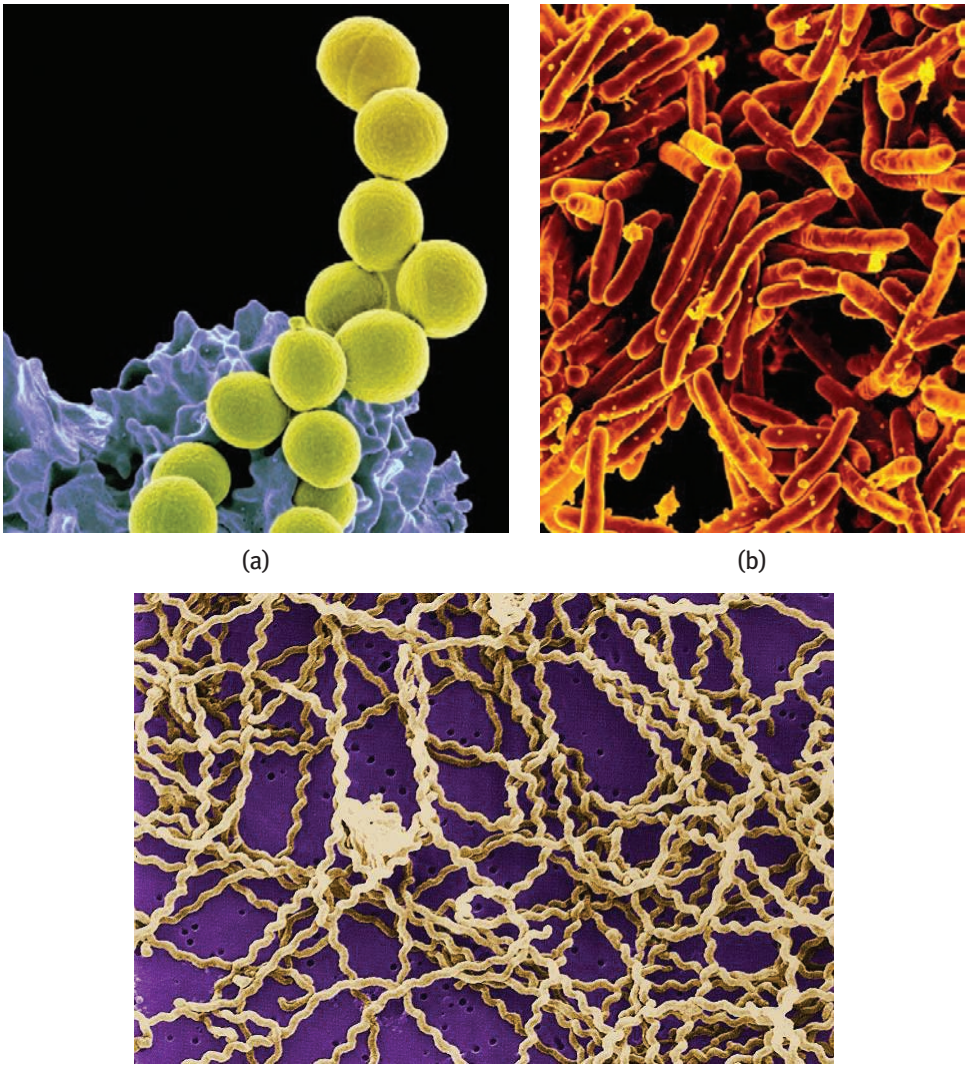
Bacteria perform essential functions for human beings, including the production of vitamin K in the intestine. Vitamin K is required for production of the plasma proteins necessary for blood clotting. Newborn infants are not yet colonized by bacteria and cannot produce clotting factors, putting them at risk for hemorrhage. When babies are born, they are given an injection of vitamin K to aid in the production of clotting factors until they have been colonized with bacteria.

rather cause disease. Pathogenic bacteria may live intracellularly or extracellularly. For example, *Chlamydia trachomatis*, a common sexually transmitted infection, lives inside cells of the reproductive tract; *Clostridium tetani*, the cause of tetanus, lives outside of cells and produces toxins that enter the bloodstream.

CLASSIFICATION OF BACTERIA BY SHAPE

Classification of bacteria by shape provides scientists and pathologists (physicians who specialize in the identification and characterization of disease) a common language to talk about bacteria, as well as a way to identify different species of bacteria.

Most bacteria exist in one of three shapes, as shown in Figure 1.7. Spherical bacteria, known as **cocci**, include common pathogens such as *Streptococcus pyogenes*.



(a) (b)

(c)

Figure 1.7. Prokaryotic Cell Shapes
(a) Cocci (*Staphylococcus aureus*), (b) Bacilli (*Mycobacterium tuberculosis*), (c) Spirilli (*Leptospira interrogans*).

Rod-shaped bacteria, like *Escherichia coli*, are known as **bacilli**. Finally, spiral-shaped bacteria, known as **spirilli**, include such species as *Treponema pallidum*, which causes syphilis.

AEROBES AND ANAEROBES

Some bacteria require oxygen for survival, while others do not. Bacteria that require oxygen for metabolism are termed **obligate aerobes**. Other bacteria that use fermentation, or some other form of cellular metabolism that does not require oxygen, are called **anaerobes**. There are different types of anaerobes. Anaerobes that cannot survive in an oxygen-containing environment are called **obligate anaerobes**; the presence of oxygen leads to the production of reactive oxygen-containing radicals in these species, which leads to cell death. Other bacteria can toggle between metabolic processes, using oxygen for aerobic metabolism if it is present, and switching to anaerobic metabolism if it is not. These bacteria are called **facultative anaerobes**. Finally, **aerotolerant anaerobes** are unable to use oxygen for metabolism, but are not harmed by its presence in the environment.

PROKARYOTIC CELL STRUCTURE

One of the main differences between prokaryotes and eukaryotes is that prokaryotes lack a nucleus and membrane-bound organelles, as shown in Figure 1.8. Prokaryotes are also single-celled organisms, meaning that each cell must be able to perform all of the functions necessary for life on its own. However, prokaryotes may live in colonies with other cells and may signal these cells to share information about the environment.

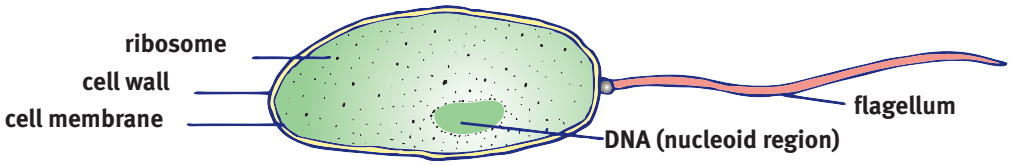


Figure 1.8. Prokaryotic Cell Structure

Cell Wall

Because prokaryotes do not form multicellular organisms, each bacterium is responsible for protecting itself from the environment. The **cell wall** forms the outer barrier of the cell. The next layer is the **cell membrane** (**plasma membrane**), which is composed of phospholipids, similar to that of a eukaryote. Together, the cell wall and the cell membrane are known as the **envelope**.

The cell wall both provides structure and controls the movement of solutes into and out of the bacterium. This allows the cell to maintain concentration gradients

Real World

Very few pathogenic bacteria are spiral shaped. The three most common are:

- *Treponema pallidum*, the cause of syphilis
- *Borrelia burgdorferi*, the cause of Lyme disease
- *Leptospira interrogans*, the cause of Weil's disease

Real World

The antibiotic penicillin targets the enzyme that catalyzes the cross-linking of peptidoglycan. If a gram-positive cell cannot cross-link its cell wall, it no longer serves as an effective barrier. The bacterium becomes susceptible to osmotic damage and lyses. Most bacteria have developed resistance mechanisms to penicillin, although a few bacteria—including *Streptococcus pyogenes*, which causes strep throat and some skin infections, and *Treponema pallidum*, which causes syphilis—are still very sensitive to this antibiotic.

Key Concept

Bacteria contain a cell wall, the composition of which is different in gram-positive and gram-negative bacteria. The human immune system can respond to the components of the cell wall, inciting an inflammatory response.

relative to the environment. In bacteria, there are two main types of cell wall: gram positive and gram negative. The type of cell wall is determined by the Gram staining process with a crystal violet stain, followed by a counterstain with a substance called *safranin*. If the envelope absorbs the crystal violet stain, it will appear deep purple, and the cell is said to be gram positive. If the envelope does not absorb the crystal violet stain, but absorbs the safranin counterstain, then the cell will appear pink-red, and the cell is said to be gram negative.

Gram-positive cell walls consist of a thick layer of **peptidoglycan**, a polymeric substance made from amino acids and sugars. In addition to its structural and barrier functions, the cell wall may also aid a pathogen by providing protection from a host organism's immune system. In addition to peptidoglycan, the gram-positive cell wall also contains **lipoteichoic acid**. The function of this acid for the bacterium is unknown, but the human immune system may be activated by exposure to these chemicals.

Gram-negative cell walls are very thin and also contain peptidoglycan, but in much smaller amounts. The cell walls of these bacteria directly abut the cell membrane. In addition to the cell wall and cell membrane, gram-negative bacteria also have **outer membranes** containing phospholipids and **lipopolysaccharides**. Interestingly, lipopolysaccharides are the part of the gram-negative bacteria that triggers an immune response in human beings; the inflammatory response to lipopolysaccharides is much stronger than the response to lipoteichoic acid.

Flagella

Flagella are long, whiplike structures that can be used for propulsion; bacteria may have one, two, or many flagella, depending on the species. Flagella can be used to move toward food or away from toxins or immune cells. This ability of a cell to detect chemical stimuli and move toward or away from them is called **chemotaxis**. The flagella are composed of a filament, a basal body, and a hook, as shown in Figure 1.9. The **filament** is a hollow, helical structure composed of **flagellin**. The **basal body** is a complex structure that anchors the flagellum to the cytoplasmic membrane and is also the motor of the flagellum, rotating at rates up to 300 Hz. The **hook** connects the filament and the basal body so that, as the basal body rotates, it exerts torque on the filament, which can thereby spin and propel the bacterium forward. The overall structure of flagella is similar in both gram-positive and gram-negative bacteria, but there are slight differences due to the different physical structure and chemical composition of the envelope in gram-positive and gram-negative bacteria. Archaea also contain flagella, but this structure is quite different from that of bacteria and is unlikely to be asked about on Test Day.

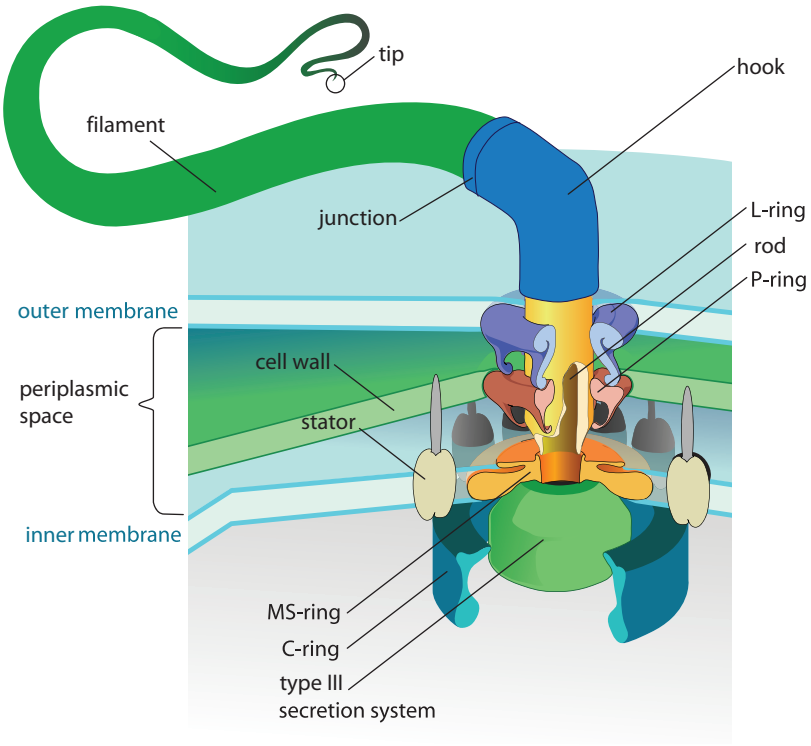

Figure 1.9. Prokaryotic Flagellum Structure
The hook connects the filament to the basal body (the complex structure of which is shown).

Other Organelles

As mentioned earlier, prokaryotes concentrate DNA in a region of the cell known as the nucleoid region, but do not contain a nuclear envelope. Prokaryotic DNA is carried on a single circular chromosome, and in bacteria this DNA is not coiled around histones (though histones are present in archaea). In addition, DNA acquired from external sources may also be carried on smaller circular structures known as **plasmids**. Plasmids carry DNA that is not necessary for survival of the prokaryote—and therefore is not considered part of the genome of the bacterium—but may confer an advantage such as antibiotic resistance.

Prokaryotes lack several key organelles, such as mitochondria. Instead, the cell membrane is used for the electron transport chain and generation of ATP. Prokaryotes do contain a primitive cytoskeleton, but it is not nearly as complex as the one found in eukaryotes. Prokaryotes also contain ribosomes, but this ribosome is a different size from that found in eukaryotes: prokaryotic ribosomes contain 30S and 50S subunits, whereas eukaryotic ribosomes contain 40S and 60S ribosomes.

Bridge

The fact that prokaryotes and eukaryotes have different-sized ribosomes should imply to you that they carry out protein synthesis in slightly different ways. These differences are highlighted in Chapter 7 of *MCAT Biochemistry Review*. This difference also allows us to target bacterial ribosomes with a number of antibiotics, including *tetracyclines*, *aminoglycosides*, and *macrolides*, while leaving the eukaryotic ribosome more or less unaffected.

MCAT Concept Check 1.3:

Before you move on, assess your understanding of the material with these questions.

1. In what ways are Archaea similar to bacteria? In what ways are Archaea similar to eukaryotes?
   - Similar to bacteria:

     _____
   - Similar to eukaryotes:

     _____

2. What are the three common shapes of bacteria?
   - _____
   - _____
   - _____

3. Compare and contrast the metabolisms of aerobic and anaerobic bacteria: (Note: Put "yes" or "no" in each box.)

	Oxygen Present		Oxygen Absent	
Type of Bacteria	Can survive	Can carry out aerobic metabolism	Can survive	Can carry out anaerobic metabolism
Obligate aerobe				
Facultative anaerobe				
Obligate anaerobe				
Aerotolerant anaerobe				

4. How do the envelopes of gram-positive and gram-negative bacteria differ?
   - Gram-positive: _____
   - Gram-negative: _____

5. How do the structures of eukaryotic and prokaryotic flagella differ?
   - Eukaryotic: _____
   - Prokaryotic: _____

1.4 Genetics and Growth of Prokaryotic Cells

As we have already explored, prokaryotic cells differ from eukaryotic cells both structurally and biochemically. Prokaryotes reproduce via asexual reproduction in the form of binary fission. In addition, prokaryotes are capable of acquiring genetic material from outside the cell and using that genetic material.

BINARY FISSION

Binary fission, shown in Figure 1.10, is a simple form of asexual reproduction seen in prokaryotes. The circular chromosome attaches to the cell wall and replicates while the cell continues to grow in size. Eventually, the plasma membrane and cell wall begin to grow inward along the midline of the cell to produce two identical daughter cells. Because binary fission requires fewer events than mitosis, it can proceed more rapidly. In fact, some strains of *E. coli* can replicate every 20 minutes under ideal growth conditions.

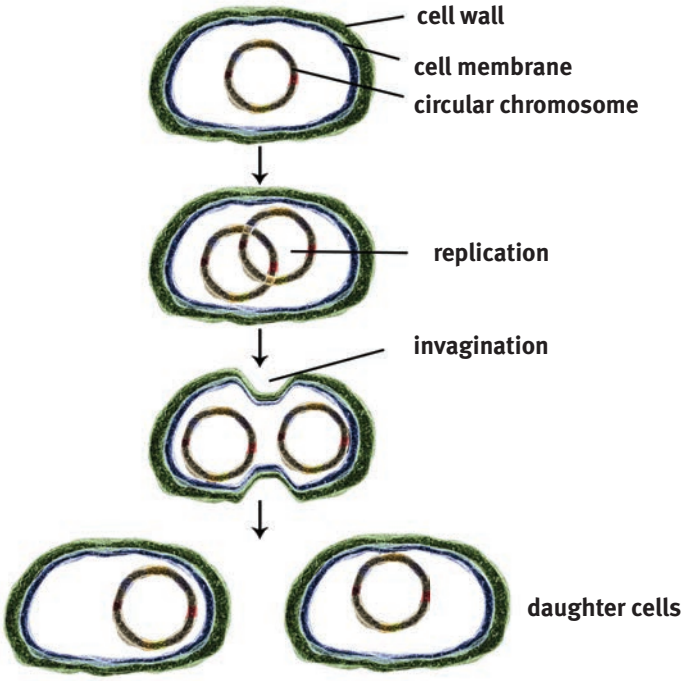

Figure 1.10. Stages of Binary Fission

GENETIC RECOMBINATION

This single circular chromosome of a prokaryotic cell contains the information that is necessary for the cell to survive and reproduce. However, many bacteria also

contain extrachromosomal (extragenomic) material known as **plasmids**. Plasmids often carry genes that impart some benefit to the bacterium, such as antibiotic resistance, some mechanisms of which are shown in Figure 1.11. Plasmids may also carry additional **virulence factors**, or traits that increase how pathogenic a bacterium is, such as toxin production, projections that allow the bacterium to attach to certain kinds of cells, or evasion of the host's immune system. A subset of plasmids called **episomes** are capable of integrating into the genome of the bacterium.

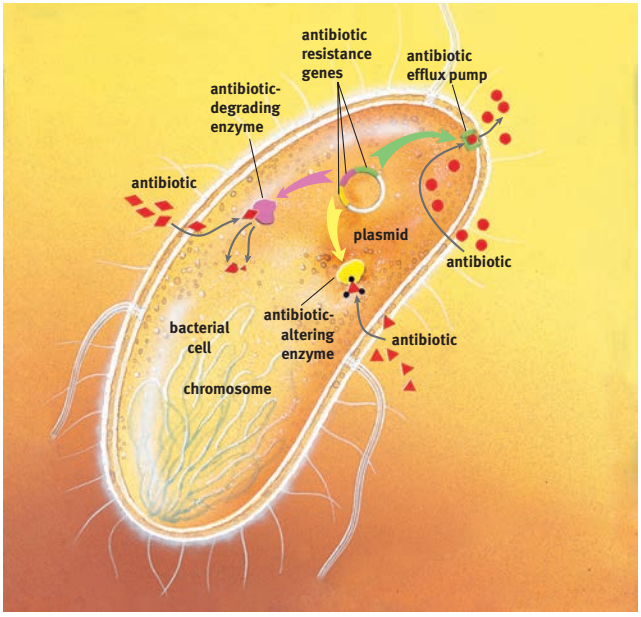

Figure 1.11. Mechanisms of Antibiotic Resistance

Bacterial genetic recombination helps increase bacterial diversity and thus permits evolution of a bacterial species over time. These recombination processes include transformation, conjugation, and transduction.

Transformation

Transformation results from the integration of foreign genetic material into the host genome. This foreign genetic material most frequently comes from other bacteria that, upon lysing, spill their contents in the vicinity of a bacterium capable of transformation. Many gram-negative rods are able to carry out this process.

Conjugation

Conjugation is the bacterial form of mating (sexual reproduction). It involves two cells forming a **conjugation bridge** between them that allows for the transfer of genetic material. The transfer is unidirectional, from the **donor male** (+) to the **recipient female** (–). The bridge is made from appendages called **sex pili** that are found on the donor male. To form the pilus, bacteria must contain plasmids known as **sex factors** that contain the necessary genes. The best-studied sex factor

is the **F** (**fertility**) **factor** in *E. coli*. Bacteria possessing this plasmid are termed F^+ cells; those without are called F^- cells. During conjugation between an F^+ and an F^- cell, the F^+ cell replicates its F factor and donates the copy to the recipient, converting it to an F^+ cell. This enables the cell obtaining the new plasmid to then transfer copies to other cells. This method of genetic recombination allows for rapid acquisition of antibiotic resistance or virulence factors throughout a colony because other plasmids can also be passed through the conjugation bridge. The process of conjugation is illustrated in Figure 1.12.

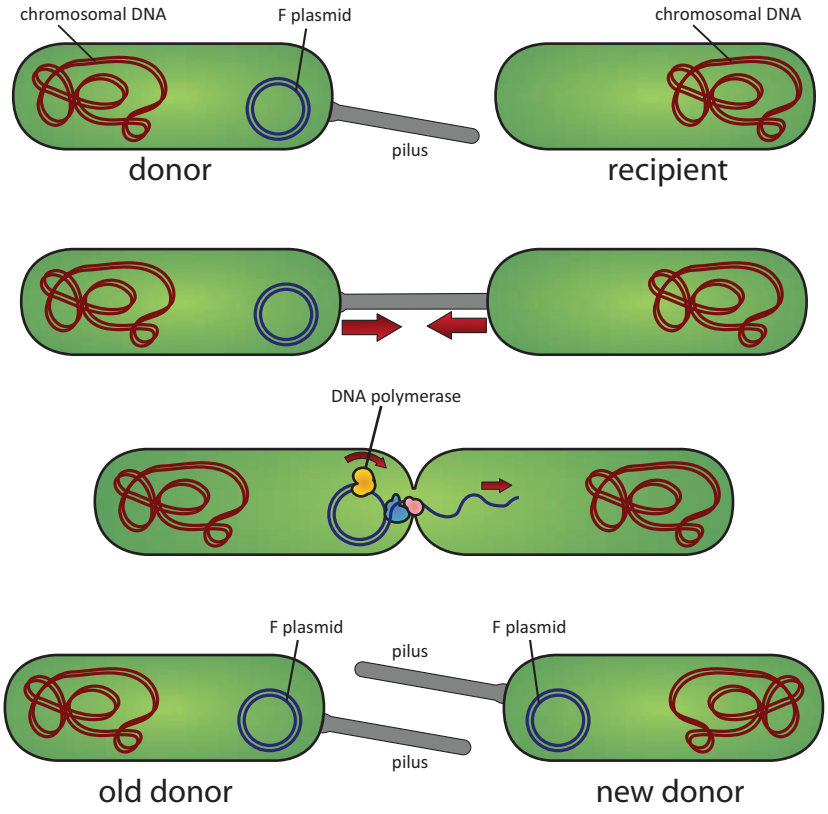

Figure 1.12. Bacterial Conjugation

The sex factor is a plasmid, but through processes such as transformation, it can become integrated into the host genome. In this case, when conjugation occurs, the entire genome replicates because it now contains the sex factor. The donor cell will then attempt to transfer an entire copy of its genome into the recipient; however, the bridge usually breaks before the full DNA sequence can be moved. Cells that have undergone this change are referred to by the abbreviation **Hfr** for **high frequency of recombination**.

Transduction

Transduction is the only genetic recombination process that requires a **vector**—a virus that carries genetic material from one bacterium to another. Viruses are obligate intracellular pathogens, which means that they cannot reproduce outside

of a host cell. Because of this, **bacteriophages** (viruses that infect bacteria) can accidentally trap a segment of host DNA during assembly. When the bacteriophage infects another bacterium, it can release this trapped DNA into the new host cell. This transferred DNA can then integrate into the genome, giving the new host additional genes. The process of transduction is shown in Figure 1.13.

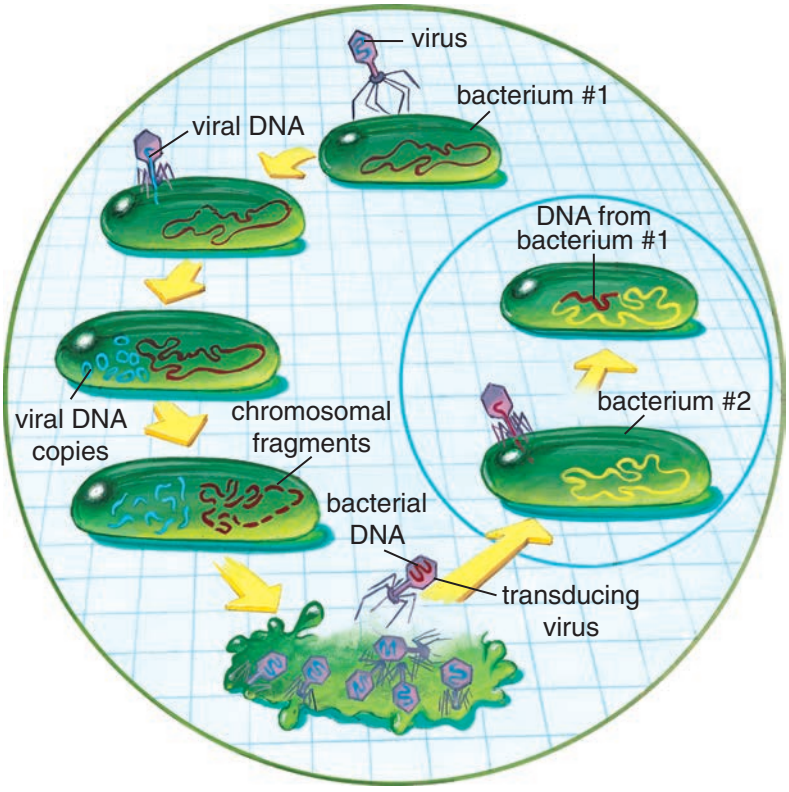

Figure 1.13. Bacterial Transduction

Transposons

Transposons are genetic elements capable of inserting and removing themselves from the genome. This phenomenon is not limited to prokaryotes; it has been seen in eukaryotes as well. If a transposon is inserted within a coding region of a gene, that gene may be disrupted.

Real World

One of the biggest challenges a doctor faces is that of patient compliance with treatment, especially antibiotics. Many patients fail to complete an entire course of antibiotics, often discontinuing the treatment because they feel better. Unfortunately, this breeds antibiotic resistance by killing off the bacteria that are nonresistant and leaving behind bacteria that are more resistant. These resistant bacteria then reproduce, resulting in recurrence of the infection. Over time, this practice has led to bacteria that are resistant to multiple antibiotics, making common infections more difficult to treat.

GROWTH

As discussed previously, bacteria reproduce via binary fission. This implies that all of the bacteria are exactly the same in a local colony (assuming no mutations or genetic recombination), and no bacteria will be dividing faster than the others. Bacteria can be said to grow in a series of phases, as shown in Figure 1.14. In a new environment, the bacteria first adapt to the new local conditions during the **lag phase**. As the bacteria adapt, growth increases, causing an exponential increase in the number of bacteria in the colony during the **exponential phase**, which can also be called

the **log phase**. As the number of bacteria in the colony grows, resources are often reduced. The reduction of resources slows reproduction, and the **stationary phase** results. After the bacteria have exceeded the ability of the environment to support the number of bacteria, a **death phase** occurs as resources in the environment have been depleted.

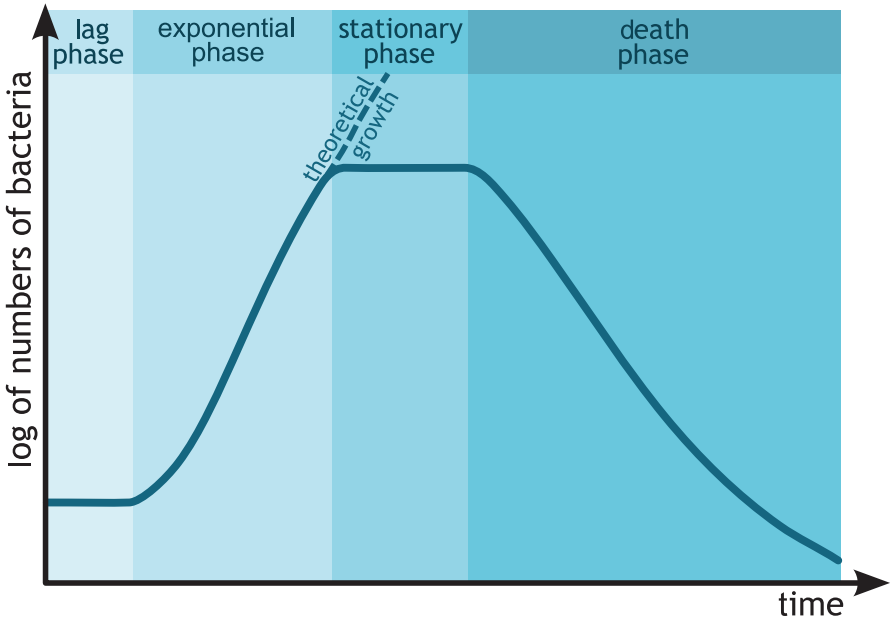

Figure 1.14. Bacterial Growth Curve

Bridge

The bacterial growth curve is an example of a semilog plot. The fact that the *y*-axis is logarithmic means that a straight line (as seen during the exponential phase) actually represents an exponential increase in the number of bacteria, not a linear increase. Semilog and log–log plots are discussed in Chapter 12 of *MCAT Physics and Math Review*.

MCAT Concept Check 1.4:

Before you move on, assess your understanding of the material with these questions.

1. Briefly describe the three mechanisms of bacterial genetic recombination:
   - Transformation:

     _____

     _____
   - Conjugation:

     _____

     _____
   - Transduction:

     _____

     _____

2. What are the four phases of the bacterial growth curve? What are the features of each phase?

Phase	Features

1.5 Viruses and Subviral Particles ★★★

At the beginning of this chapter, we discussed the cell theory and noted that viruses do not fit the definition of living things because they are acellular. Viruses may be as small as 20 nm or as large as 300 nm. For reference, prokaryotes are 1–10 μm, and eukaryotes are about ten times larger. Unlike eukaryotic cells, viruses lack organelles and a nucleus.

VIRAL STRUCTURE

Viruses are composed of genetic material, a protein coat, and sometimes an envelope containing lipids. The genetic information may be circular or linear, single- or double-stranded, and composed of either DNA or RNA. The protein coat is known as a **capsid**. If an envelope is present, it will surround the capsid and is composed of phospholipids and virus-specific proteins. The envelope is very sensitive to heat, detergents, and desiccation; thus, enveloped viruses are easier to kill. On the other hand, viruses that do not have an envelope are more resistant to sterilization and are likely to persist on surfaces for an extended period of time.

Because viruses cannot reproduce independently, they are considered obligate intracellular parasites. Viruses must express and replicate genetic information within a **host cell** because they lack ribosomes to carry out protein synthesis. After hijacking a cell's machinery, a virus will replicate and produce viral progeny, called **virions**, which can be released to infect additional cells.

Bacteriophages are viruses that specifically target bacteria. They do not actually enter bacteria; rather, they simply inject their genetic material, leaving the remaining structures outside the infected cell. In addition to a capsid, bacteriophages contain a tail sheath and tail fibers, as shown in Figure 1.15. The **tail sheath** can act like a syringe, injecting genetic material into a bacterium. The **tail fibers** help the bacteriophage to recognize and connect to the correct host cell.

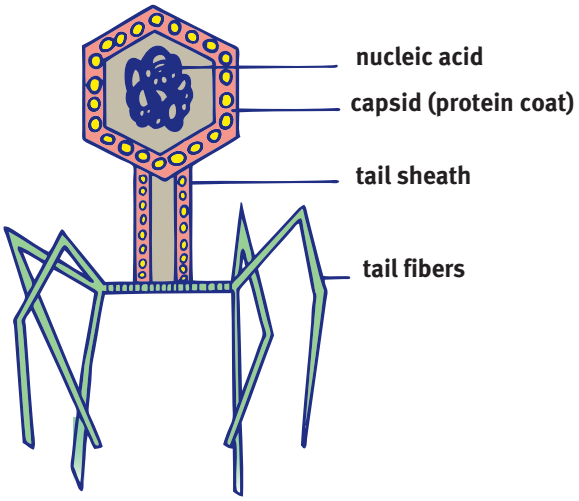

Figure 1.15. Structure of a Bacteriophage

VIRAL GENOMES

Viral genomes come in a variety of shapes and sizes. Some are made of only a few genes, while others have several hundred. In addition, viral genomes may be made of either DNA or RNA, and may be single- or double-stranded in both cases.

Single-stranded RNA viruses may be positive sense or negative sense. **Positive sense** implies that the genome may be directly translated to functional proteins by the ribosomes of the host cell, just like mRNA. **Negative-sense** RNA viruses are a bit more complicated: these viruses require synthesis of an RNA strand *complementary* to the negative-sense RNA strand, which can then be used as a template for protein synthesis. Negative-sense RNA viruses must carry an ***RNA replicase*** in the virion to ensure that the complementary strand is synthesized.

Retroviruses are enveloped, single-stranded RNA viruses in the family *Retroviridae*; usually, the virion contains two identical RNA molecules. These viruses carry an enzyme known as ***reverse transcriptase***, which synthesizes DNA from single-stranded RNA. The DNA then integrates into the host cell genome, where it is replicated and transcribed as if it were the host cell's own DNA. This is a clever mechanism because the integration of the genetic material into the host cell genome allows for the cell to be infected indefinitely, and the only way to cure the infection is to kill the infected cell itself. The human immunodeficiency virus (HIV) is a retrovirus that utilizes this life cycle, which is one of the characteristics that make HIV so difficult to treat, as shown in Figure 1.16.

Real World

Both retroviruses and transduction are under investigation as methods of gene therapy. It is theorized that retroviruses and transduction methods can deliver functional versions of missing or altered genes, so that the correct proteins can be synthesized and certain disease states can be alleviated. Gene therapy is discussed in Chapter 6 of *MCAT Biochemistry Review*.

Efforts to devise vaccines and new treatments for HIV depend on knowledge of the virus's life cycle. HIV invades host cells and commandeers their machinery to make more copies of itself. First, a protein called *envelope* on the virus must bind to CD4 and CCR5 proteins on the cell surface (1). As the virus fuses with the cell, it empties its contents into the cytoplasm (2). A viral enzyme, reverse transcriptase, then copies the virus's RNA genome into double-stranded DNA (3), often making errors that generate diversity in the virus copies. Another viral enzyme, *integrase*, inserts the copy into the host DNA (4). Cell machinery transcribes the viral genes back into RNA (including RNA that can serve as templates for proteins) that travels to the cytoplasm, where ribosomes produce the encoded proteins (5). Viral RNA and proteins then move toward the cell membrane, where they gather into a budding virus particle (6). In the immature new virus copy, the HIV protease enzyme modifies viral protein chains, enabling the particles, or virions, to mature into a form that is ready to infect a new cell (7).

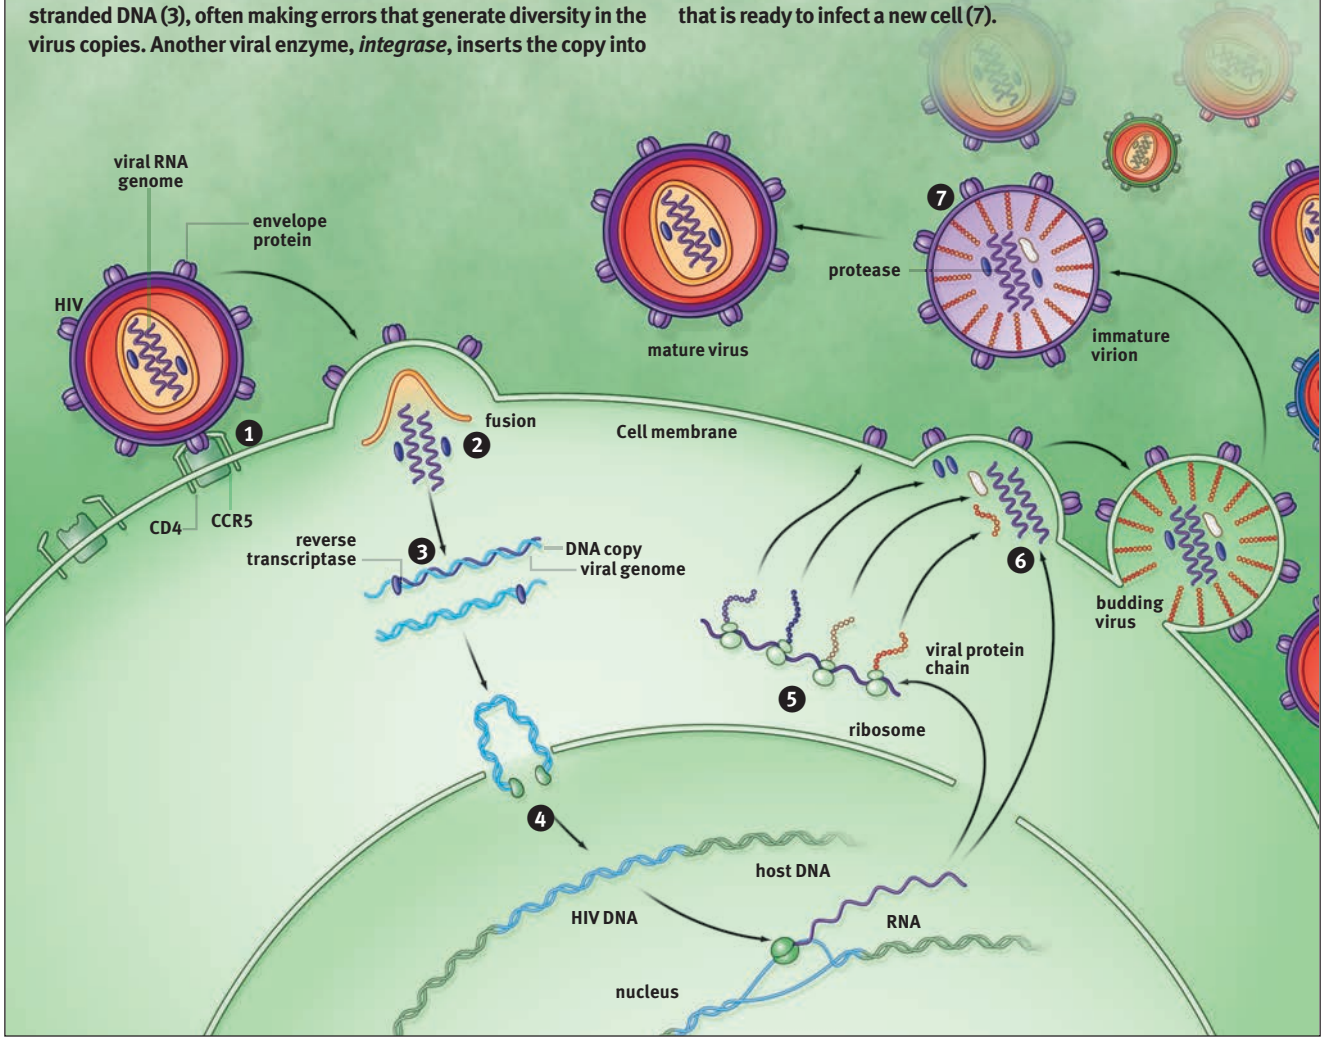

Figure 1.16. Life Cycle of the Human Immunodeficiency Virus (HIV)

VIRAL LIFE CYCLE

As we have already discussed, viruses must infect a host cell and use the host cell's machinery in order to reproduce. Here, we will discuss the viral life cycle in detail.

Infection

Viruses can only infect a specific set of cells. In order to infect a cell, the virus has to bind to specific receptors on the host cell. Without the proper receptors, a cell is essentially invisible to the virus. Once the virus binds the correct receptor, the virus and the cell are brought into close enough proximity to permit additional interactions. Enveloped viruses fuse with the plasma membrane of a cell, allowing entry of the virion into the host cell. Sometimes a host cell may misinterpret the binding of a virus to the membrane as nutrients or other useful molecules and will actually bring the virus into the cytoplasm via endocytosis. As mentioned earlier, bacteriophages use tail fibers to anchor themselves to the cell membrane and then inject their viral genome into the host bacterium using the tail sheath. Some tail fibers even have enzymatic activity, allowing for both penetration of the cell wall and the formation of pores in the cell membrane.

Depending on the virus, different portions of the virion will be inserted into host cells. Enveloped viruses such as HIV fuse with the membrane and enter the cell intact, whereas bacteriophages only insert their genetic material, leaving their capsids outside the host cell.

Translation and Progeny Assembly

After infection, translation of viral genetic material must occur in order for the virus to reproduce. This requires translocation of the genetic material to the correct location in the cell. Most DNA viruses must go to the nucleus in order to be transcribed to mRNA. The mRNA then goes to the cytoplasm, where it is translated to proteins. Genetic material from positive-sense RNA viruses stays in the cytoplasm, where it is directly translated to protein by host cell ribosomes. Negative-sense RNA viruses require synthesis of a complementary RNA strand via RNA replicase, which can then be translated to form proteins. DNA formed through reverse transcription in retroviruses also travels to the nucleus, where it can be integrated into the host genome.

Using the ribosomes, tRNA, amino acids, and enzymes of the host cell, the viral RNA is translated into protein. Many of these proteins are structural capsid proteins and allow for creation of new virions in the cytoplasm in the host cell. Once the viral genome has been replicated, it can be packaged within the capsid. Note that the viral genome must be returned to its original form before packaging; for example, retroviruses must transcribe new copies of their single-stranded RNA from the DNA that entered the host genome. A single virus may create anywhere from hundreds to many thousands of new virions within a single host cell.

Real World

HIV must bind to a receptor called CCR5 on white blood cells in order to infect them. Some people lack this receptor and are thus immune to HIV. There was recently a case in which an HIV-positive man with leukemia received a bone marrow transplant from a donor that lacked CCR5. Not only was his leukemia cured, but this transplant also resulted in remission of his HIV infection because the white blood cells from his newly acquired bone marrow were not susceptible to HIV infection.

Progeny Release

Viral progeny may be released in multiple ways. First, the viral invasion may initiate cell death, which results in spilling of the viral progeny. Second, the host cell may lyse as a result of being filled with extremely large numbers of virions. Lysis is actually a disadvantage for the virus because the virus can no longer use the cell to carry out its life cycle. Finally, a virus can leave the cell by fusing with its plasma membrane as shown in Figure 1.17, a process known as **extrusion**. This process allows for survival of the host cell, and continued use of the host cell by the virus. A virus in this state is said to be in a **productive cycle**.

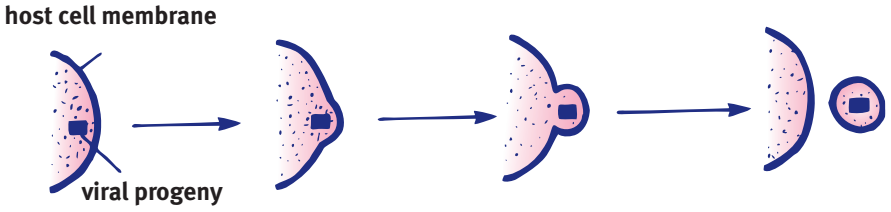

Figure 1.17. Viral Extrusion

Lytic and Lysogenic Cycles

Depending on growth conditions and the specific virus, bacteriophages may enter a lytic or lysogenic life cycle. These two phases are similar to the lysis and productive cycle methods of progeny release discussed above.

During a **lytic cycle**, the bacteriophage makes maximal use of the cell's machinery with little regard for the survival of the host cell. Once the host is swollen with new virions, the cell lyses, and other bacteria can be infected. Bacteria in the lytic phase are termed **virulent**.

In the event that the virus does not lyse the bacterium, it may integrate into the host genome as a **provirus** or **prophage**, beginning the **lysogenic cycle**. In this case, the virus will be replicated as the bacterium reproduces because it is now a part of the host's genome. Although the virus may remain integrated into the host genome indefinitely, environmental factors (radiation, light, or chemicals) will cause the provirus to leave the genome and revert to a lytic cycle at some point. As mentioned earlier, trapping of segments of the bacterial genome can occur when the provirus leaves the genome, which allows transduction of genes from one bacterium to another. Although bacteriophages can kill a host bacterium, there may be some benefit to the bacterium having them integrated in the lysogenic cycle. Infection with one strain of phage generally makes the bacterium less susceptible to **superinfection** (simultaneous infection) with other phages. Because the provirus is relatively innocuous, there may be some evolutionary advantage to this association. The lytic and lysogenic cycles are contrasted in Figure 1.18.

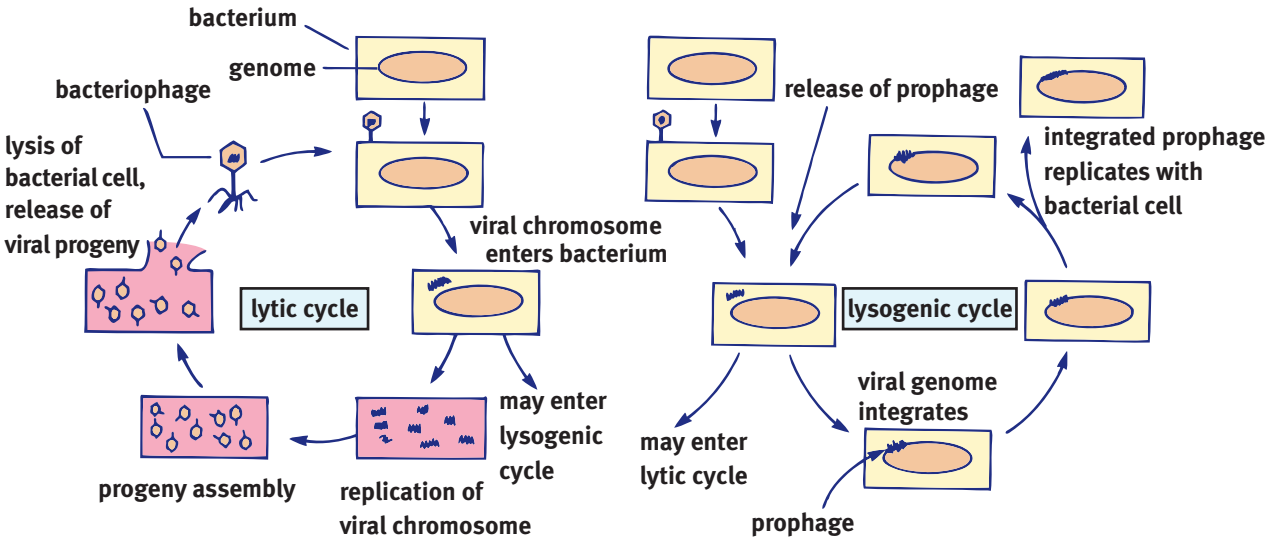

Figure 1.18. Lytic *vs.* Lysogenic Cycles of Bacteriophages

PRIONS AND VIROIDS

Prions and viroids are very small (subviral) particles that can cause disease under certain circumstances.

Prions

Prions are infectious proteins and are, thus, also nonliving things. Prions cause disease by triggering misfolding of other proteins, usually involving the conversion of a protein from an α-helical structure to a β-pleated sheet. This drastically reduces the solubility of the protein, as well as the ability of the cell to degrade the misfolded protein. Eventually, protein aggregates form, and function of the cell is reduced. Prions are known to cause *bovine spongiform encephalopathy* (mad cow disease), *Creutzfeldt–Jakob disease*, and *familial fatal insomnia* in humans.

Viroids

Viroids are small pathogens consisting of a very short circular single-stranded RNA that infect plants. Viroids can bind to a large number of RNA sequences and will silence genes in the plant genome. This prevents synthesis of necessary proteins and can subsequently cause metabolic and structural derangements in the plant cell. Viroids are classically thought of as plant pathogens, but a few examples of human viroids do exist, including the hepatitis D virus (HDV). Alone, HDV is innocuous; however, when coinfected with hepatitis B virus (HBV), HDV is able to exert its silencing function on human hepatocytes.

MCAT Concept Check 1.5:
Before you move on, assess your understanding of the material with these questions.

1. Why are viruses considered obligate intracellular parasites?

_____

_____

2. Coronavirus, which causes the common cold, is described as an enveloped, single-stranded positive-sense RNA virus. What does this description indicate about the virus?

_____

_____

3. Briefly describe the pathway of retroviral nucleic acids from infection of a host cell to release of viral progeny:

_____

_____

_____

4. What are the differences between the lytic and lysogenic cycles?
   - Lytic cycle:

     _____

     _____

   - Lysogenic cycle:

     _____

     _____

5. How do prions cause disease?

_____

_____

Conclusion

Our first chapter introduced the basis of all biology: the cell theory. All living things are made of prokaryotic or eukaryotic cells. Prokaryotes are simpler and do not contain membrane-bound organelles. Eukaryotes contain membrane-bound organelles

with highly specialized functions. While eukaryotic organisms (especially humans!) will be the primary focus on Test Day, an understanding of prokaryotic structure and physiology is necessary to understand infection. Viruses are nonliving infectious particles that must invade cells in order to reproduce. Finally, we discussed the smallest infectious particles, prions and viroids.

Our discussions from here on out will focus primarily on eukaryotes, but you will spend significant time in your clinical career battling the pathogens we've presented in this chapter. Vaccines are available for a number of bacteria (*Bacillus anthracis* [anthrax], *Corynebacterium diphtheriae* [diphtheria], *Haemophilus influenzae* type B [many upper respiratory and ear infections], *Neisseria meningitidis* [some cases of bacterial meningitis], *Streptoccocus pneumoniae* [many cases of bacterial pneumonia], *Clostridium tetani* [tetanus], *Salmonella typhi* [typhoid], and *Bordetella pertussis* [whooping cough]) and viruses (varicella zoster virus [chicken pox and shingles], hepatitis A and B viruses, human papillomavirus [HPV], influenza, measles, mumps, polio, rabies, rotavirus, rubella, and yellow fever). Those for which we do not have vaccines may be targeted with antibiotic and antiviral therapies; the appropriate pharmacotherapy is almost always predicated on an understanding of the bacterial or viral physiology one is targeting and the known resistance patterns in the local area. In other words, the principles presented in this chapter will show up in your everyday life as a physician; it is important not to just memorize but to *understand* the content in this chapter.

We've discussed one method of cellular reproduction—the division of a bacterial cell into two by binary fission. Eukaryotic cells also must replicate, but use a different process: mitosis. It is to this process, as well as meiosis and the human reproductive system, that we turn our attention in the next chapter.

CONCEPT SUMMARY

Cell Theory

- The **cell theory** has four basic tenets:
  - All living things are composed of cells.
  - The cell is the basic functional unit of life.
  - Cells arise only from preexisting cells.
  - Cells carry genetic information in the form of DNA. This genetic material is passed on from parent to daughter cell.
- Viruses are not considered living things because they are acellular, cannot reproduce without the assistance of a host cell, and may contain RNA as their genetic material.

Eukaryotic Cells

- **Eukaryotes** have membrane-bound organelles, a nucleus, and may form multicellular organisms.
- The cell membrane and membranes of organelles contain phospholipids, which organize to form hydrophilic interior and exterior surfaces with a hydrophobic core.
- The **cytosol** suspends the organelles and allows diffusion of molecules throughout the cell.
- The eukaryotic organelles each serve specific functions:
  - The **nucleus** contains DNA organized into **chromosomes**. It is surrounded by the **nuclear membrane** or **envelope**, a double membrane that contains **nuclear pores** for two-way exchange of materials between the nucleus and cytosol. DNA is organized into coding regions called **genes**.
  - The **nucleolus** is a subsection of the nucleus in which ribosomal RNA (rRNA) is synthesized.
  - **Mitochondria** contain an outer and inner membrane. The **outer membrane** forms a barrier with the cytosol; the **inner membrane** is folded into **cristae** and contains enzymes for the electron transport chain. Between the membranes is the **intermembrane space**; inside the inner mitochondrial membrane is the mitochondrial **matrix**. Mitochondria can divide independently of the nucleus via binary fission; they can trigger **apoptosis** by releasing mitochondrial enzymes into the cytoplasm.
  - **Lysosomes** contain hydrolytic enzymes that can break down substances ingested by endocytosis and cellular waste products. When these enzymes are released, **autolysis** of the cell can occur.

- The **endoplasmic reticulum** (**ER**) is a series of interconnected membranes and is continuous with the nuclear envelope. The **rough ER** (**RER**) is studded with ribosomes, which permit translation of proteins destined for secretion. The **smooth ER** (**SER**) is used for lipid synthesis and detoxification.
- The **Golgi apparatus** consists of stacked membrane-bound sacs in which cellular products can be modified, packaged, and directed to specific cellular locations.
- **Peroxisomes** contain hydrogen peroxide and can break down very long chain fatty acids via β-oxidation. They also participate in phospholipid synthesis and the pentose phosphate pathway.

- The **cytoskeleton** provides stability and rigidity to the overall structure of the cell, while also providing transport pathways for molecules within the cell.
  - **Microfilaments** are composed of **actin**. They provide structural protection for the cell and can cause muscle contraction through interactions with **myosin**. They also help form the **cleavage furrow** during **cytokinesis** in mitosis.
  - **Microtubules** are composed of **tubulin**. They create pathways for motor proteins like **kinesin** and **dynein** to carry vesicles. They also contribute to the structure of **cilia** and **flagella**, where they are organized into nine pairs of microtubules in a ring with two microtubules at the center (**9 + 2 structure**). **Centrioles** are found in **centrosomes** and are involved in microtubule organization in the mitotic spindle.
  - **Intermediate filaments** are involved in cell–cell adhesion or maintenance of the integrity of the cytoskeleton; they help anchor organelles. Common examples include keratin and desmin.
- **Epithelial tissues** cover the body and line its cavities, protecting against pathogen invasion and desiccation. Some epithelial cells absorb or secrete substances, or participate in sensation.
  - In most organs, epithelial cells form the **parenchyma**, or the functional parts of the organ.
  - Epithelial cells may be polarized, with one side facing a lumen or the outside world, and the other side facing blood vessels and structural cells.
  - Epithelia can be classified by the number of layers they contain: **simple epithelia** have one layer, **stratified epithelia** have many layers, and **pseudostratified epithelia** appear to have multiple layers because of differences in cell heights, but actually have only one layer.
  - Epithelia can be classified by the shapes of the cells they contain: **cuboidal cells** are cube-shaped, **columnar cells** are long and narrow, and **squamous cells** are flat and scalelike.

- **Connective tissues** support the body and provide a framework for epithelial cells.
  - In most organs, connective tissues form the **stroma** or support structure by secreting materials to form an **extracellular matrix**.
  - Bone, cartilage, tendons, ligaments, adipose tissue, and blood are all connective tissues.

Classification and Structure of Prokaryotic Cells

- **Prokaryotes** do not contain membrane-bound organelles; they organize their genetic material in a single circular molecule of DNA concentrated in the **nucleoid region**.
- There are three overarching domains of life; prokaryotes account for two of these:
  - **Archaea** are often extremophiles, living in harsh environments (high temperature, high salinity, no light) and often using alternative sources of energy, like chemosynthesis. They have similarities to both eukaryotes (start translation with methionine, similar RNA polymerases, histones) and bacteria (single circular chromosome, divide by binary fission or budding).
  - **Bacteria** have many similar structures to eukaryotes, and have complex relationships with humans, including **mutualistic symbiosis** and **pathogenesis**.
  - **Eukarya** is the only non-prokaryotic domain.
- Bacteria can be classified by shape:
  - Spherical bacteria are called **cocci**.
  - Rod-shaped bacteria are called **bacilli**.
  - Spiral-shaped bacteria are called **spirilli**.
- Bacteria can be classified based on metabolic processes:
  - **Obligate aerobes** require oxygen for metabolism.
  - **Obligate anaerobes** cannot survive in oxygen-containing environments and can only carry out anaerobic metabolism.
  - **Facultative anaerobes** can survive in environments with or without oxygen and will toggle metabolic processes based on the environment.
  - **Aerotolerant anaerobes** cannot use oxygen for metabolism, but can survive in an oxygen-containing environment.
- The cell wall and cell membrane of bacteria form the **envelope**. Together, they control the movement of solutes into and out of the cell.
  - Bacteria can be classified by the color their cell walls turn during Gram staining with a crystal violet stain, followed by a counterstain with safranin. Gram-positive bacteria turn purple, while gram-negative bacteria turn pink-red.

- Gram-positive bacteria have a thick cell wall composed of **peptidoglycan** and **lipoteichoic acid**.
- Gram-negative bacteria have a thin cell wall composed of peptidoglycan and an outer membrane containing phospholipids and **lipopolysaccharides**.

- Bacteria may have one, two, or many flagella that generate propulsion to move the bacterium toward food or away from immune cells. Moving in response to chemical stimuli is called **chemotaxis**. Bacterial flagella contain a filament composed of flagellin, a basal body that anchors and rotates the flagellum, and a hook that connects the two.
- Prokaryotes carry out the electron transport chain using the cell membrane.
- Prokaryotic ribosomes are smaller than eukaryotic ribosomes (30S and 50S, rather than 40S and 60S).

Genetics and Growth of Prokaryotic Cells

- Prokaryotes multiply through **binary fission**, in which the chromosome replicates while the cell grows in size, until the cell wall begins to grow inward along the midline of the cell and divides it into two identical daughter cells.
- In addition to the single circular chromosome in prokaryotes, extrachromosomal material can be carried in **plasmids**. Plasmids may contain antibiotic resistance genes or **virulence factors**. Plasmids that can integrate into the genome are called **episomes**.
- Bacterial genetic recombination increases bacterial diversity.
  - **Transformation** is the acquisition of genetic material from the environment, which can be integrated into the bacterial genome.
  - **Conjugation** is the transfer of genetic material from one bacterium to another across a **conjugation bridge**; a plasmid can be transferred from **F^+ cells** to **F^- cells**, or a portion of the genome can be transferred from an **Hfr cell** to a recipient.
  - **Transduction** is the transfer of genetic material from one bacterium to another using a bacteriophage as a vector.
  - **Transposons** are genetic elements that can insert into or remove themselves from the genome.
- Bacterial growth follows a predictable pattern:
  - The bacteria adapt to new local conditions during the **lag phase**.
  - Growth then increases exponentially during the **exponential** (**log**) **phase**.
  - As resources are reduced, growth levels off during the **stationary phase**.
  - As resources become insufficient, bacteria undergo a **death phase**.

Viruses and Subviral Particles

- Viruses contain genetic material, a protein coat (**capsid**), and sometimes a lipid-containing envelope.
- Viruses are obligate intracellular parasites, meaning that they cannot survive and replicate outside of a **host cell**. Individual virus particles are called **virions**.
- Bacteriophages are viruses that target bacteria. In addition to the other structures, they contain a **tail sheath**, which injects the genetic material into a bacterium, and **tail fibers**, which allow the bacteriophage to attach to the host cell.
- Viral genomes may be made of various nucleic acids:
  - They may be composed of DNA or RNA and may be single- or double-stranded.
  - Single-stranded RNA viruses may be **positive sense** (can be translated by the host cell) or **negative sense** (a complementary strand must be synthesized using **RNA replicase**, which can then be translated).
  - **Retroviruses** contain a single-stranded RNA genome, to which a complementary DNA strand is made using **reverse transcriptase**. The DNA strand can then be integrated into the genome.
- Viruses infect cells by attaching to specific receptors, and then either fusing with the plasma membrane, being brought in by endocytosis, or injecting their genome into the cell.
- The virus reproduces by replicating and translating genetic material using the host cell's ribosomes, tRNA, amino acids, and enzymes.
- Viral progeny are released through cell death, lysis, or **extrusion**.
- Bacteriophages have two specific life cycles:
  - In the **lytic cycle**, the bacteriophage produces massive numbers of new virions until the cell lyses. Bacteria in the lytic phase are termed **virulent**.
  - In the **lysogenic cycle**, the virus integrates into the host genome as a provirus or prophage, which can then reproduce along with the cell. The provirus then leaves the genome in response to a stimulus at some later time and enters the lytic cycle.
- **Prions** are infectious proteins that trigger misfolding of other proteins, usually converting an α-helical structure to a β-pleated sheet. This decreases the solubility and degradability of the misfolded protein.
- **Viroids** are plant pathogens that are small circles of complementary RNA that can turn off genes, resulting in metabolic and structural derangements of the cell and—potentially—cell death.

ANSWERS TO CONCEPT CHECKS

1.1

1. All living things are made of cells. The cell is the basic functional unit of life. All cells arise from other cells. Genetic information is carried in the form of deoxyribonucleic acid (DNA) and is passed from parent to daughter cell.

1.2

1. The nucleus stores genetic information and is the site of transcription. The mitochondria are involved in ATP production and apoptosis. Lysosomes break down molecules ingested through endocytosis and cellular waste products, and can also be involved in apoptosis. The rough endoplasmic reticulum synthesizes proteins destined for secretion. The smooth endoplasmic reticulum is involved in lipid synthesis and detoxification. The Golgi apparatus packages, modifies, and distributes cellular products. Peroxisomes break down very long chain fatty acids, synthesize lipids, and contribute to the pentose phosphate pathway.
2. Peroxisomes are dependent on hydrogen peroxide for their functions, so an enzyme deficiency that results in an inability to form hydrogen peroxide would likely result in an inability to digest very long chain fatty acids. These fatty acids would build up in peroxisomes until most of the cellular contents were displaced by oversized peroxisomes. This would ultimately result in cell death.
3. Microfilaments are composed of actin. Microtubules are composed of tubulin. Intermediate filaments differ by cell type, but include keratin, desmin, vimentin, and lamins.
4. Centrioles consist of nine triplets of microtubules around a hollow center, while flagella consist of nine doublets on the outside, with two microtubules on the inside.
5. Endothelial cells and α-cells are epithelial cells. Fibroblasts, osteoblasts, and chondroblasts are connective tissue cells.

1.3

1. Archaea are similar to bacteria in that both are single-celled organisms that lack a nucleus or membrane-bound organelles, contain a single circular chromosome, divide by binary fission or budding, and overall share a similar structure. They are similar to eukaryotes in that they start translation with methionine, contain similar RNA polymerases, and associate their DNA with histones.
2. The three common shapes of bacteria are spherical (cocci), rod-shaped (bacilli), and spiral-shaped (spirilli).

3.

	Oxygen Present		Oxygen Absent	
Type of Bacteria	Can survive	Can carry out aerobic metabolism	Can survive	Can carry out anaerobic metabolism
Obligate aerobe	Yes	Yes	No	No
Facultative anaerobe	Yes	Yes	Yes	Yes
Obligate anaerobe	No	No	Yes	Yes
Aerotolerant anaerobe	Yes	No	Yes	Yes

4. Gram-positive bacteria have a thick layer of peptidoglycan and lipoteichoic acid, and contain no outer membrane. Gram-negative bacteria have a thin layer of peptidoglycan, but also have an outer membrane containing lipopolysaccharides and phospholipids.
5. Eukaryotic flagella contain microtubules composed of tubulin, organized in a 9 + 2 arrangement. Bacterial flagella are made of flagellin and consist of a filament, a basal body, and a hook.

1.4

1. Transformation is the acquisition of genetic material from the environment that can be integrated into the bacterial genome. Conjugation is the transfer of genetic material from one bacterium to another across a conjugation bridge; a plasmid can be transferred from F^+ cells to F^- cells, or a portion of the genome can be transferred from an Hfr cell to a recipient. Transduction is the transfer of genetic material from one bacterium to another using a bacteriophage as a vector.

2.

Phase	Features
Lag phase	Bacteria get used to environment; little growth during this time
Exponential phase	Bacteria use available resources to multiply at an exponential rate
Stationary phase	Bacterial multiplication ceases as resources are used up
Death phase	Bacteria die as resources become insufficient to support the colony

1.5

1. Viruses do not contain organelles such as ribosomes; therefore, in order to reproduce and synthesize proteins, viruses must infect cells and hijack their cellular machinery.

2. This description indicates that the virus contains an outer layer of phospholipids with an inner capsid. Within the capsid, there is single-stranded RNA that can be immediately translated to protein by the ribosomes of the host cell.
3. The nucleic acid enters as single-stranded RNA, which undergoes reverse transcription (using reverse transcriptase) to form double-stranded DNA. This DNA can enter the host genome and replicate with the host cell. The DNA is transcribed to mRNA, which can be used to make structural proteins. This mRNA doubles as the viral genome for new virions. Once new virions are assembled from the structural proteins and mRNA (single-stranded RNA) genome, the virions can be released to infect other cells.
4. In the lytic cycle, bacteriophages replicate in the host cell in extremely high numbers until the host cell lyses and releases the virions. In the lysogenic cycle, the bacteriophage genome enters the host genome and replicates with the host cell as a provirus. At some point (after exposure to a particular stimulus), the provirus leaves the host genome and can be used to synthesize new virions.
5. Prions cause disease by triggering a change in the conformation of a protein from an α-helix to a β-pleated sheet. This change reduces solubility of the protein and makes it highly resistant to degradation.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Hyperbaric oxygen may be used as a treatment for certain types of bacterial infections. In this therapy, the patient is placed in a chamber in which the partial pressure of oxygen is significantly increased, increasing the partial pressure of oxygen in the patient's tissues. This treatment is most likely used for infections with:

A. obligate aerobic bacteria.
B. facultative anaerobic bacteria.
C. aerotolerant anaerobic bacteria.
D. obligate anaerobic bacteria.

2. Which of the following does NOT describe connective tissue cells?

A. They account for most cells in muscles, bones, and tendons.
B. They secrete substances to form the extracellular matrix.
C. In organs, they tend to form the stroma.
D. In organs, they provide support for epithelial cells.

3. Which of the following types of nucleic acid could form the genome of a virus?

I. Single-stranded RNA
II. Double-stranded DNA
III. Single-stranded DNA

A. I only
B. II only
C. I and II only
D. I, II, and III

4. Which of the following activities occurs in the Golgi apparatus?

A. Synthesis of proteins
B. Modification and distribution of proteins
C. Breakdown of lipids and carbohydrates
D. Production of ATP

5. Mitochondrial DNA is:

I. circular.
II. self-replicating.
III. single-stranded.

A. I only
B. II only
C. I and II only
D. I, II, and III

6. Which of the following is NOT a function of the smooth endoplasmic reticulum?

A. Lipid synthesis
B. Poison detoxification
C. Protein synthesis
D. Transport of proteins

7. What is the main function of the nucleolus?

A. Ribosomal RNA synthesis
B. DNA replication
C. Cell division
D. Chromosome assembly

8. Which of the following organelles is surrounded by a single membrane?

A. Lysosomes
B. Mitochondria
C. Nuclei
D. Ribosomes

9. Which of the following is NOT a difference that would allow one to distinguish a prokaryotic and a eukaryotic cell?

A. Ribosomal subunit weight
B. Presence of a nucleus
C. Presence of a membrane on the outside surface of the cell
D. Presence of membrane-bound organelles

10. Which of the following does NOT contain tubulin?

A. Cilia
B. Flagella
C. Microfilaments
D. Centrioles

11. Herpes simplex virus (HSV) enters the human body and remains dormant in the nervous system until it produces an outbreak after exposure to heat, radiation, or other stimuli. Which of the following statements correctly describes HSV?

A. While it remains dormant in the nervous system, the virus is in its lytic cycle.
B. During an outbreak, the virus is in the lysogenic cycle.
C. Herpes simplex virus adds its genetic information to the genetic information of the cell.
D. The herpes simplex virus contains a tail sheath and tail fibers.

12. Resistance to antibiotics is a well-recognized medical problem. Which mechanism(s) can account for a bacterium's ability to increase its genetic variability and thus adapt itself to resist different antibiotics?

I. Binary fission
II. Conjugation
III. Transduction

A. I and II only
B. I and III only
C. II and III only
D. I, II, and III

13. A bacterial cell is noted to be resistant to penicillin. The bacterium is transferred to a colony that lacks the fertility factor, and the rest of the colony does not become resistant to penicillin. However, the penicillin-resistant cell has also started to exhibit other phenotypic characteristics, including secretion of a novel protein. Which of the following methods of bacterial recombination is NOT likely to account for this change?

A. Conjugation
B. Transformation
C. Transduction
D. Infection with a bacteriophage

14. In Alzheimer's disease, a protein called the amyloid precursor protein (APP) is cleaved to form a protein called β-amyloid. This protein has a β-pleated sheet structure and precipitates to form plaques in the brain. This mechanism of disease is most similar to which of the following pathogens?

A. Bacteria
B. Viruses
C. Prions
D. Viroids

15. After infection of a cell, a viral particle must transport itself to the nucleus in order to produce viral proteins. What is the likely genomic content of the virus?

A. Double-stranded DNA
B. Double-stranded RNA
C. Positive-sense RNA
D. Negative-sense RNA

Explanations to Discrete Practice Questions

1. D

Obligate anaerobes cannot survive in the presence of oxygen and would likely be killed by such a therapy, treating the infection. The other types of bacteria listed can all survive in the presence of oxygen and would likely not be treated using this therapy.

2. A

While bones and tendons are composed predominantly of connective tissue cells, muscle tissue is considered a different tissue type. Other examples of connective tissue include cartilage, ligaments, adipose tissue, and blood. Connective tissue often secretes substances to form the extracellular matrix, such as collagen and elastin, eliminating **choice (B)**. **Choices (C)** and **(D)** are essentially identical and can both be eliminated: in organs, connective tissue often forms the support structure for epithelial cells, called the stroma.

3. D

In a virus, the nucleic acid can be either DNA or RNA and—in both cases—can be either single- or double-stranded. Therefore, all of the types of nucleic acids listed here could be used for a viral genome, making **choice (D)** the correct answer.

4. B

The Golgi apparatus consists of a stack of membrane-enclosed sacs. It receives vesicles and their contents from the endoplasmic reticulum, modifies them (through glycosylation, phosphorylation, and other mechanisms), repackages them into vesicles, and distributes them to appropriate locations in the cell. Protein synthesis occurs in ribosomes and rough endoplasmic reticulum, eliminating **choice (A)**. Lipid and carbohydrate breakdown takes place in the peroxisomes and cytoplasm, eliminating **choice (C)**. ATP production occurs in the mitochondria, eliminating **choice (D)**.

5. C

Mitochondria are thought to have evolved from an anaerobic prokaryote engulfing an aerobic prokaryote and establishing a symbiotic relationship; therefore, mitochondrial DNA, or mDNA, is likely to be similar to bacterial DNA. Both mDNA and bacterial DNA are organized into a single circular chromosome of double-stranded DNA that can replicate during binary fission. Therefore, Statements I and II are correct, while Statement III is incorrect.

6. C

The smooth endoplasmic reticulum is involved in the transport of materials throughout the cell, in lipid synthesis, and in the detoxification of drugs and poisons. Proteins from the rough ER can cross into the smooth ER, where they are secreted into cytoplasmic vesicles and transported to the Golgi apparatus. Thus, from the given choices, protein synthesis is not a function of the smooth ER, but rather of the free ribosomes or the ribosomes associated with the rough ER. **Choice (C)** is therefore the correct answer.

7. A

The nucleolus (not to be confused with the nucleus in general) is a dense structure within the nucleus where ribosomal RNA (rRNA) is synthesized. **Choice (A)** is therefore the correct answer.

8. A

Lysosomes are vesicular organelles that digest material using hydrolytic enzymes. They are surrounded by a single membrane. Both mitochondria and nuclei are surrounded by double membranes, eliminating **choices (B)** and **(C)**. Ribosomes must not be surrounded by membranes because they are found not only in eukaryotes, but also in prokaryotes, which lack any membrane-bound organelles, eliminating **choice (D)**.

9. C

The main differences between prokaryotes and eukaryotes include: prokaryotes do not have a nucleus, while eukaryotes do, eliminating **choice (B)**; prokaryotes have ribosomal subunits of 30S and 50S, while eukaryotes have ribosomal subunits of 40S and 60S, eliminating **choice (A)**; and prokaryotes do not have membrane-bound organelles, whereas eukaryotes do, eliminating **choice (D)**. The presence of a membrane on the outer surface of the cell could not distinguish a prokaryotic cell from a eukaryotic one because both gram-negative bacteria and animal cells share this feature. Thus, **choice (C)** is the correct answer.

10. C

Tubulin is the primary protein in microtubules, which are responsible for the structure and movement of cilia and flagella, eliminating **choices (A)** and **(B)**. Centrioles organize microtubules in the mitotic spindle, eliminating **choice (D)**. Microfilaments are not composed of tubulin, but rather actin, making **choice (C)** the correct answer.

11. C

Viruses can exist in either the lytic or lysogenic cycle; they may even switch between them throughout their lifetime. During the lytic cycle, the virus's DNA takes control of the host cell's genetic machinery, manufacturing numerous progeny. In the end, the host cell bursts (lyses) and releases new virions, each capable of infecting other cells. In the lysogenic cycle, viral DNA is added to the host cell's genome, where it can remain dormant for days or years. Either spontaneously or as a result of environmental circumstances, the provirus can reemerge and enter a lytic cycle. Thus, **choices (A)** and **(B)** are incorrect because they reverse which part of the cycle the virus is in. **Choice (D)** describes features of bacteriophages, which are viruses that infect bacteria—not the human nervous system. **Choice (C)** accurately describes how HSV operates during the lysogenic cycle, making it the correct answer.

12. C

Bacterial cells reproduce by binary fission, an asexual process in which the progeny is identical to the parent. Therefore, Statement I does not increase genetic variability. Conjugation can be described as a sexual mating in bacteria; it is the transfer of genetic material between two bacteria that are temporarily joined. Transduction occurs when fragments of the bacterial chromosome accidentally become packaged into viral progeny produced during a viral infection and can subsequently be introduced into another bacterium by the viral vector. Therefore, both Statements II and III increase bacterial genetic variability.

13. A

A bacterial cell that does not rapidly cause a phenotypic change in the rest of the colony is likely not F^+, meaning that this cell is not able to form a sex pilus for conjugation. The expression of new phenotypic characteristics indicate that this bacterium may have acquired some quantity of genetic information, which can be acquired by either transformation, **choice (B)**, or transduction (which occurs via bacteriophage infection), **choices (C)** and **(D)**.

14. C

Prions are infectious proteins that cause misfolding of other proteins. Primarily, prions cause a shift toward β-pleated sheet confirmations, which leads to decreased solubility and degradability of proteins, ultimately leading to disease. This mechanism is very similar to the one described here for Alzheimer's disease, making **choice (C)** the correct answer.

15. A

A virus that requires transport to the nucleus in order to produce viral proteins likely requires use of nuclear RNA polymerase in order to create mRNA that can be translated to protein. Only DNA viruses require this transport before any protein can be synthesized.

Concept Summary 72

Introduction

All mammals share certain characteristics: milk-producing mammary glands, three bones in the middle ear and one in the lower jaw, fur or hair, heterodont dentition (different kinds of teeth), and both sebaceous (oil-producing) and sudoriferous (sweat) glands. What about placenta formation during embryonic development? This is a characteristic of humans, as we'll explore in Chapter 3 of *MCAT Biology Review*, but there are two groups of mammals that birth their young a bit differently: prototherians and metatherians.

Prototherians (monotremes), which include the duckbilled platypus and echidna (spiny anteater), encase their developing embryos within hard-shelled amniotic eggs and lay them to be hatched, like reptiles. This method of development is referred to as oviparity. Metatherians (marsupials) include koalas and kangaroos. A typical metatherian fetus (joey) undergoes some development in its mother's uterus and then climbs its way out of the birth canal and into her marsupium, or pouch. It might seem a bit strange that something as essential as reproduction could be so different between mammalian species, but the truth is that there is a wide variety of reproductive mechanisms in nature. Many organisms reproduce without a sexual partner. Others can reproduce sexually or asexually depending on environmental conditions. In the Chapter 1 of *MCAT Biology Review*, we explored how bacteria and viruses reproduce. In this chapter, we'll explore how eukaryotic cells reproduce, as well as the male and female reproductive systems.

2.1 The Cell Cycle and Mitosis ★★★

In animals, autosomal cells are said to be **diploid** (***2n***), which means that they contain two copies of each chromosome. Germ cells, on the other hand, are **haploid** (***n***), containing only one copy of each chromosome. In humans, these numbers are 46 and 23, respectively; we inherit 23 chromosomes from each parent. Eukaryotic cells replicate through the **cell cycle**, a specific series of phases during which a cell grows, synthesizes DNA, and divides. Derangements of the cell cycle can lead to unchecked cell division and may be responsible for the formation of cancer.

THE CELL CYCLE

The cell cycle, shown in Figure 2.1, is a perennial MCAT favorite. For actively dividing cells, the cell cycle consists of four stages: G_1, S, G_2, and M. The first three stages (G_1, S, and G_2) are known collectively as **interphase**. Interphase is the longest part of the cell cycle; even actively dividing cells spend about 90 percent of their time in interphase. Cells that do not divide spend all of their time in an offshoot of G_1 called G_0. During the **G_0 stage**, the cell is simply living and serving its function, without any preparation for division.

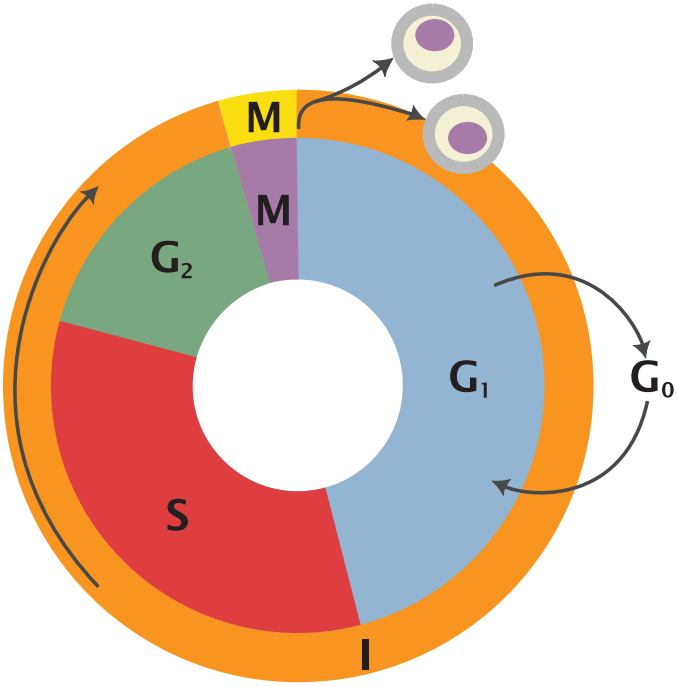

Figure 2.1. The Cell Cycle

During interphase, individual chromosomes are not visible with light microscopy. Rather, they are in a less condensed form known as **chromatin**. This is because the DNA must be available to *RNA polymerase* so that genes can be transcribed. During mitosis, however, it is preferable to condense the DNA into tightly coiled chromosomes to avoid losing any genetic material during cell division.

G_1 Stage: Presynthetic Gap

During the **G_1 stage**, cells create organelles for energy and protein production (mitochondria, ribosomes, and endoplasmic reticulum), while also increasing their size. In addition, passage into the S (synthesis) stage is governed by a **restriction point**. Certain criteria, such as containing the proper complement of DNA, must be met for the cell to pass the restriction point and enter the synthesis stage.

S Stage: Synthesis of DNA

During the **S stage**, the cell replicates its genetic material so that each daughter cell will have identical copies. After replication, each chromosome consists of two identical **chromatids** that are bound together at a specialized region known as the **centromere**, as shown in Figure 2.2. Note that the ploidy of the cell does not change even though the number of chromatids has doubled. In other words, humans in this stage still only have 46 chromosomes, even though 92 chromatids are present. Cells entering G_2 have twice as much DNA as cells in G_1.

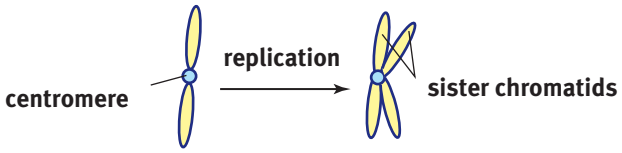

Figure 2.2. Chromosome Replication
A single chromatid replicates to form two sister chromatids.

G_2 Stage: Postsynthetic Gap

During the **G_2 stage**, the cell passes through another quality control checkpoint. DNA has already been duplicated, and the cell checks to ensure that there are enough organelles and cytoplasm to divide between two daughter cells. Furthermore, the cell checks to make sure that DNA replication proceeded correctly to avoid passing on an error to daughter cells that may further replicate the error in their progeny.

M Stage: Mitosis

The **M stage** consists of mitosis itself along with cytokinesis. Mitosis is divided into four phases: prophase, metaphase, anaphase, and telophase. The features of each phase will be discussed in the next section. Cytokinesis is the splitting of the cytoplasm and organelles into two daughter cells.

Key Concept

Each chromatid is composed of a complete double-stranded molecule of DNA. Sister chromatids are identical copies of each other. The term *chromosome* may be used to refer to either a single chromatid before S phase or the pair of chromatids attached at the centromere after S phase.

Key Concept

In autosomal cells, division results in two genetically identical daughter cells. In germ cells, the daughter cells are not equivalent.

CONTROL OF THE CELL CYCLE

The cell cycle is controlled by checkpoints, most notably between the G_1 and S phase, and the G_2 and M phase. At the G_1/S checkpoint, the cell determines if the DNA is in good enough condition for synthesis. As mentioned above, this checkpoint is also known as the restriction point. If there has been damage to the DNA, the cell cycle goes into arrest until the DNA has been repaired. The main protein in control of this is known as ***p53***.

At the G_2/M checkpoint, the cell is mainly concerned with ensuring that the cell has achieved adequate size and the organelles have been properly replicated to support two daughter cells. p53 also plays a role in the G_2/M checkpoint.

The molecules responsible for the cell cycle are known as **cyclins** and **cyclin-dependent kinases** (**CDK**). In order to be activated, CDKs require the presence of the right cyclins. During the cell cycle, concentrations of the various cyclins increase and decrease during specific stages. These cyclins bind to CDKs, creating an activated CDK–cyclin complex. This complex can then phosphorylate transcription factors. **Transcription factors** then promote transcription of genes required for the next stage of the cell cycle.

Cancer

Cell cycle control is essential to ensure that cells that are damaged or inadequately sized do not divide. When cell cycle control becomes deranged, and damaged cells are allowed to undergo mitosis, **cancer** may result. One of the most common mutations found in cancer is mutation of the gene that produces p53, called *TP53*. When this gene is mutated, the cell cycle is not stopped to repair damaged DNA. This allows for mutations to accumulate, eventually resulting in a cancerous cell that divides continuously and without regard to the quality or quantity of the new cells produced. Often, cancer cells undergo rapid cell division, creating **tumors**. Eventually, if the cell begins to produce the right factors (such as proteases that can digest basement membranes or factors that encourage blood vessel formation), the damaged cells are then able to reach other tissues. This may include both local invasion as well as distant spread of cancerous cells through the bloodstream or lymphatic systems. This latter result is known as **metastasis**.

Bridge

Cancer-causing genes can often be classified into oncogenes (genes that, when mutated, actively promote cell division) and tumor suppressor genes (genes that, when mutated, lose their ability to regulate or pause the cell cycle). Different cancer types are often associated with specific mutations in either oncogenes or tumor suppressor genes, or both. The biochemistry of these genes is discussed in Chapter 6 of *MCAT Biochemistry Review*.

MITOSIS

Mitosis, shown in Figure 2.3, is the process by which two identical daughter cells are created from a single cell. Mitosis consists of four distinct phases—prophase, metaphase, anaphase, and telophase—and occurs in **somatic cells**, or cells that are not involved in sexual reproduction.

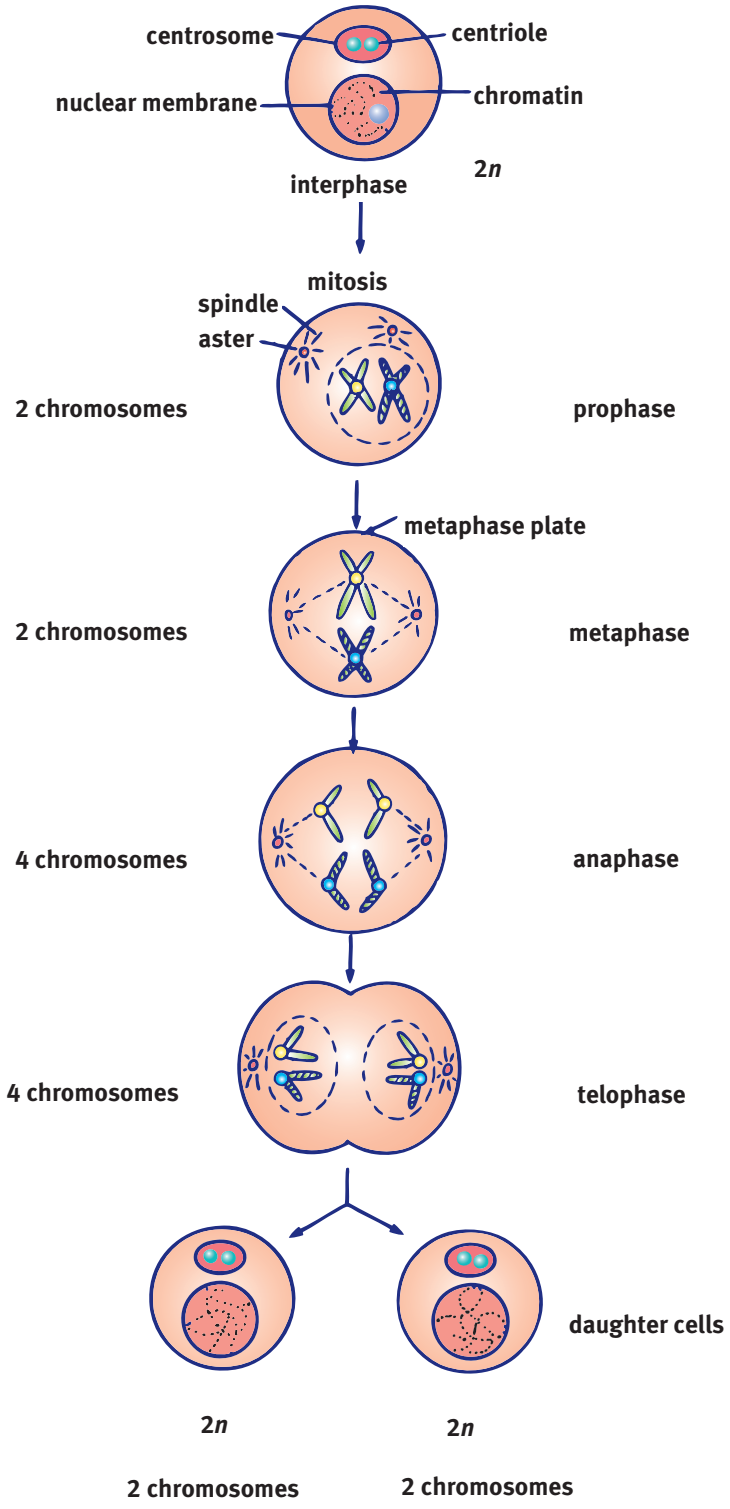

Figure 2.3. Mitosis
Mitosis results in two identical daughter cells.

Key Concept

The phases of mitosis:

- Prophase—chromosomes condense, spindle forms
- Metaphase—chromosomes align
- Anaphase—sister chromatids separate
- Telophase—new nuclear membranes form

Prophase

Prophase is the first phase in mitosis. The first step in prophase involves condensation of the chromatin into chromosomes. Also, the centriole pairs separate and move toward opposite poles of the cell. These paired cylindrical organelles, shown in Figure 2.4, are located outside the nucleus in a region known as the **centrosome** and are responsible for the correct division of DNA. Once the centrioles migrate to opposite poles of the cell, they begin to form **spindle fibers**, which are made of microtubules. This defines the centrosome as one of the two **microtubule organizing centers** of the cell—the other being the basal body of a flagellum or cilium. Each of the fibers radiates outward from the centrioles. Some microtubules form **asters** that anchor the centrioles to the cell membrane. Others extend toward the middle of the cell. The nuclear membrane dissolves during prophase, allowing these spindle fibers to contact the chromosomes. The nucleoli become less distinct, and may disappear completely. **Kinetochores** appear at the centromere. Kinetochores are protein structures located on the centromeres that serve as attachment points for specific fibers of the **spindle apparatus** appropriately called **kinetochore fibers**.

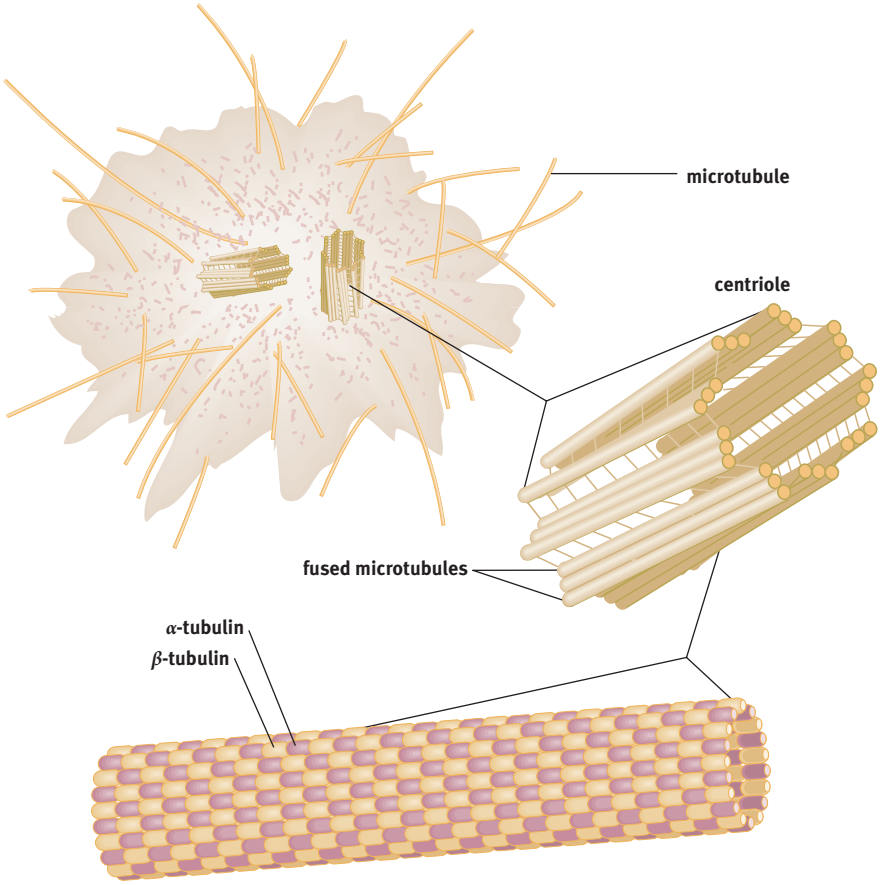

Figure 2.4. The Centrosome
Each centrosome contains two tubulin-based centrioles responsible for proper movement of the chromosomes during mitosis.

Metaphase

In **metaphase**, the centriole pairs are now at opposite ends of the cell. The kinetochore fibers interact with the fibers of the spindle apparatus to align the chromosomes at the **metaphase plate** (**equatorial plate**), which is equidistant between the two poles of the cell.

Anaphase

During **anaphase**, the centromeres split so that each chromatid has its own distinct centromere, thus allowing the sister chromatids to separate. The sister chromatids are pulled toward the opposite poles of the cell by the shortening of the kinetochore fibers.

Telophase and Cytokinesis

Telophase is essentially the reverse of prophase. The spindle apparatus disappears. A nuclear membrane reforms around each set of chromosomes, and the nucleoli reappear. The chromosomes uncoil, resuming their interphase form. Each of the two new nuclei has received a complete copy of the genome identical to the original genome and to each other.

At the end of telophase, **cytokinesis** is the separation of the cytoplasm and organelles so that each daughter cell has sufficient supplies to survive on its own. Each cell undergoes a finite number of divisions before programmed death; for human somatic cells, this is usually between 20 and 50. After that, the cell can no longer divide continuously.

MCAT Concept Check 2.1:

Before you move on, assess your understanding of the material with these questions.

1. What are the five stages of the cell cycle? What happens in each stage?

Cell Cycle Stage	Features

2. What are the four phases of mitosis? What happens in each phase?

Mitotic Phase	Features

2.2 Meiosis ★★★

Whereas mitosis occurs in somatic tissue and results in two identical daughter cells, meiosis occurs in **gametocytes** (**germ cells**) and results in up to four nonidentical sex cells (**gametes**). Meiosis shares some similarities with mitosis. In both processes, for instance, genetic material must be duplicated, chromatin is condensed to form chromosomes, and microtubules emanating from centrioles are involved in dividing genetic material. However, the MCAT tends to ask about the differences between these two processes.

In contrast to mitosis, which consists of one round each of replication and division, meiosis consists of one round of replication followed by two rounds of division, as shown in Figure 2.5. **Meiosis I** results in homologous chromosomes being separated, generating haploid daughter cells; this is known as **reductional division**. **Meiosis II** is similar to mitosis, in that it results in the separation of sister chromatids, and is known as **equational division**.

MEIOSIS I

The human genome is composed of 23 **homologous pairs** of chromosomes (**homologues**), each of which contains one chromosome inherited from each parent. This brings up an important note about terminology: whereas homologous pairs are considered separate chromosomes (such as maternal chromosome 15 and paternal chromosome 15), sister chromatids are identical strands of DNA connected at the centromere. Thus, after S phase, there are 92 chromatids organized into 46 chromosomes, which are organized into 23 homologous pairs.

Prophase I

During **prophase I**, the chromatin condenses into chromosomes, the spindle apparatus forms, and the nucleoli and nuclear membrane disappear. The first major difference between meiosis and mitosis occurs at this point: homologous

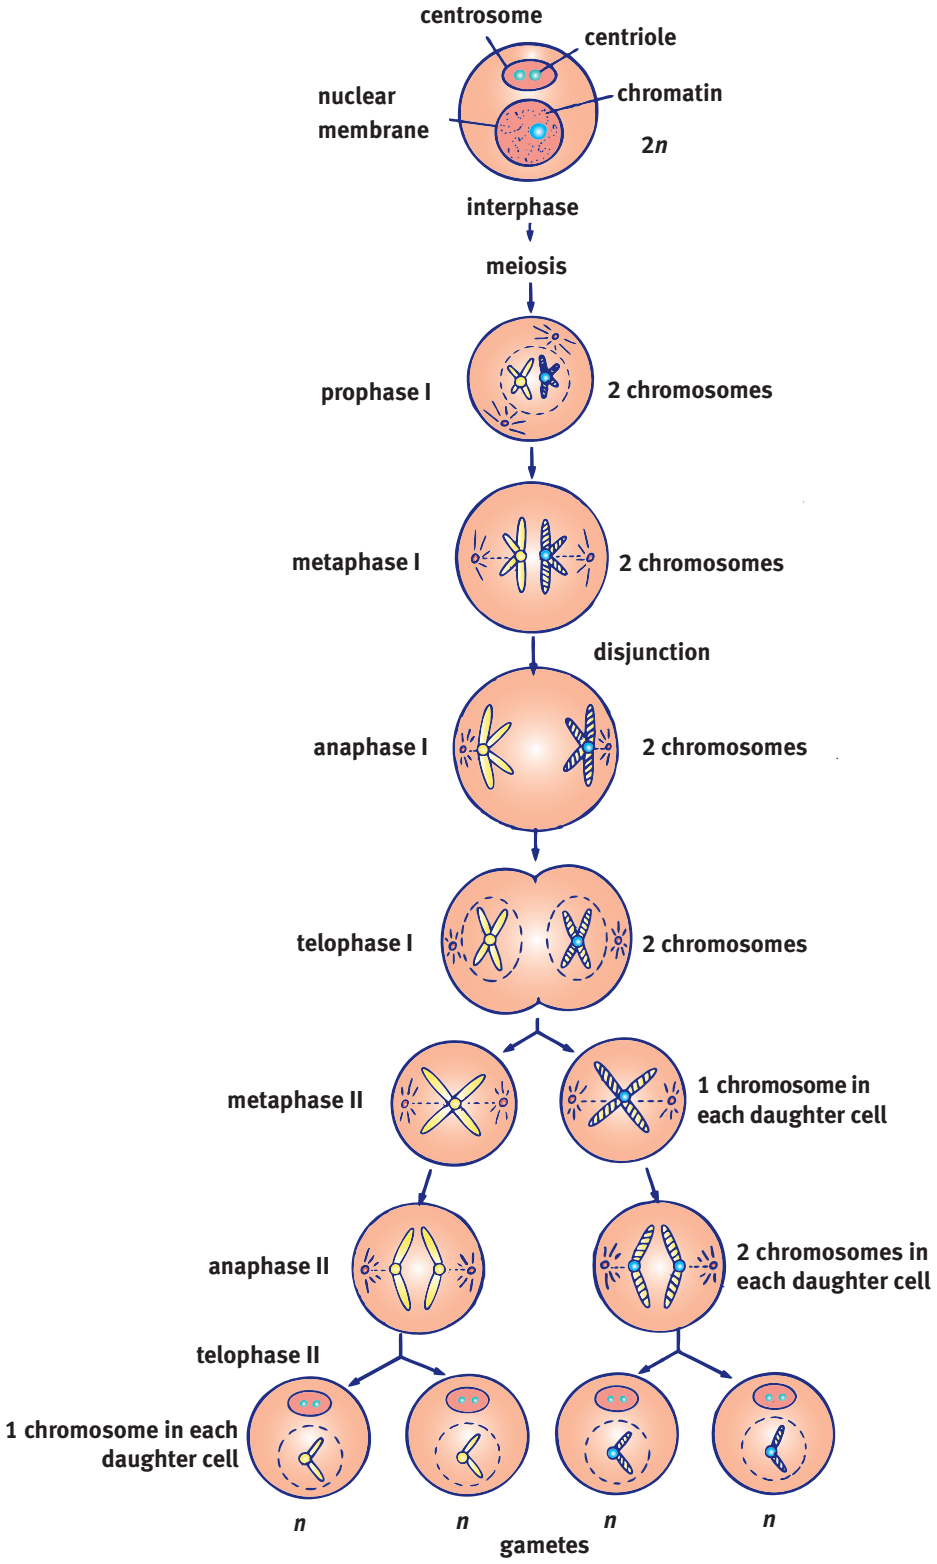

Figure 2.5. Meiosis
Meiosis results in up to four nonidentical daughter cells.

chromosomes come together and intertwine in a process called **synapsis**. At this point, each chromosome consists of two sister chromatids, so each synaptic pair contains four chromatids and is referred to as a **tetrad**; the homologous chromosomes are held together by a group of proteins called the **synaptonemal complex**. Chromatids of homologous chromosomes may break at the point of contact, called the **chiasma** (plural: **chiasmata**) and exchange equivalent pieces of DNA, as shown in Figure 2.6. This process is called **crossing over**, and can be characterized by the number of crossover events that occur in one strand of DNA, including **single crossovers** and **double crossovers**. Note that crossing over occurs between homologous chromosomes and not between sister chromatids of the same chromosome—the latter are identical, so crossing over would not produce any change. Those chromatids involved are left with an altered but structurally complete set of genes. Such genetic **recombination** can unlink linked genes, thereby increasing the variety of genetic combinations that can be produced via gametogenesis. Linkage refers to the tendency for genes to be inherited together; genes that are located further from each other physically are less likely to be inherited together, and more likely to undergo crossing over relative to each other. Thus, as opposed to asexual reproduction, which produces identical offspring, sexual reproduction provides the advantage of great genetic diversity, which is believed to increase the ability of a species to evolve and adapt to a changing environment.

Real World

The rate of gene unlinking is used to map differences between two genes on the same chromosome. The farther apart two genes are, the more likely they are to become unlinked during crossing over. These statistics can then be used to determine the distance between genes on the chromosome, measured in units called centimorgans.

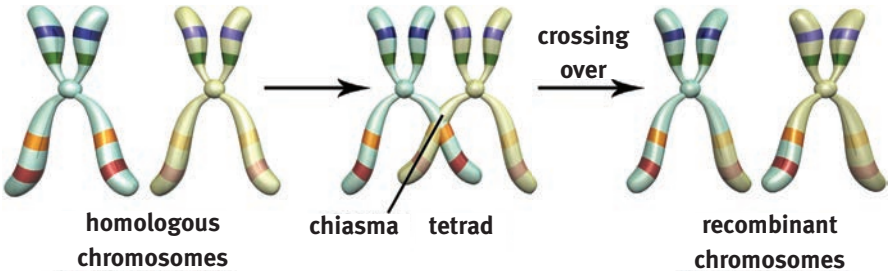

Figure 2.6. Synapsis
During prophase I, homologous chromosomes can exchange genetic material via crossing over.

Because of crossing over, each daughter cell will have a unique pool of alleles (genes coding for alternative forms of a given trait) from a random mixture of maternal and paternal origin. In classical genetics, crossing over explains **Mendel's second law (of independent assortment)**, which states that the inheritance of one allele has no effect on the likelihood of inheriting certain alleles for other genes.

Metaphase I

During **metaphase I**, homologous pairs (tetrads) align at the metaphase plate, and each pair attaches to a separate spindle fiber by its kinetochore. Note the difference from mitosis: in mitosis, each chromosome is lined up on the metaphase plate by two spindle fibers (one from each pole); in meiosis, homologous chromosomes are lined up across from each other at the metaphase plate and are held by one spindle fiber.

Anaphase I

During **anaphase I**, homologous pairs separate and are pulled to opposite poles of the cell. This process is called **disjunction**, and it accounts for **Mendel's first law (of segregation)**. During disjunction, each chromosome of paternal origin separates (or disjoins) from its homologue of maternal origin, and either chromosome can end up in either daughter cell. Thus, the distribution of homologous chromosomes to the two intermediate daughter cells is random with respect to parental origin. This separating of the two homologous chromosomes is referred to as **segregation**.

Telophase I

During **telophase I**, a nuclear membrane forms around each new nucleus. At this point, each chromosome still consists of two sister chromatids joined at the centromere. The cells are now haploid; once homologous chromosomes separate, only *n* chromosomes are found in each daughter cell (23 in humans). The cell divides into two daughter cells by cytokinesis. Between cell divisions, there may be a short rest period, or **interkinesis**, during which the chromosomes partially uncoil.

MEIOSIS II

Meiosis II is very similar to mitosis in that sister chromatids—rather than homologues—are separated from each other.

Prophase II

During **prophase II**, the nuclear envelope dissolves, nucleoli disappear, the centrioles migrate to opposite poles, and the spindle apparatus begins to form.

Metaphase II

During **metaphase II**, the chromosomes line up on the metaphase plate.

Anaphase II

During **anaphase II**, the centromeres divide, separating the chromosomes into sister chromatids. These chromatids are pulled to opposite poles by spindle fibers.

Telophase II

During **telophase II**, a nuclear membrane forms around each new nucleus. Cytokinesis follows, and two daughter cells are formed. Thus, by completion of meiosis II, up to four haploid daughter cells are produced per gametocyte. We use the phrase *up to* because oogenesis, discussed later in this chapter, may result in fewer than four cells if an egg remains unfertilized after ovulation.

Key Concept

It is critical to understand how meiosis I is different from mitosis. The chromosome number is halved (reductional division) in meiosis I, and the daughter cells have the haploid number of chromosomes (23 in humans). Meiosis II is similar to mitosis in that sister chromatids are separated from one another; therefore, no change in ploidy is observed.

Real World

If, during anaphase I or II of meiosis, homologous chromosomes (anaphase I) or sister chromatids (anaphase II) fail to separate, one of the resulting gametes will have two copies of a particular chromosome and the other gamete will have none. Subsequently, during fertilization, the resulting zygote may have too many or too few copies of that chromosome. Nondisjunction can affect both autosomal chromosomes (such as trisomy 21, resulting in Down syndrome) and the sex chromosomes (such as Klinefelter and Turner syndromes).

Key Concept

Mitosis	Meiosis
$2n \rightarrow 2n$	$2n \rightarrow n$
Occurs in all dividing cells	Occurs in sex cells only
Homologous chromosomes do not pair	Homologous chromosomes align on opposite sides of the metaphase plate
No crossing over	Crossing over can occur

MCAT Concept Check 2.2:
Before you move on, assess your understanding of the material with these questions.

1. What is the ploidy of the daughter cells produced from meiosis I? From meiosis II?
   - Meiosis I: _____
   - Meiosis II: _____

2. What is the difference between homologous chromosomes and sister chromatids?
   - Homologous chromosomes:

     _____
   - Sister chromatids:

     _____

3. For each phase of meiosis I listed below, what are the differences from the analogous phase of mitosis?

Meiotic Phase	Differences from Mitotic Phase
Prophase I	
Metaphase I	
Anaphase I	
Telophase I	

2.3 The Reproductive System ★★★★

Biological **sex** is determined by the 23rd pair of chromosomes, with XX being female and XY being male. An ovum can only carry the X chromosome, while sperm can carry either the X or Y chromosome. The **X chromosome** carries a sizeable amount of genetic information; mutations in these genes can cause **sex-linked** (X-linked) disorders. Males are termed **hemizygous** with respect to many of the genes on the X chromosome because they only have one copy. Therefore, a male with a disease-causing allele on the unpaired part of X chromosome will necessarily express that allele. Females, on the other hand, may be homozygous or heterozygous with respect to genes on the X chromosome. Most X-linked disorders are recessively inherited; therefore, females express these disorders far less frequently than males. Females carrying a diseased allele on an X-chromosome, but not exhibiting the disease, are said to be **carriers**.

Mnemonic
Sex-linked is X-linked.

Comparatively, the **Y chromosome** contains very little genetic information. One notable gene on the Y chromosome is ***SRY*** (**sex-determining region Y**), which codes for a transcription factor that initiates testis differentiation and, thus, the formation of male gonads. Therefore, in the absence of the Y chromosome, all zygotes will be female. In the presence of the Y chromosome, a zygote will be male.

MALE REPRODUCTIVE ANATOMY

The male reproductive system is shown in Figure 2.7.

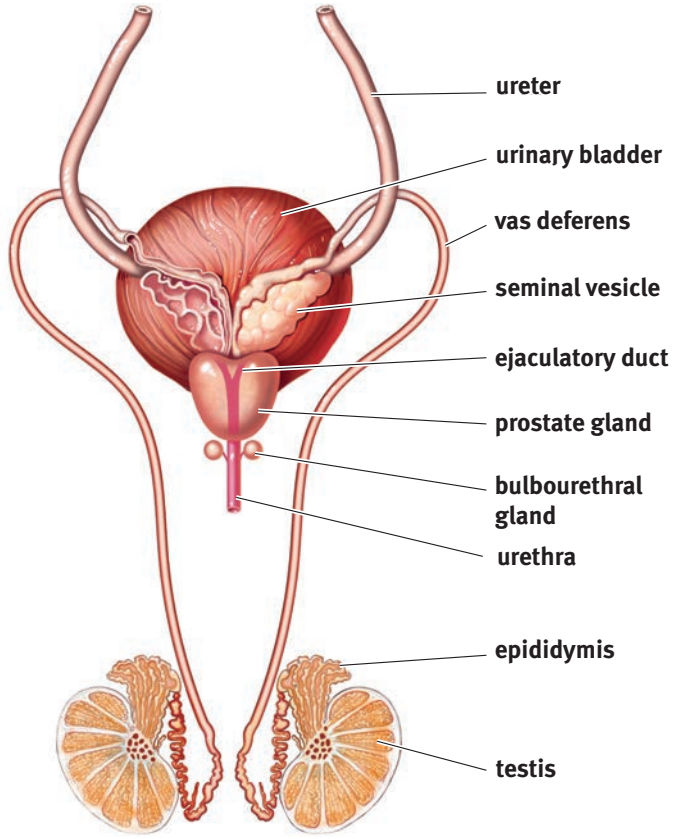

Figure 2.7. Male Reproductive System

In males, the primitive gonads develop into the **testes**. The testes have two functional components: the **seminiferous tubules** and the **interstitial cells** (**of Leydig**). **Sperm** are produced in the highly coiled seminiferous tubules, where they are nourished by **Sertoli cells**. The cells of Leydig secrete **testosterone** and other male sex hormones (**androgens**). The testes are located in the **scrotum**, which is an external pouch that hangs below the **penis** and maintains a temperature 2° to 4°C lower than the body. In fact, there is a layer of muscle around the vas deferens (ductus deferens) that can raise and lower the testis to maintain the proper temperature for sperm development.

Real World

In reality, there are a handful of Y-linked diseases, most of which result in reduced fertility. A father will pass a Y-linked disease to all of his sons, assuming fertility has not been lost. These diseases are extremely rare, and are not included on the official MCAT content lists.

Mnemonic

Pathway of sperm through the male reproductive system: **SEVE(N) UP**

- **S**eminiferous tubules
- **E**pididymis
- **V**as deferens (also called the ductus deferens)
- **E**jaculatory duct
- (**N**othing)
- **U**rethra
- **P**enis

Real World

The prostate enlarges with age and frequently causes problems in older males, including *benign prostatic hyperplasia.* Because the prostate surrounds the urethra, classic symptoms of this condition include urinary frequency, urgency, and nighttime awakenings to use the bathroom.

As sperm are formed, they are passed to the **epididymis** where their flagella gain motility, and they are then stored until ejaculation. During **ejaculation**, sperm travel through the **vas deferens** to the **ejaculatory duct** at the posterior edge of the prostate gland. The two ejaculatory ducts then fuse to form the **urethra**, which carries sperm through the **penis** as they exit the body. In males, the reproductive and urinary systems share a common pathway; this is not the case in females.

As sperm pass through the reproductive tract, they are mixed with **seminal fluid**, which is produced through a combined effort by the seminal vesicles, prostate gland, and bulbourethral gland. The **seminal vesicles** contribute fructose to nourish sperm, and both the seminal vesicles and **prostate gland** give the fluid mildly alkaline properties so the sperm will be able to survive in the relative acidity of the female reproductive tract. The **bulbourethral** (**Cowper's**) **glands** produce a clear viscous fluid that cleans out any remnants of urine and lubricates the urethra during sexual arousal. The combination of sperm and seminal fluid is known as **semen**.

Spermatogenesis

As mentioned above, **spermatogenesis**, the formation of haploid sperm through meiosis, occurs in the seminiferous tubules. In males, the diploid stem cells are known as **spermatogonia**. After replicating their genetic material (S stage), they develop into diploid **primary spermatocytes**. The first meiotic division will result in haploid **secondary spermatocytes**, which then undergo meiosis II to generate haploid **spermatids**. Finally, the spermatids undergo maturation to become mature **spermatozoa**. Spermatogenesis results in four functional sperm for each spermatogonium.

Mature sperm are very compact. They consists of a head (containing the genetic material), a midpiece (which generates ATP from fructose), and a flagellum (for motility), as shown in Figure 2.8. The **midpiece** is filled with mitochondria, which generate the energy to be used as the sperm swims through the female reproductive tract to reach the ovum in the fallopian tubes. Each sperm **head** is covered by a cap known as an **acrosome**. This structure is derived from the Golgi apparatus and is necessary to penetrate the **ovum**. Once a male reaches sexual maturity during puberty, approximately 3 million sperm are produced per day through the rest of life.

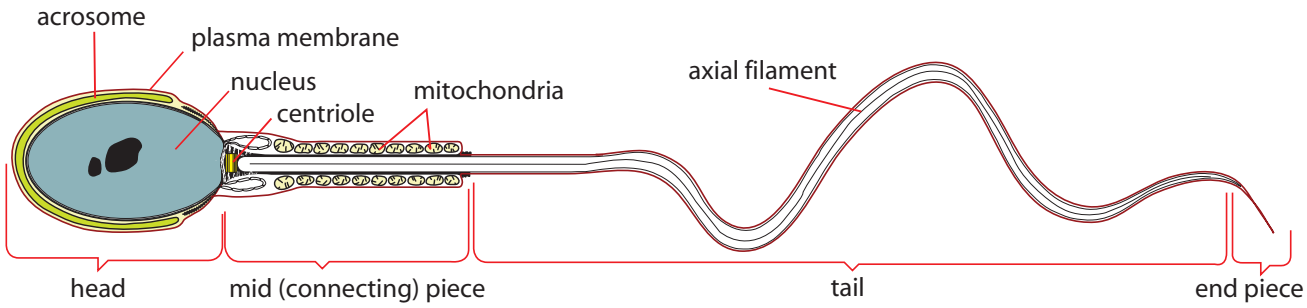

Figure 2.8. Structure of a Mature Sperm

FEMALE REPRODUCTIVE ANATOMY

Unlike the male reproductive system, all of the female reproductive organs are internal, as shown in Figure 2.9. The gonads, known as **ovaries**, produce estrogen and progesterone. The ovaries are located in the pelvic cavity; each consists of thousands of **follicles**, which are multilayered sacs that contain, nourish, and protect immature **ova** (eggs). Between puberty and menopause, one egg per month is **ovulated** into the **peritoneal sac**, which lines the abdominal cavity. It is then drawn into the **fallopian tube** or **oviduct**, which is lined with cilia to propel the egg forward. The fallopian tubes are connected to the muscular **uterus**, which is the site of fetal development. The lower end of the uterus, known as the **cervix**, connects to the **vaginal canal**, where sperm are deposited during intercourse. The vagina is also the passageway through which childbirth occurs. The external female anatomy is known collectively as the **vulva**. As mentioned earlier, females have separate excretory and reproductive tracts.

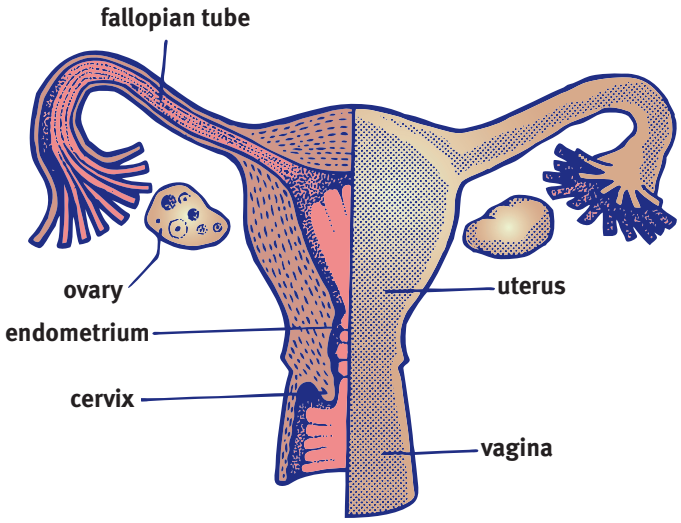

Figure 2.9. Female Reproductive System

Oogenesis

The production of female gametes is known as **oogenesis**. Although gametocytes undergo the same meiotic process in both females and males, there are some significant differences between the two sexes. First, there is no unending supply of stem cells analogous to spermatogonia in females; all of the oogonia a woman will ever have are formed during fetal development. By birth, all of the oogonia have already undergone DNA replication and are considered **primary oocytes**. These cells are 2*n*, like primary spermatocytes, and are actually arrested in prophase I. Once a woman reaches **menarche** (her first menstrual cycle), one primary oocyte per month will complete meiosis I, producing a **secondary oocyte** and a polar body. The division is characterized by unequal cytokinesis, which doles ample cytoplasm to one daughter cell (the secondary oocyte) and nearly none to the other (the polar body). The polar body generally does not divide any further and will never produce functional gametes. The secondary oocyte, on the other hand, remains arrested in metaphase II and does not complete the remainder of meiosis II unless fertilization occurs.

Oocytes are surrounded by two layers: the zona pellucida and the corona radiata. The **zona pellucida** surrounds the oocyte itself and is an acellular mixture of glycoproteins that protect the oocyte and contain compounds necessary for sperm cell binding. The **corona radiata** lies outside the zona pellucida and is a layer of cells that adhered to the oocyte during ovulation. Meiosis II is triggered when a sperm cell penetrates these layers with the help of acrosomal enzymes. The secondary oocyte undergoes the second meiotic division to split into a mature ovum and another polar body, which will eventually be broken down. A mature ovum is a very large cell consisting of large quantities of cytoplasm and organelles; indeed, the ovum contributes nearly everything to the zygote (half of the DNA and all of the cytoplasm, organelles [including mitochondria], RNA for early cellular processes, and physical space), whereas sperm only contribute half of the DNA. Upon completion of meiosis II, the haploid **pronuclei** of the sperm and the ovum join, creating a diploid **zygote**.

SEXUAL DEVELOPMENT

The ability to reproduce is under hormonal control. Prior to puberty, the **hypothalamus** restricts production of **gonadotropin-releasing hormone** (**GnRH**). At the start of puberty, this restriction is lifted as the hypothalamus releases pulses of GnRH, which then triggers the **anterior pituitary gland** to synthesize and release **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**). These hormones trigger the production of other sex hormones that develop and maintain the reproductive system.

Male Sexual Development

During the fetal period (from 9 weeks after fertilization until birth), presence of the Y chromosome allows for production of androgens, resulting in male sexual differentiation. For the duration of infancy and childhood, androgen production is low. **Testosterone**, produced by the testes, increases dramatically during puberty, and sperm production begins. In order to achieve this, there is a delicate interplay of FSH and LH stimulation on two cell types in the testes. FSH stimulates the Sertoli cells and triggers sperm maturation, whereas LH causes the interstitial cells to produce testosterone. Testosterone not only develops and maintains the male reproductive system, but also results in the development of **secondary sexual characteristics**, such as facial and axillary hair, deepening of the voice, and changes in growth patterns. Testosterone production remains high through adulthood and declines as men age. This hormone exerts negative feedback on the hypothalamus and anterior pituitary, so that production is limited to appropriate levels.

Female Sexual Development

The ovaries, which are derived from the same embryonic structures as the testes, are also under the control of FSH and LH secreted by the anterior pituitary. The ovaries produce estrogens and progesterone.

Estrogens are secreted in response to FSH, and they result in the development and maintenance of the female reproductive system and female secondary sexual characteristics (breast growth, widening of the hips, changes in fat distribution). In the embryo, estrogens stimulate development of the reproductive tract. In adults, estrogens lead to the thickening of the lining of the uterus (**endometrium**) each month in preparation for the implantation of a zygote.

Progesterone is secreted by the **corpus luteum**—the remnant follicle that remains after ovulation—in response to LH. Interestingly, progesterone is involved in the development and maintenance of the endometrium, but not in the initial thickening of the endometrium—this is the role of estrogen. This means that both estrogen and progesterone are required for the generation, development, and maintenance of an endometrium capable of supporting a zygote. By the end of the first trimester of a pregnancy, progesterone is supplied by the placenta, and the corpus luteum atrophies and ceases to function.

Real World

If the receptors for testosterone are absent or defective, it cannot exert its effects. The result is a condition called *androgen insensitivity syndrome* (AIS), in which a genetic male (XY) has female secondary sexual characteristics. In complete androgen insensitivity, a genetic male will appear female at birth. Often, these individuals are not discovered until puberty when they are examined for amenorrhea (failure to menstruate).

Mnemonic

Estrogen **est**ablishes and **pro**gesterone **pro**tects the endometrium.

THE MENSTRUAL CYCLE

During the reproductive years (from menarche to menopause), estrogen and progesterone levels rise and fall in a cyclic pattern. In response, the endometrial lining will grow and be shed. This is known as the **menstrual cycle** and can be divided into four events, as shown in Figure 2.10: the follicular phase, ovulation, the luteal phase, and menstruation.

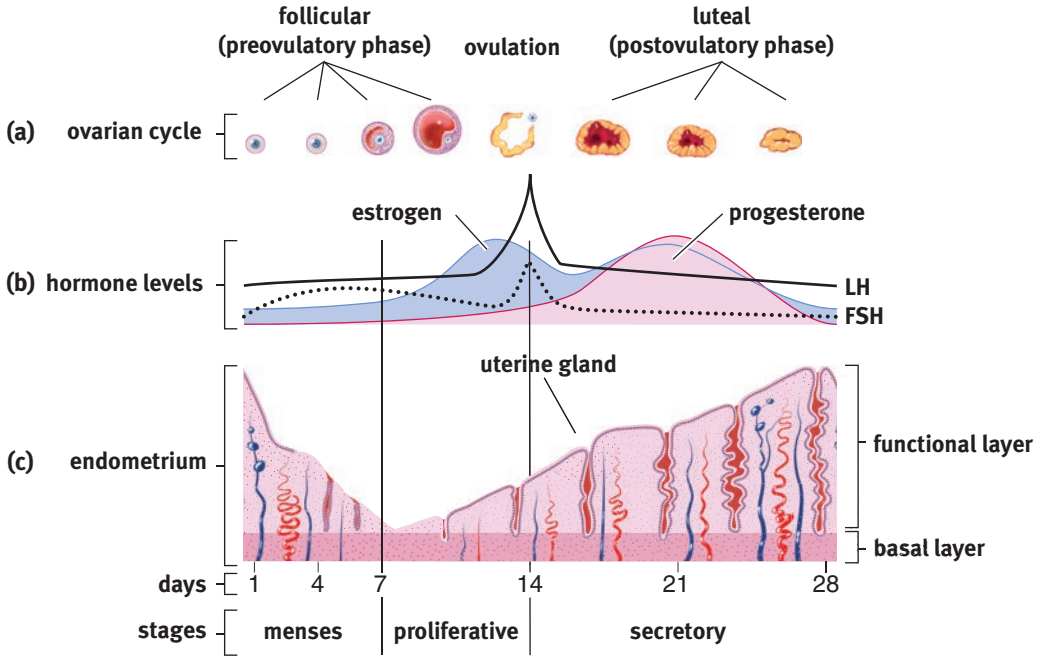

Figure 2.10. The Menstrual Cycle
(a) Follicule-stimulating hormone (FSH) facilitates the maturation of a single ovum; (b) The peak of luteinizing hormone (LH) around day 14 marks ovulation, the release of the oocyte from the follicle; (c) The endometrial lining of the uterus reaches its peak in the luteal phase and is shed at the beginning of the next cycle.

Follicular Phase

The **follicular phase** begins when the **menstrual flow**, which sheds the uterine lining of the previous cycle, begins. GnRH secretion from the hypothalamus increases in response to the decreased concentrations of estrogen and progesterone, which fall off toward the end of each cycle. The higher concentrations of GnRH cause increased secretions of both FSH and LH. These two hormones work in concert to develop several ovarian follicles. The follicles begin to produce estrogen, which has negative feedback effects and causes the GnRH, LH, and FSH concentrations to level off. Estrogen works to regrow the endometrial lining, stimulating vascularization and glandularization of the **decidua**.

Ovulation

Estrogen is interesting in that it can have both negative and positive feedback effects. Late in the follicular phase, the developing follicles secrete higher and higher concentrations of estrogen. Eventually, estrogen concentrations reach a

threshold that paradoxically results in positive feedback, and GnRH, LH, and FSH levels spike. The surge in LH is important; it induces **ovulation**, the release of the ovum from the ovary into the abdominal (peritoneal) cavity.

Luteal Phase

After ovulation, LH causes the ruptured follicle to form the corpus luteum, which secretes progesterone. Remember that estrogen helps regenerate the uterine lining, but it is progesterone that maintains it for implantation. Progesterone levels begin to rise, while estrogen levels remain high. The high levels of progesterone again cause negative feedback on GnRH, FSH, and LH, preventing the ovulation of multiple eggs.

Menstruation

Assuming that implantation does not occur, the corpus luteum loses its stimulation from LH, progesterone levels decline, and the uterine lining is sloughed off. The loss of high levels of estrogen and progesterone removes the block on GnRH so that the next cycle can begin.

Pregnancy

On the other hand, if fertilization *has* occurred, the resulting zygote will develop into a blastocyst that will implant in the uterine lining and secrete **human chorionic gonadotropin** (**hCG**). This hormone is an analog of LH, meaning that it looks very similar chemically and can stimulate LH receptors. This maintains the corpus luteum. hCG is critical during first trimester development because it is the estrogen and progesterone secreted by the corpus luteum that keep the uterine lining in place. By the second trimester, hCG levels decline because the placenta has grown to a sufficient size to secrete progesterone and estrogen by itself. The high levels of estrogen and progesterone continue to serve as negative feedback mechanisms, preventing further GnRH secretion.

Menopause

As a woman ages, her ovaries become less sensitive to FSH and LH, resulting in ovarian atrophy. As estrogen and progesterone levels drop, the endometrium also atrophies, and menstruation stops. Also, because the negative feedback on FSH and LH is removed, the blood levels of these two hormones rise. This is called **menopause**. Profound physical and physiological changes usually accompany this process, including flushing, hot flashes, bloating, headaches, and irritability. Menopause usually occurs between the ages of 45 and 55.

Real World

Oral contraceptive pills (OCPs) are simply estrogen/progesterone (or progesterone-only) preparations. These block conception by inhibiting LH and FSH release through negative feedback, thereby inhibiting ovulation. When a woman takes the placebo pills at the end of the month, withdrawal menstruation still occurs because estrogen and progesterone levels drop, but there is no egg that passes with the menstrual flow.

MCAT Expertise

The MCAT likes to test your ability to identify graphs of the blood concentrations of FSH, LH, estrogen, and progesterone through the menstrual cycle. Be sure to know when each peaks by studying Figure 2.10.

Key Concept

Menstrual cycle:

- Follicles mature during the follicular phase (FSH, LH)
- LH surge at midcycle triggers ovulation
- Ruptured follicle becomes corpus luteum, which secretes estrogen and progesterone to build up uterine lining in preparation for implantation; LH and FSH are inhibited
- If fertilization does not occur, corpus luteum atrophies, progesterone and estrogen levels decrease, menses occurs, and LH and FSH levels begin to rise again

MCAT Concept Check 2.3:

Before you move on, assess your understanding of the material with these questions.

1. What are the functions of interstitial cells of Leydig and Sertoli cells?
   - Interstitial cells of Leydig:

     _____

   - Sertoli cells:

     _____

2. During which phase of meiosis is a primary oocyte arrested? During which phase of meiosis is a secondary oocyte arrested?
   - Primary oocyte:

     _____

   - Secondary oocyte:

     _____

3. What is an acrosome? What organelle forms the acrosome?

   _____

   _____

4. What are the four phases of the female menstrual cycle? What are the features and relative hormone concentrations of each phase? (Note: Draw in symbols to signify the levels of each hormone, such as ↑, =, and ↓)

Phase	Key Features	FSH	LH	Estrogen	Progesterone

Conclusion

In this chapter, we explored one of the key tenets of the cell theory—how cells produce more copies of themselves. We first examined mitosis, which results in genetically identical diploid daughter cells. We then moved on to meiosis, which results in genetically nonidentical haploid daughter cells, or gametes. We then looked at the male and female reproductive systems, which form these gametes, each of which contains half of the normal complement of genetic information. Finally, we explored basic reproductive endocrinology and saw how testosterone and estrogen are key for development of the reproductive systems and the secondary sex characteristics that develop at puberty.

Formation of gametes is only half the story, of course. It serves us no good as a species to form sex cells if the cells cannot interact to form another human. Ultimately, gametes must accomplish their purpose: passing on the genes, the instructions for life, from one generation to another. Thus, we turn our attention in the next chapter to the next steps of fertilization, embryogenesis, and birth. The development of another human is a humbling and inspiring process. Indeed, it is through the union of one egg and one sperm that every human being on the planet today—and since the beginning of the human race—came to be in existence.

CONCEPT SUMMARY

The Cell Cycle and Mitosis

- **Diploid** (**2*n***) cells have two copies of each chromosome; **haploid** (***n***) cells have one copy.
- The cell cycle contains five stages. The G_1, S, and G_2 stages are collectively called **interphase**, during which the DNA is uncoiled in the form of **chromatin**.
  - In the **G_1** stage (**presynthetic gap**), cells create organelles for energy and protein production, while also increasing their size. The **restriction point**, during which the DNA is checked for quality, must be passed for the cell to move into the S stage.
  - In the **S** stage (**synthesis**), DNA is replicated. The strands of DNA, called **chromatids**, are held together at the centromere.
  - In the **G_2** stage (**postsynthetic gap**), there is further cell growth and replication of organelles in preparation for mitosis. Another quality checkpoint must be passed for the cell to enter into mitosis.
  - In the **M** stage (**mitosis**), mitosis and cytokinesis occur.
  - In the **G_0** stage, the cell performs its function without any preparation for division.
- **p53** plays a role in the two major checkpoints of the cell cycle (G_1 to S, and G_2 to M).
- **Cyclins** and **cyclin-dependent kinases** (**CDK**) rise and fall during the cell cycle. Cyclins bind to CDKs, phosphorylating and activating **transcription factors** for the next stage of the cell cycle.
- **Cancer** occurs when cell cycle control becomes deranged, allowing damaged cells to undergo mitosis without regard to quality or quantity of the new cells produced. Cancerous cells may begin to produce factors that allow them to escape their site and invade or **metastasize** elsewhere.
- Mitosis produces two genetically identical diploid daughter cells from a single cell and occurs in s**omatic cells**.
- Mitosis has four phases:
  - In **prophase**, the chromosomes condense, nuclear membrane dissolves, nucleoli disappear, centrioles migrate to opposite sides of the cell, and the **spindle apparatus** begins to form. The **kinetochore** of each chromosome is contacted by a spindle fiber.
  - In **metaphase**, chromosomes line up along the **metaphase plate** (**equatorial plate**).
  - In **anaphase**, sister chromatids are separated and pulled to opposite poles.

- In **telophase**, the nuclear membrane reforms, spindle apparatus disappears, and cytosol and organelles are split between the two daughter cells through **cytokinesis**.

Meiosis

- **Meiosis** occurs in **gametocytes** (**germ cells**) and produces up to four nonidentical haploid sex cells (**gametes**).
- Meiosis has one round of replication and two rounds of division (the **reductional** and **equational** divisions).
- In **meiosis I**, homologous pairs of chromosomes (homologues) are separated from each other. **Homologues** are chromosomes that are given the same number, but are of opposite parental origin.
  - In **prophase I**, the same events occur as in prophase of mitosis, except that homologues come together and intertwine in a process called **synapsis**. The four chromatids are referred to as a **tetrad**, and **crossing over** exchanges genetic material from one chromatid with material from a chromatid in the homologous chromosome. This accounts for **Mendel's second law** (**of independent assortment**).
  - In **metaphase I**, homologous chromosomes line up on opposite sides of the metaphase plate.
  - In **anaphase I**, homologous chromosomes are segregated to opposite poles of the cell. This accounts for **Mendel's first law** (**of segregation**).
  - In **telophase I**, the chromosomes may or may not fully decondense, and the cell may enter **interkinesis** after cytokinesis.
- In **meiosis II**, sister chromatids are separated from each other in a process that is functionally identical to mitosis. **Sister chromatids** are copies of the same DNA held together at the centromere.

The Reproductive System

- Biological sex is determined by the 23rd pair of chromosomes in humans, with XX being female and XY being male.
  - The **X chromosome** carries a sizeable amount of genetic information; mutations of X-linked genes can cause sex-linked disorders. Males are **hemizygous** with respect to the unpaired genes on the X chromosome, so they will express sex-linked disorders, even if they only have one recessive disease-carrying allele. Women with one copy of the affected allele are called **carriers**.
  - The **Y chromosome** carries little genetic information, but contains the ***SRY*** (**sex-determining region Y**) gene, which causes the gonads to differentiate into testes.

- The male reproductive system contains both internal and external structures.
  - **Sperm** develop in the **seminiferous tubules** in the **testes**. They are nourished by **Sertoli cells**.
  - **Interstitial cells** (**of Leydig**) secrete **testosterone** and other male sex hormones (**androgens**).
  - The testes are located in the **scrotum**, which hangs outside of the abdominal cavity and has a temperature 2° to 4°C lower than the rest of the body.
  - Once formed, sperm gain motility in the **epididymis** and are stored there until ejaculation.
  - During **ejaculation**, sperm travel through the **vas deferens** to the **ejaculatory duct** to the **urethra** and out through the **penis**.
  - The **seminal vesicles** contribute fructose to nourish sperm and produce alkaline fluid.
  - The **prostate gland** also produces alkaline fluid.
  - The **bulbourethral glands** produce a clear viscous fluid that cleans out any remnants of urine and lubricates the urethra during sexual arousal.
  - **Semen** is composed of sperm and **seminal fluid** from the glands above.
- In **spermatogenesis**, four haploid sperm are produced from a **spermatogonium**.
  - After S stage, the germ cells are called **primary spermatocytes**.
  - After meiosis I, the germ cells are called **secondary spermatocytes**.
  - After meiosis II, the germ cells are called **spermatids**.
  - After maturation, the germ cells are called **spermatozoa**.
- Sperm contain a head, midpiece, and flagellum.
  - The **head** contains the genetic material and is covered with an **acrosome**—a modified Golgi apparatus that contains enzymes that help the sperm fuse to and penetrate the ovum.
  - The **midpiece** generates ATP from fructose and contains many mitochondria.
  - The **flagellum** promotes motility.
- The female reproductive system only contains internal structures.
  - **Ova** (eggs) are produced in **follicles** in the **ovaries**.
  - Once each month, an egg is **ovulated** into the **peritoneal sac** and is drawn into the **fallopian tube** or **oviduct**.
  - The fallopian tubes are connected to the **uterus**, the lower end of which is called the **cervix**.
  - The **vaginal canal** lies below the cervix and is the site where sperm are deposited during intercourse. Birth also occurs through the vaginal canal.
  - The external female anatomy is known as the **vulva**.

- In **oogenesis**, one haploid ovum and a variable number of polar bodies are formed from an **oogonium**.
  - At birth, all oogonia have already undergone replication and are considered **primary oocytes**. They are arrested in prophase I.
  - The ovulated egg each month is a **secondary oocyte**, which is arrested in metaphase II.
  - If the oocyte is fertilized, it will complete meiosis II to become a true ovum.
  - Cytokinesis is uneven in oogenesis. The cell receiving very little cytoplasm and organelles is called a **polar body**.
  - Oocytes are surrounded by the **zona pellucida**, an acellular mixture of glycoproteins that protect the oocyte and contain the compounds necessary for sperm binding, and the **corona radiata**, which is a layer of cells that adhered to the oocyte during ovulation.
- **Gonadotropin-releasing hormone** (**GnRH**) from the **hypothalamus** causes the release of **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**), the functions of which depend on the sex of the individual.
  - In males, FSH stimulates the Sertoli cells and triggers spermatogenesis, while LH causes the interstitial cells to produce testosterone. **Testosterone** is responsible for the maintenance and development of the male reproductive system and male secondary sex characteristics (facial and axillary hair, deepening of the voice, and changes in growth patterns).
  - In females, FSH stimulates development of the ovarian follicles, while LH causes ovulation. These hormones also stimulate production of estrogens and progesterone.
- The menstrual cycle is a periodic growth and shedding of the endometrial lining.
  - In the **follicular phase**, GnRH secretion stimulates FSH and LH secretion, which promotes follicle development. Estrogen is released, stimulating vascularization and glandularization of the **decidua**.
  - **Ovulation** is stimulated by a sudden surge in LH. This surge occurs because estrogen stops having negative feedback effects at a certain threshold and begins to have positive feedback effects.
  - In the **luteal phase**, LH promotes the ruptured follicle to become the corpus luteum, which secretes progesterone that maintains the uterine lining. High estrogen and progesterone levels cause negative feedback on GnRH, LH, and FSH.
  - **Menstruation** occurs if there is no fertilization. As the estrogen and progesterone levels drop, the endometrial lining is sloughed off, and the block on GnRH production is removed.

- If fertilization does occur, the blastula produces **human chorionic gonadotropin** (**hCG**) which, as an LH analog, can maintain the corpus luteum. Near the end of the first trimester, hCG levels drop as the placenta takes over progesterone production.

- **Menopause** occurs when the ovaries stop producing estrogen and progesterone, usually between ages 45 and 55. Menstruation stops and FSH and LH levels rise. Physical and physiological changes accompanying menopause include flushing, hot flashes, bloating, headaches, and irritability.

ANSWERS TO CONCEPT CHECKS

2.1

1.

Cell Cycle Stage	Features
G_1	Cell grows and performs its normal functions. DNA is examined and repaired.
S	DNA is replicated.
G_2	Cell continues to grow and replicates organelles in preparation for mitosis. Cell continues to perform its normal functions.
M	Mitosis (cell division) occurs.
G_0	The cell performs its normal functions and is not planning to divide.

2.

Mitotic Phase	Features
Prophase	Chromosomes condense, nuclear membrane dissolves, nucleoli disappear, centrioles migrate to opposite poles and begin forming the spindle apparatus
Metaphase	Chromosomes gather along the metaphase plate in the center of the cell under the guidance of the spindle apparatus
Anaphase	Sister chromatids separate, and a copy of each chromosome migrates to opposite poles
Telophase and Cytokinesis	Chromosomes decondense, nuclear membrane reforms, nucleoli reappear, spindle apparatus breaks down, cell divides into two identical daughter cells

2.2

1. After meiosis I, there are two haploid daughter cells. After meiosis II, there are up to four haploid gametes.
2. Homologous chromosomes are related chromosomes of opposite parental origin (such as maternal chromosome 15 and paternal chromosome 15, or—in males—the X and Y chromosomes). Sister chromatids are identical copies of the same DNA that are held together at the centromere. After S phase, a cell contains 92 chromatids, 46 chromosomes, and 23 homologous pairs.

3.

Meiotic Phase	Differences from Mitotic Phase
Prophase I	Homologous chromosomes come together as tetrads during synapsis; crossing over
Metaphase I	Homologous chromosomes line up on opposite sides of the metaphase plate, rather than individual chromosomes lining up on the metaphase plate
Anaphase I	Homologous chromosomes separate from each other; centromeres do not break
Telophase I	Chromatin may or may not decondense; interkinesis occurs as the cell prepares for meiosis II

2.3

1. The interstitial cells of Leydig secrete testosterone and other male sex hormones (androgens). Sertoli cells nourish sperm during their development.
2. A primary oocyte is arrested in prophase I, while a secondary oocyte is arrested in metaphase II.
3. The acrosome contains enzymes that are capable of penetrating the corona radiata and zona pellucida of the ovum, permitting fertilization to occur. It is a modified Golgi apparatus.

4.

Phase	Key Features	FSH	LH	Estrogen	Progesterone
Follicular	Egg develops, endometrial lining becomes vascularized and glandularized	↑	=	↓, then ↑	↓
Ovulation	Egg is released from follicle into peritoneal cavity	↑	↑↑	↑	↓
Luteal	Corpus luteum produces progesterone to maintain endometrium	↓	=	↑	↑
Menses	Shedding of endometrial lining	↓	↓	↓	↓

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following is the correct sequence of the development of a mature sperm cell?

A. Spermatid → spermatocyte → spermatogonium → 2° spermatocyte → spermatozoan
B. Spermatogonium → 1° spermatocyte → 2° spermatocyte → spermatid → spermatozoan
C. Spermatozoan → 1° spermatocyte → 2° spermatocyte → spermatogonium → spermatid
D. Spermatogonium → 1° spermatocyte → 2° spermatocyte → spermatozoan → spermatid

2. Which of the following correctly pairs the stage of development of an egg cell with the relevant point in a woman's life cycle?

A. From birth to menarche—prophase II
B. At ovulation—metaphase I
C. At ovulation—metaphase II
D. At fertilization—prophase II

3. Some studies suggest that in patients with Alzheimer's disease, there is a defect in the way the spindle apparatus attaches to the kinetochore fibers. At which stage of mitotic division would one first expect to be able to visualize this problem?

A. Prophase
B. Metaphase
C. Anaphase
D. Telophase

4. A researcher wishes to incorporate a radiolabeled deoxyadenine into the genome of one of the two daughter cells that would arise as a result of mitosis. What is the latest stage of cellular development during which the radiolabeled deoxyadenine could be added to achieve this result?

A. G_1
B. G_2
C. M
D. S

5. Certain ovarian tumors called granulosa cell tumors are known to produce excessive levels of estrogen. A physician who diagnoses a granulosa cell tumor should look for a secondary cancer in which of the following parts of the reproductive tract?

A. Fallopian tube
B. Cervix
C. Endometrium
D. Vagina

6. Upon ovulation, the oocyte is released into the:

A. fallopian tube.
B. follicle.
C. abdominal cavity.
D. uterus.

7. Cancer cells are cells in which mitosis occurs continuously, without regard to quality or quantity of the cells produced. For this reason, most chemotherapies attack rapidly dividing cells. At which point(s) in the cell cycle could chemotherapy effectively prevent cancer cell division?

I. S stage

II. Prophase

III. Metaphase

A. I only
B. I and II only
C. II and III only
D. I, II, and III

8. Which of the following INCORRECTLY pairs a structure of the male reproductive system with a feature of the structure?

A. Seminal vesicles—produce alkaline fructose-containing secretions
B. Epididymis—surrounded by muscle to raise and lower the testes
C. Vas deferens—tube connecting the epididymis to the ejaculatory duct
D. Cowper's glands—produce a fluid to clear traces of urine in the urethra

9. What is the last point in the meiotic cycle in which the cell has a diploid number of chromosomes?

A. During interphase
B. During telophase I
C. During interkinesis
D. During telophase II

10. Which of the following does NOT likely contribute to genetic variability?

A. Random fertilization of an egg by a sperm
B. Random segregation of homologous chromosomes
C. Crossing over between homologous chromosomes during meiosis
D. Replication of the DNA during S stage

11. Which of the following statements correctly identifies a key difference between mitosis and meiosis?

A. In metaphase of mitosis, replicated chromosomes line up in single file; in metaphase II of meiosis, replicated chromosomes line up on opposite sides of the metaphase plate.
B. During anaphase of mitosis, homologous chromosomes separate; during anaphase of meiosis I, sister chromatids separate.
C. At the end of telophase of mitosis, the daughter cells are identical to each other; at the end of meiosis I, the daughter cells are identical to the parent cell.
D. During metaphase of mitosis, centromeres are present directly on the metaphase plate; during metaphase of meiosis I, there are no centromeres on the metaphase plate.

12. Which of the following is true regarding prophase?

A. The chromosomes separate and move to opposite poles of the cell.
B. The spindle apparatus disappears.
C. The chromosomes uncoil.
D. The nucleoli disappear.

13. An individual who is phenotypically female is found to have only one copy of a disease-carrying recessive allele on the X chromosome, yet she demonstrates all of the classic symptoms of the disease. Geneticists determine she has a genotype that likely arose from nondisjunction in one of her parents. What is the likely genotype of this individual?

A. 46,XX (46 chromosomes, with XX for sex chromosomes)
B. 46,XY
C. 45,X
D. 47,XXY

14. During which phase of the menstrual cycle does progesterone concentration peak?

A. Follicular phase
B. Ovulation
C. Luteal phase
D. Menses

15. Which of the following would NOT be seen during pregnancy?

A. High levels of hCG in the first trimester
B. High levels of progesterone throughout the pregnancy
C. Low levels of FSH in the first trimester
D. High levels of GnRH throughout the pregnancy

Explanations to Discrete Practice Questions

1. B

Diploid cells called spermatogonia differentiate into primary spermatocytes, which undergo the first meiotic division to yield two haploid secondary spermatocytes. These undergo a second meiotic division to become immature spermatids. The spermatids then undergo a series of changes leading to the production of mature sperm, or spermatozoa.

2. C

From the time of birth until shortly before ovulation, all egg cells are arrested at the prophase stage of meiosis I. These cells are referred to as primary oocytes. At ovulation, the egg cell has completed meiosis I and is now arrested in metaphase II as a haploid cell called a secondary oocyte. When a sperm penetrates the outer layers of the secondary oocyte, it completes meiosis II to become a mature ovum.

3. A

The spindle apparatus first interacts with the kinetochore fibers near the end of prophase. While the spindle apparatus aligns the chromosomes at the equatorial plate during metaphase, **choice (B)**, the initial connection of the microtubule to the kinetochore occurs in prophase.

4. D

To ensure that the labeled deoxyadenine will be incorporated into the DNA of one of the daughter cells, we have to insert the nucleotide before DNA replication has been completed. Because replication occurs during S stage, we could introduce the deoxyadenine during G_1 or S stage. Because G_1 precedes S, the latest point the deoxyadenine could be added is the S stage.

5. C

Estrogen is known to cause growth of the endometrial lining during the follicular phase of the menstrual cycle, and its levels stay high during the luteal phase to promote vascularization and glandularization of this tissue. Excessive levels of estrogen may provide a strong enough signal for cell growth to promote tumor formation, or even cancer. The other tissues listed in this question require estrogen for development, but are not strongly associated with rapid tissue growth due to estrogen.

6. C

This subtle point about ovulation eludes most students and remains hard to believe until the organs are examined in anatomy class in medical school. The ruptured ovarian follicle releases an oocyte into the abdominal cavity, close to the entrance of the fallopian tube. With the aid of beating cilia, the oocyte is drawn into the fallopian tube, through which it travels until it reaches the uterus. If it is fertilized in the fallopian tube, it will implant in the uterine wall. If fertilization does not occur, it will be expelled along with the uterine lining during menstruation.

7. D

The question is asking us to determine at which points in the cell cycle we can prevent or at least lower the number of cells undergoing mitosis. One idea would be to prevent DNA synthesis during the S stage of the cell cycle. Without the DNA being replicated, two viable daughter cells could not be formed. Another idea would be preventing the mitotic cycle from occurring altogether in prophase by preventing spindle apparatus formation, preventing the nuclear membrane from dissolving, or other processes during this phase. Similarly, a treatment that would act on cells in the

metaphase stage of the cell cycle would also interfere with the mitotic cycle. Therefore, any of the three solutions presented would be a viable option.

8. B

The epididymis is the site of sperm maturation at the posterior side of the testis. In the epididymis, sperm gain mobility and are stored until ejaculation. It is the vas deferens (ductus deferens) that is surrounded by muscle that raises and lowers the testis to maintain a constant temperature suitable for sperm production, not the epididymis.

9. B

The first meiotic division (reductional division) separates homologous chromosomes to opposite poles of the cell during anaphase I. Near the end of telophase I, cytokinesis occurs, resulting in two haploid (*n*) daughter cells. Thus, during interkinesis and anaphase II, the daughter cells are already haploid, eliminating **choices (C)** and **(D)**. The cell is diploid during interphase, **choice (A)**, but remains diploid up until the end of telophase I.

10. D

The safest way to answer this question correctly is to go through each answer choice and eliminate the ones that contribute to genetic variability. The random fertilization of an egg by a sperm, the random segregation of homologous chromosomes during anaphase I, and crossing over between homologous chromosomes during prophase I all contribute to genetic variability during sexual reproduction because they result in novel combinations of genetic material, eliminating **choices (A)**, **(B)**, and **(C)**. S stage, **choice (D)**, should specifically *not* cause increased genetic variability; the DNA should be copied precisely, without error, meaning that both strands of DNA should be identical.

11. D

The key differences between mitosis and meiosis primarily appear during meiosis I. Of note, synapsis and crossing over occurs during prophase I, and homologous chromosomes are separated during meiosis I (rather than sister chromatids, as in mitosis). While the location of the centromeres relative to the metaphase plate may seem a trivial point, it is representative of the fact that homologous chromosomes line up on opposite sides of the equatorial plate in meiosis, in contrast to the alignment of each chromosome directly upon the metaphase plate in mitosis.

12. D

In prophase, the chromatin condenses into chromosomes, the spindle apparatus forms, and the nucleoli and nuclear membrane disappear. **Choice (A)** describes anaphase, whereas **choices (B)** and **(C)** describe telophase.

13. C

Nondisjunction refers to the incorrect segregation of homologous chromosomes during anaphase I, or of sister chromatids during anaphase II. In either case, one daughter cell ends up with two copies of related genetic material, while the other receives zero. Immediately, this should eliminate **choices (A)** and **(B)**, which show a normal complement of chromosomes (46). An individual who has only one recessive disease-carrying allele, and yet still expresses the disease, likely does not have a dominant allele for the given trait. This is seen in males, who are hemizygous for many X-linked genes, and can also be seen in women with Turner syndrome (45,X), who have only one X chromosome. Thus, **choice (C)** is the answer.

14. C

Progesterone peaks during the luteal phase, as it supports the endometrium for potential implantation of a blastula. Progesterone levels are relatively low during follicular phase and ovulation, eliminating **choices (A)** and **(B)**. Withdrawal of progesterone actually causes menses, eliminating **choice (D)**.

15. D

During the first trimester of pregnancy, the corpus luteum is preserved by human chorionic gonadotropin (hCG); hence, progesterone secretion by the corpus luteum is maintained during the first trimester. This eliminates **choice (A)**. During the second trimester, hCG levels decline, but progesterone levels rise because the hormone is now secreted by the placenta itself, eliminating **choice (B)**. High levels of progesterone and estrogen inhibit GnRH secretion, thus preventing FSH and LH secretion and the onset of a new menstrual cycle. This eliminates **choice (C)** and validates **choice (D)**.

Concept Summary 109

Introduction

Is it a boy or a girl? It's one of the most common questions asked of pregnant women. The suspense around learning the baby's sex never fails to excite family and friends. For centuries, members of the elder generations have offered advice on how to predict the outcome or even plan it—*Dangle a needle over your belly by a thread. Does it swing side to side or in circles?*

In the modern world, needle dangling doesn't carry the same credibility as technological advances like ultrasonography. This radiographic technique is performed by placing a probe that emits high-frequency sound waves near the tissue to be examined. The probe transduces an image onto a computer screen, which can be measured to determine gestational age, screen for multiple pregnancies or anomalies, and identify the baby's sex. So how early can we determine a baby's sex? All embryos begin female by default—that is, for a male fetus to develop, it must undergo not only masculinization via the gene product of *SRY*, but also defeminization. These processes occur (or don't) around six to eight weeks postfertilization. Don't expect any answers before 16 to 17 weeks, however, because ultrasonography equipment does not have high enough resolution yet to give immediate answers.

In this chapter, we'll continue the discussion from the previous chapter by beginning with fertilization, the formation of a diploid zygote from the union of a sperm and an ovum. We'll then follow development from this point until the birth of an autonomously breathing baby. We'll examine how the cells of a developing human divide and differentiate. We'll also explore some specific system differences that exist between developing fetuses and adults as we present an overview of the stages of pregnancy and childbirth.

3.1 Early Developmental Stages ★★★

In this first section, we explore development from the formation of a diploid zygote until neurulation, or the formation of the neural tube that will differentiate into the nervous system.

FERTILIZATION

As discussed in Chapter 2 of *MCAT Biology Review*, a secondary oocyte is ovulated from the follicle on approximately day 14 of the menstrual cycle. The secondary oocyte travels into the fallopian tube, where it can be fertilized up to 24 hours after ovulation. Fertilization, shown in Figure 3.1, usually occurs in the widest part of the fallopian tube, called the **ampulla**. When the sperm meets the secondary oocyte in the fallopian tube, it binds to the oocyte and releases acrosomal enzymes that enable the head of the sperm to penetrate through the corona radiata and zona pellucida. Once the first sperm comes into direct contact with the secondary oocyte's cell membrane, it forms a tubelike structure known as the **acrosomal apparatus**, which extends to and penetrates the cell membrane. Its pronucleus may then freely enter the oocyte once meiosis II has come to completion. After penetration of the sperm through the cell membrane, the **cortical reaction**, a release of calcium ions, occurs. These calcium ions depolarize the membrane of the ovum, which serves two purposes: depolarization prevents fertilization of the ovum by multiple sperm cells, and the increased calcium concentration increases the metabolic rate of the newly formed diploid **zygote**. The now depolarized and impenetrable membrane is called the **fertilization membrane**.

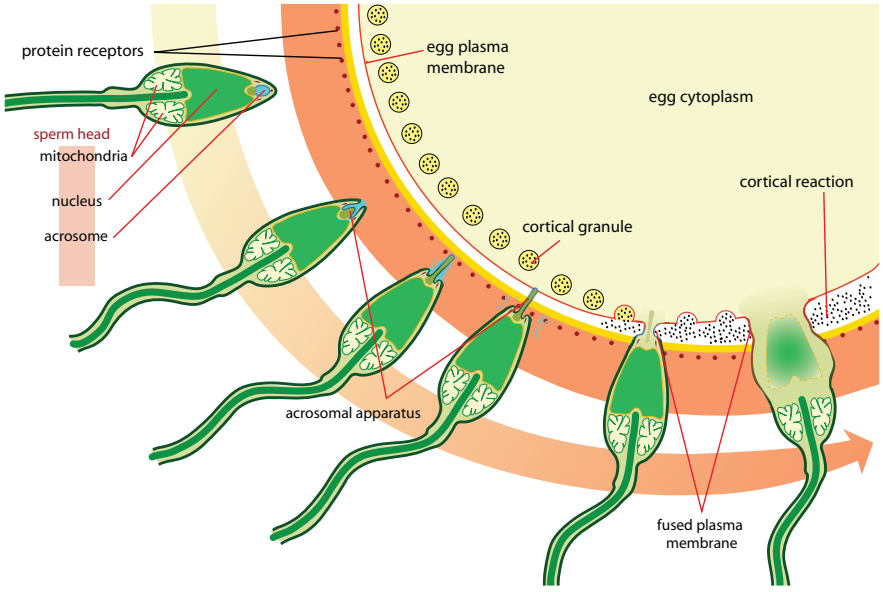

Figure 3.1. Fertilization

Twins

Twins can occur by two different mechanisms. **Dizygotic**, or **fraternal twins**, form from fertilization of two different eggs released during one ovulatory cycle by two different sperm. Each zygote will implant in the uterine wall, and each develops its own placenta, chorion, and amnion—these structures are discussed later in the chapter. If the zygotes implant close together, the placentas may overgrow onto each other. Fraternal twins are no more genetically similar than any other pair of siblings.

Monozygotic, or **identical twins**, form when a single zygote splits into two. Because the genetic material is identical, so too will be the genomes of the offspring. If division is incomplete, **conjoined twins** may result, in which the two offspring are physically attached at some point. Monozygotic twins can be classified by the number of structures they share. Monochorionic/monoamniotic twins share the same amnion and chorion. Monochorionic/diamniotic twins each have their own amnion, but share the same chorion. Dichorionic/diamniotic twins each have their own amnions and chorions. Which type of twinning occurs is a result of when the separation occurred. As more gestational structures are shared, there are more risks as the fetuses grow and develop.

CLEAVAGE

After fertilization in the fallopian tubes, the zygote must travel to the uterus for implantation. If it arrives too late, there will no longer be an endometrium capable of supporting the embryo. In the process of moving to the uterus for implantation, the zygote undergoes rapid mitotic cell divisions in a process called **cleavage**. The first cleavage officially creates an embryo, as it nullifies one of the zygote's defining characteristics: unicellularity. Although several rounds of mitosis occur, the total size of the embryo remains unchanged during the first few divisions, as shown in Figure 3.2. By dividing into progressively smaller cells, the cells increase two ratios: the nuclear-to-cytoplasmic (N:C) ratio and the surface area-to-volume ratio. Thus, the cells achieve increased area for gas and nutrient exchange relative to overall volume. There are two types of cleavage: indeterminate and determinate. **Indeterminate cleavage** results in cells that can still develop into complete organisms. In fact, monozygotic twins have identical genomes because they both originate from indeterminately cleaved cells of the same embryo. **Determinate cleavage** results in cells with fates that are, as the term implies, already determined. In other words, these cells are committed to **differentiating** into a certain type of cell.

Figure 3.2. An 8-Cell Embryo
The embryo has undergone three cleavage events at this point.

BLASTULATION

Several divisions later, the embryo becomes a solid mass of cells known as a **morula**, as shown in Figure 3.3. This term comes from the Latin word for mulberry, which might help us grasp what an embryo at this stage looks like.

Figure 3.3. Morula
The morula is a solid ball of cells.

Mnemonic

Remember that a **blast**ula is an embryo with a **blast**ed-out cavity.

Once the morula is formed, it undergoes **blastulation**, which forms the **blastula**, a hollow ball of cells with a fluid-filled inner cavity known as a **blastocoel**. The mammalian blastula is known as a **blastocyst** and consists of two noteworthy cell groups, as shown in Figure 3.4: the trophoblast and inner cell mass. The **trophoblast cells** surround the blastocoel and give rise to the chorion and later the placenta, whereas the **inner cell mass** protrudes into the blastocoel and gives rise to the organism itself.

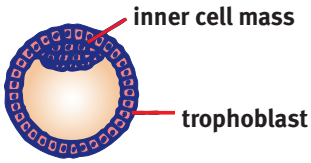

Figure 3.4. Blastula
The blastula contains a fluid-filled cavity called the blastocoel.

Implantation

The blastula moves through the fallopian tube to the uterus, where it burrows into the endometrium. The trophoblast cells are specialized to create an interface between the maternal blood supply and the developing embryo. These trophoblastic cells give rise to the **chorion**, an extraembryonic membrane that develops into the placenta. The trophoblasts form **chorionic villi**, which are microscopic fingerlike projections that penetrate the endometrium. As these chorionic villi develop into the placenta, they support maternal–fetal gas exchange. The embryo is connected to the placenta by the **umbilical cord**, which consists of two arteries and one vein encased in a gelatinous substance. The vein carries freshly oxygenated blood rich with nutrients from the placenta to the embryo. The umbilical arteries carry deoxygenated blood and waste to the placenta for exchange.

Until the placenta is functional, the embryo is supported by the **yolk sac**. The yolk sac is also the site of early blood cell development. There are two other extraembryonic membranes that require discussion: the allantois and the amnion. The **allantois** is involved in early fluid exchange between the embryo and the yolk sac. Ultimately, the umbilical cord is formed from remnants of the yolk sac and the allantois. The allantois is surrounded by the **amnion**, which is a thin, tough membrane filled with amniotic fluid. This fluid serves as a shock absorber during pregnancy, lessening the impact of maternal motion on the developing embryo. In addition to forming the placenta, the chorion also forms an outer membrane around the amnion, adding an additional level of protection. The anatomy of these structures is shown in Figure 3.5.

Real World

Sometimes the blastula implants itself outside the uterus, a situation known as an ectopic pregnancy. Over 95% of ectopic pregnancies occur in the fallopian tube. Ectopic pregnancies are generally not viable because the narrow fallopian tube is not an environment in which an embryo can properly grow. If the embryo does not spontaneously abort, the tube may rupture, and a considerable amount of hemorrhaging may occur. In fact, a suspected ectopic pregnancy is often a surgical emergency.

Real World

Amniocentesis is the process of aspirating amniotic fluid by inserting a thin needle into the amniotic sac. The amniotic fluid contains fetal cells that can be examined for chromosomal abnormalities as well as sex determination. Amniocentesis is recommended for pregnant women over 35 if earlier screening tests (blood tests and ultrasound) indicate a high chance of chromosomal abnormalities in the fetus. Women in this age group have a higher rate of meiotic nondisjunction, which can result in genetic aberrations such as Down syndrome.

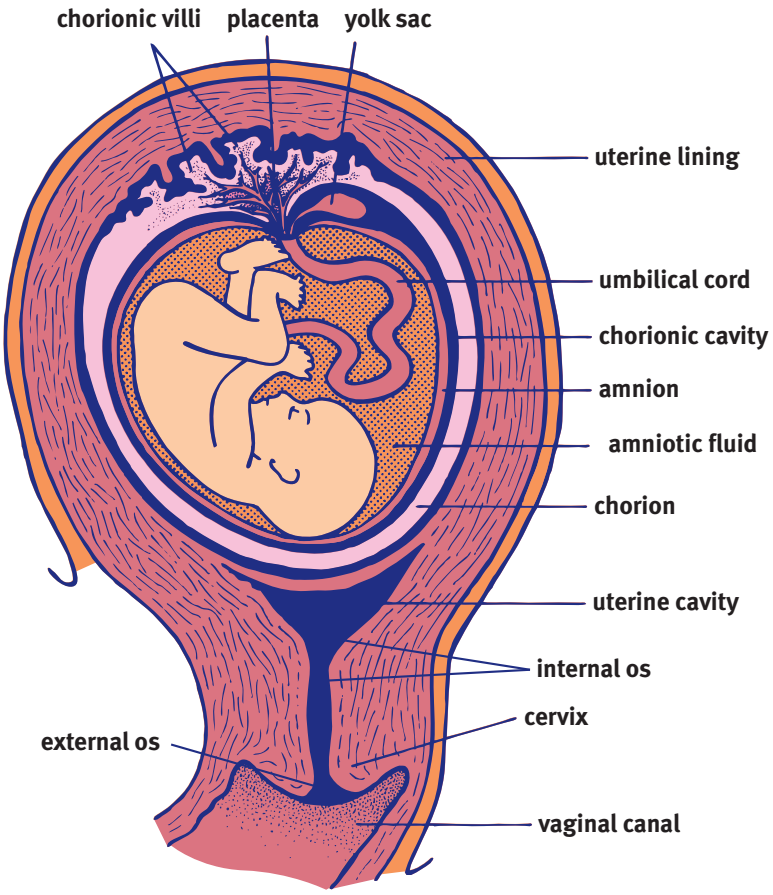

Figure 3.5. Anatomy of Pregnancy

GASTRULATION

Once the cell mass implants, it can begin further developmental processes such as **gastrulation**, the generation of three distinct cell layers. The early developmental processes up to this point are shown in Figure 3.6. Much of our knowledge of development comes from the study of other organisms that have varying degrees of similarity to human development. In sea urchins, gastrulation begins with a small invagination in the blastula. Cells continue moving toward the invagination, resulting in elimination of the blastocoel. To visualize this, imagine inflating a balloon and then poking one of the sides with your finger. If you kept pushing, eventually the rubber from one side of the balloon would come into contact with the other side. If the two membranes could merge, as occurs in development, this would create a tube through the middle of the balloon. In living things, the result of this process is called a **gastrula**. The membrane invagination into the blastocoel is called the **archenteron**, which later develops into the gut. The opening of the archenteron is called the **blastopore**. In **deuterostomes**, such as humans, the blastopore develops into the anus. In **protostomes**, it develops into the mouth.

Mnemonic

How can we remember the blastopore's fate in protostomes *vs*. deuterostomes? Think about how parents talk to toddlers—*deuterostome* starts with *deu*, which looks like *duo*, meaning *two*. Thus, **deu**terostomes develop the anus—the orifice associated with **"number two"**—from the blastopore. Protostomes must start at the other end (the mouth).

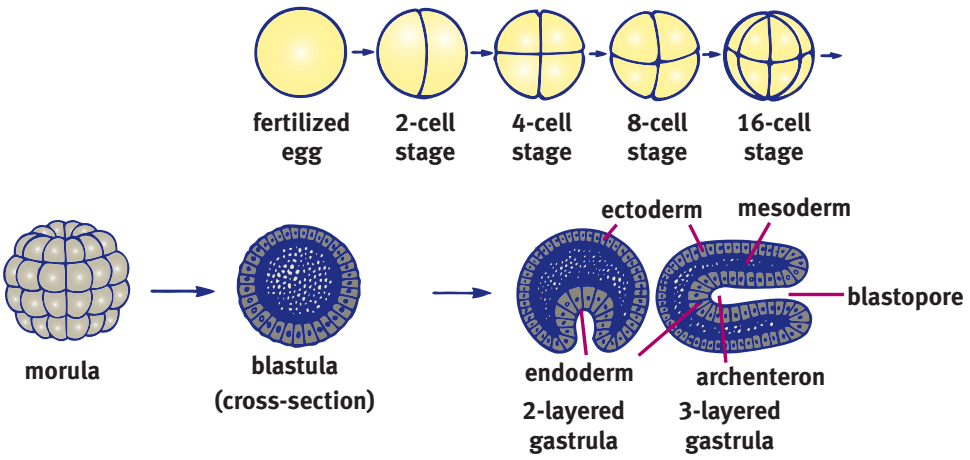

Figure 3.6. Early Stages of Embryonic Development

Primary Germ Layers

Eventually, some cells will also migrate into what remains of the blastocoel. This establishes three layers of cells called **primary germ layers**.

The outermost layer is called the **ectoderm** and gives rise to the integument, including the epidermis, hair, nails, and the epithelia of the nose, mouth, and lower anal canal. The lens of the eye, nervous system (including adrenal medulla), and inner ear are also derived from ectoderm.

The middle layer is called the **mesoderm** and develops into several different systems including the musculoskeletal, circulatory, and most of the excretory systems. Mesoderm also gives rise to the gonads as well as the muscular and connective tissue layers of the digestive and respiratory systems and the adrenal cortex.

The innermost layer is called the **endoderm** and forms the epithelial linings of the digestive and respiratory tracts, including the lungs. The pancreas, thyroid, bladder, and distal urinary tracts, as well as parts of the liver, are derived from endoderm.

Differentiation

So how is it that cells with the same genes are able to develop into such distinctly different cell types with highly specialized functions? Primarily, it is by **selective transcription** of the genome. In other words, only the genes needed for that particular cell type are transcribed. Thus, in pancreatic islet cells, the genes to produce specific hormones (insulin, glucagon, or somatostatin) are turned on, while these same genes are turned off in other cell types. Selective transcription is often related to the concept of **induction**, which is the ability of one group of cells to influence the fate of other nearby cells. This process is mediated by chemical substances called **inducers**, which diffuse from the **organizing cells** to the **responsive cells**. These chemicals are responsible for processes such as the

Mnemonic

The primary germ layers:

- Ectoderm—"attracto"derm (things that attract us to others, such as cosmetic features and "smarts")
- Mesoderm—"means"oderm (the means of getting around as an organism, such as bones and muscle; the means of getting around in the body, such as the circulatory system; the means of *getting around*, such as the gonads)
- Endoderm—linings of "endernal" organs (the digestive and respiratory tract, and accessory organs attached to these systems)

MCAT Expertise

The MCAT likes to test on the dual embryonic origin of the adrenal glands. The adrenal cortex is derived from the mesoderm, but the adrenal medulla is derived from the ectoderm (because the adrenal medulla contains some nervous tissue).

guidance of neuronal axons. This process also ensures proximity of different cell types that work together within an organ.

NEURULATION

Once the three germ layers are formed, **neurulation**, or development of the nervous system, can begin. Remember that the nervous system is derived from the ectoderm. How, then, do cells originating on the surface of the embryo (ectoderm) end up inside the final organism? First, a rod of mesodermal cells known as the **notochord** forms along the long axis of the organism like a primitive spine (in fact, small remnants of notochord persist in the intervertebral discs between vertebrae). The notochord induces a group of overlying ectodermal cells to slide inward to form **neural folds**, which surround a **neural groove**, as shown in Figure 3.7. The neural folds grow toward one another until they fuse into a **neural tube**, which gives rise to the central nervous system. At the tip of each neural fold are **neural crest cells**. These cells migrate outward to form the peripheral nervous system (including the sensory ganglia, autonomic ganglia, adrenal medulla, and Schwann cells) as well as specific cell types in other tissues (such as calcitonin-producing cells of the thyroid, melanocytes in the skin, and others). Finally, ectodermal cells will migrate over the neural tube and crests to cover the rudimentary nervous system.

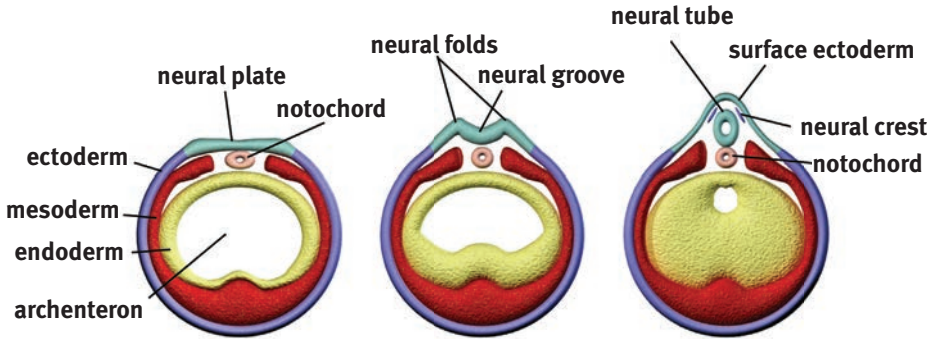

Figure 3.7. Formation of the Neural Tube

Real World

Failure of the neural tube to close results in either spina bifida (in which some or all of the spinal cord may be exposed to the outside world) or anencephaly (in which the brain fails to develop and the skull is left open). The severity of spina bifida's effects range from no significant distress to death, whereas anencephaly is universally fatal. Women who wish to conceive are encouraged to take folate (folic acid) to prevent this complication; it is recommended that all women of childbearing age supplement their diets with folate in advance of getting pregnant because neurulation often occurs before pregnancy is detected.

PROBLEMS IN EARLY DEVELOPMENT

Early development is a highly sensitive time during the development of a human being. During this stage, as the germ layers are forming and then organogenesis (the production of organs) begins, teratogens may have far-reaching and highly detrimental effects. **Teratogens** are substances that interfere with development, causing defects or even death of the developing embryo. However, each teratogen will not have the same effect on every embryo or fetus. It is believed that the genetics of the individual embryo influences the effects of the teratogen. In addition to genetics, the route of exposure, length of exposure, rate of placental transmission of the teratogen, and the exact identity of the teratogen will also affect the overall outcome. Some common

teratogens include alcohol, prescription drugs, viruses, bacteria, and environmental chemicals including polycyclic aromatic hydrocarbons.

In addition to teratogens, development can also be influenced by maternal health. Certain conditions may cause changes in the overall physiology of the mother, resulting in overexposure or underexposure of the embryo or fetus to certain chemicals. For example, diabetic mothers with hyperglycemia (high blood glucose) can have poor birth outcomes. Overexposure to sugar *in utero* can lead to a fetus that is too large to be delivered and who suffers from hypoglycemia soon after birth (due to synthesizing very high levels of insulin to compensate). Maternal folic acid deficiency may prevent complete closure of the neural tube, resulting in spina bifida or anencephaly, in which parts of the nervous system are exposed to the outside world or covered with a thin membrane. However, like teratogens, maternal health issues can have variable effects on the developing fetus. Spina bifida may be so severe as to result in profound disability, or may be completely asymptomatic and only detected by a tuft of hair overlying the area. Overall, trends and associations can certainly be found between various environmental conditions and genes during development; however, it is somewhat unpredictable and highly variable.

MCAT Concept Check 3.1:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between determinate and indeterminate cleavage?
   - Determinate cleavage:

     _____
   - Indeterminate cleavage:

     _____

2. From zygote to gastrula, what are the various stages of development?

   _____

3. During which stage of development does implantation occur?

   _____

4. What are the primary germ layers, and what organs are formed from each?

Germ Layer	Organs

5. What is induction?

_____

_____

6. What tissues do neural crest cells develop into?

_____

_____

3.2 Mechanisms of Development ★★

As described earlier, cells undergo determinate cleavage to commit to a particular cell line, and inducers can be used to communicate from one group of differentiating cells to another. In this section, we take a more specific look at the biochemical properties of these developmental mechanisms, as well as a few selected others.

CELL SPECIALIZATION

An adult human being is composed of approximately 37 trillion cells. These cells are organized into tissues, which form organs within organ systems. In order to create an organism as complex as a human being, each cell must perform a specialized function. In addition, the cells in an organ must be organized such that the organ can function properly. For example, the pancreas must create both digestive enzymes (*trypsin*, *carboxypeptidases A* and *B*, *pancreatic lipase*, and others) and endocrine hormones (*insulin*, *glucagon*, and *somatostatin*). The cells that synthesize digestive enzymes must be located such that the cell products can enter ducts to ultimately empty into the duodenum. Likewise, the cells that synthesize endocrine hormones must be located near a blood vessel to put their products into systemic circulation. In order to accomplish this, the cell must be determined and then differentiated.

Determination

As described earlier, **determination** is the commitment of a cell to having a particular function in the future. Prior to determination, the cell can become any cell type. After determination, the cell is committed to a specific lineage. There are multiple pathways by which determination may occur. If during cleavage, the existing mRNA and protein in the parent cell has been asymmetrically distributed between the daughter cells, the presence of specific mRNA and protein molecules may result in determination. Determination may also occur due to secretion of specific molecules from nearby cells. These molecules, also called **morphogens**, may cause nearby cells to follow a particular developmental

pathway. Determination is a commitment to a particular cell type, but note that the cell has not yet actually produced the products it needs to carry out the functions of that cell type—that is the goal of differentiation.

Differentiation

After a cell's fate has been determined, the cell must begin to undertake changes that cause the cell to develop into the determined cell type. This includes changing the structure, function, and biochemistry of the cell to match the cell type through **differentiation**.

Cells that have not yet differentiated, or which give rise to *other* cells that will differentiate, are known as **stem cells**. Stem cells exist in embryonic tissues as well as adult tissues. The tissues a particular stem cell can differentiate into are determined by its **potency**. Cells with the greatest potency are called **totipotent** and include embryonic stem cells; totipotent cells can ultimately differentiate into any cell type, either in the fetus or in placental structures. After the 16-cell stage, the cells of the morula begin to differentiate into two groups: the inner cell mass and the trophoblast cells. After a few more cycles of cell division, these totipotent cells start to differentiate into the three germ cell layers. At this stage, the cells are said to be **pluripotent**; these cells can differentiate into any cell type except for those found in the placental structures. Finally, as the cells continue to become more specialized, they are said to be **multipotent**. Multipotent stem cells can differentiate into multiple types of cells within a particular group. For example, hematopoietic stem cells are cells that are capable of differentiating into all of the cells found in blood, including the various types of white blood cells, red blood cells, and platelets—but not into skin cells, neurons, or muscle cells. While we use all of these different terms to describe potency, it is important to recognize that potency is a spectrum, not a series of strict definitions. Also, note that stem cells exist not only in embryos, but also in adults—we have stem cells that give rise to skin, blood, and the epithelial lining of the digestive tract, among others.

Over the last few decades, stem cell research has been a hotly contested issue. While harvesting of embryonic stem cells, highlighted in Figure 3.8, ultimately results in destruction of the embryo, it is thought that these cells could be used to regenerate human tissues, including the spinal cord (following injury) and cardiac myocytes (following a heart attack). There are also immunologic concerns, as transplantation of stem cells of a different genetic makeup would evoke an immune response, resulting in rejection. In addition, pluripotent cells may not always differentiate into the desired tissue, once implanted, and may even become cancerous.

Key Concept

When a cell is determined, it is committed to a particular cell lineage. When the cell differentiates, it assumes the structure, function, and biochemistry of that cell type.

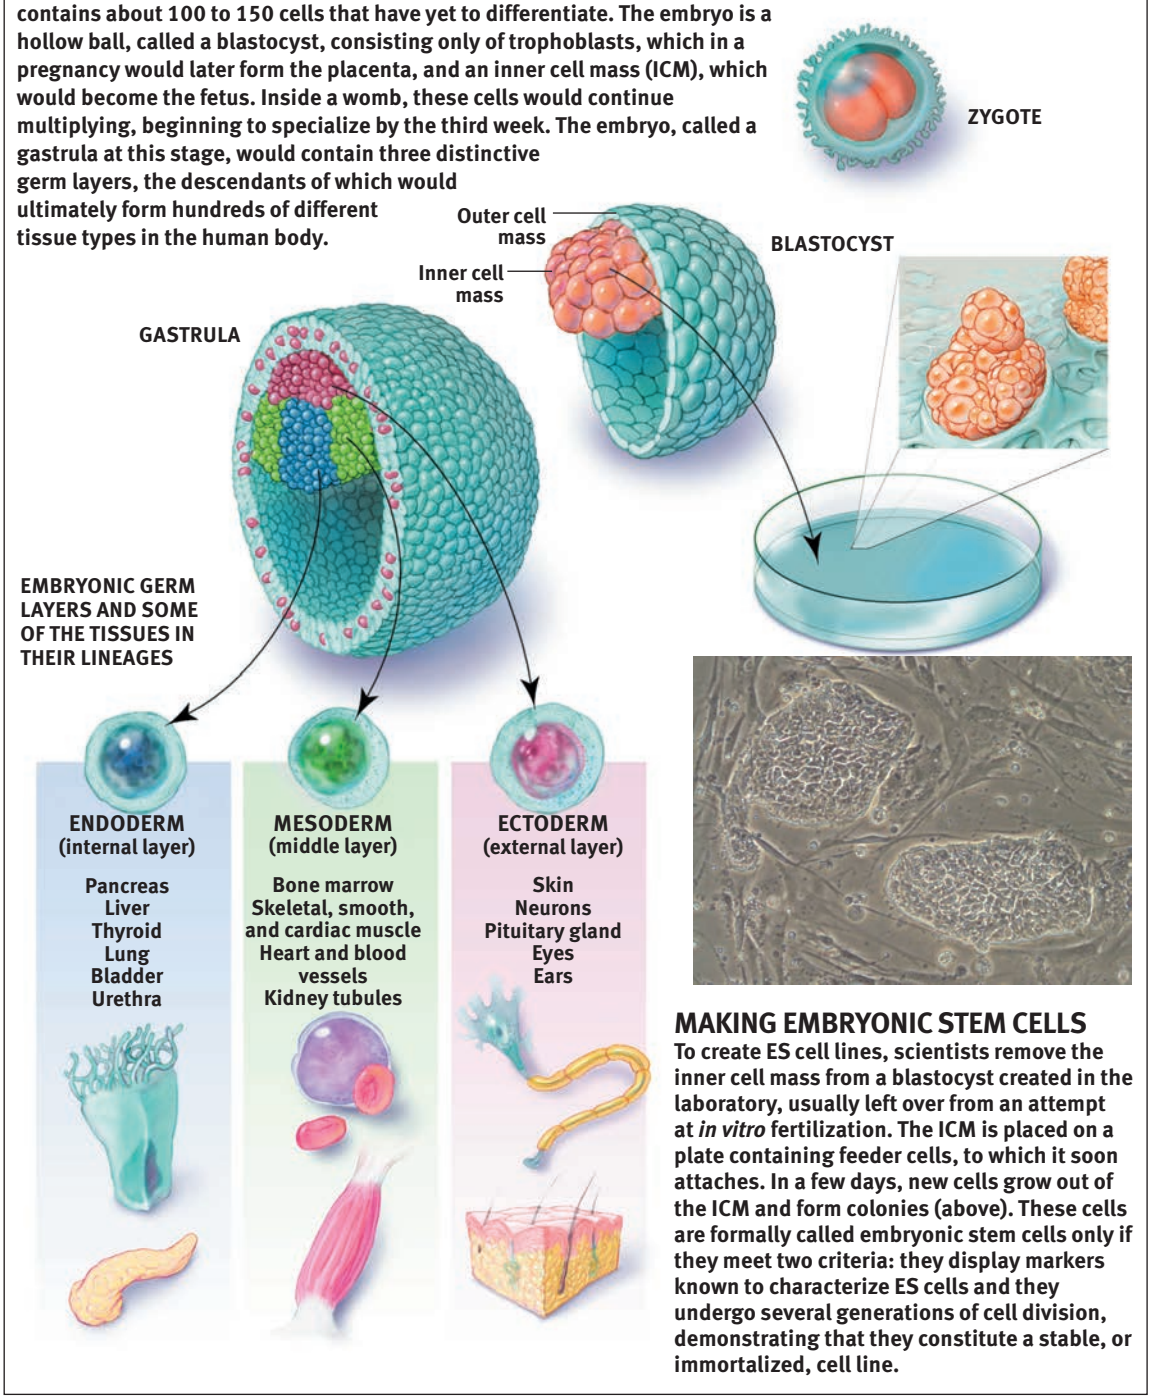
Key Concept

Stem cells are able to differentiate into different cell types. The potency of the stem cell determines how many different cell types a stem cell can become. As cells become more differentiated, the potency of the cell gets more narrow (from totipotent to pluripotent to multipotent).

Embryonic stem (ES) cells are derived from the portion of a very early-stage embryo that would eventually give rise to an entire body. Because ES cells originate in this primordial stage, they retain pluripotency—the ability to form any cell type in the body.

CELL FATE

Less than a week after a human egg is fertilized, the developing embryo contains about 100 to 150 cells that have yet to differentiate. The embryo is a hollow ball, called a blastocyst, consisting only of trophoblasts, which in a pregnancy would later form the placenta, and an inner cell mass (ICM), which would become the fetus. Inside a womb, these cells would continue multiplying, beginning to specialize by the third week. The embryo, called a gastrula at this stage, would contain three distinctive germ layers, the descendants of which would ultimately form hundreds of different tissue types in the human body.



MAKING EMBRYONIC STEM CELLS

To create ES cell lines, scientists remove the inner cell mass from a blastocyst created in the laboratory, usually left over from an attempt at *in vitro* fertilization. The ICM is placed on a plate containing feeder cells, to which it soon attaches. In a few days, new cells grow out of the ICM and form colonies (above). These cells are formally called embryonic stem cells only if they meet two criteria: they display markers known to characterize ES cells and they undergo several generations of cell division, demonstrating that they constitute a stable, or immortalized, cell line.

Figure 3.8. Embryonic Stem Cells

In order to address this controversy, many researchers have begun investigating adult stem cells. At best, these cells are multipotent, able to differentiate into only a few different cell types. Researchers may take adult stem cells and use various transcription factors to increase potency in these cells. One of the potential advantages of this is that a stem cell can be taken from a patient (usually from blood, bone marrow, or adipose tissue), induced to become a different tissue type, and then implanted into that same patient. This offers reduced risk of rejection of foreign tissue. However, it is challenging to induce differentiation into the correct cell type, and most organs have a complex structure that depends on a number of different cell types, each of which requires different signals. Research is ongoing and holds promise, despite limited success so far.

Bridge

Stem cells are a cornerstone of biotechnology. Gene studies can be performed by introducing altered embryonic stem cells that contain transgenes into mice. Stem cells lacking a particular gene can be used to create knockout mice. These processes are discussed in Chapter 6 of *MCAT Biochemistry Review*.

CELL–CELL COMMUNICATION

The determination and differentiation of a cell depends on the location of the cell itself as well as the identity of the surrounding cells. The developing cell receives signals from organizing cells around it and may also secrete its own signals. As discussed previously, surrounding tissues induce a developing cell to become a particular cell type via inducers; the term *inducer* may also refer to the cell secreting the signal. The cell that is induced is called a **responder** (responsive cell); to be induced, a responder must be **competent**, or able to respond to the inducing signal.

Cell–cell communication can occur via autocrine, paracrine, juxtacrine, or endocrine signals. **Autocrine** signals act on the same cell that secreted the signal in the first place. **Paracrine** signals act on cells in the local area. **Juxtacrine** signals do not usually involve diffusion, but rather feature a cell directly stimulating receptors of the adjacent cell. Finally, **endocrine** signals involve secreted hormones that travel through the bloodstream to a distant target tissue.

Inducers

Inducers are commonly **growth factors**, which are peptides that promote differentiation and mitosis in certain tissues. Most growth factors only function on specific cell types or in certain areas, as determined by the competence of these cells. In this way, certain growth factors can code for particular tissues. For example, *Pax6* is expressed in the ectoderm of the head, but in no other location. Therefore, as the optic vesicle approaches the overlying ectoderm producing this factor, development of the lens of the eye is induced. Interestingly, induction is not always a one-way pathway. To that end, differentiation of the lens then triggers the optic vesicle to form the optic cup, which ultimately becomes the retina. This is known as **reciprocal development**. Most tissues will be exposed to multiple inducers during the course of development.

One of the main methods of signaling occurs via the use of gradients. Morphogens, or molecules that cause determination of cells, diffuse through the organism.

Real World

In development of the eyes, lateral outpocketings from the brain (optic vesicles) grow out and touch the overlying ectoderm. The optic vesicle induces the ectoderm to form the lens placode. The lens placode in turn induces the optic vesicle to create the optic cup. The optic cup then induces the lens placode to develop into the cornea and lens. Experiments with frog embryos show that if this ectoderm is subsequently transplanted to the trunk (after the optic vesicles have grown out), a lens will develop in the trunk. If, however, the ectoderm is transplanted before the outgrowth of the optic vesicles, it will not.

Locations closer to the origin of the morphogen will be exposed to higher concentrations, while areas further away will have less exposure. Multiple morphogens are secreted simultaneously, resulting in unique combinations of morphogen exposure throughout the organism, which can thereby induce the differentiation of specific cell types. Some common morphogens include transforming growth factor beta (TGF-β), sonic hedgehog (Shh), and epidermal growth factor (EGF).

CELL MIGRATION, CELL DEATH, AND REGENERATION

Induction and differentiation allow for the creation of different types of cells; however, these cells are not always in the right location to carry out their function. Further, the sculpting of various anatomic structures requires not only differentiation, but death of some cells. Certain organs also have the ability to recreate injured or surgically removed portions of tissue.

Cell Migration

Cells must be able to disconnect from adjacent structures and migrate to their anatomically correct location. For example, the anterior pituitary gland originates from a segment of oral ectoderm and must migrate from the top of the mouth to its final location just below the hypothalamus. Neural crest cells also undergo extensive migration. These cells form at the edge of the neural folds during neurulation and then migrate throughout the body to form many different structures, including the sensory ganglia, autonomic ganglia, adrenal medulla, and Schwann cells, as well as specific cell types in other tissues, such as calcitonin-producing cells of the thyroid, melanocytes in the skin, and others.

Cell Death

Apoptosis, or programmed cell death, occurs at various times in development. For example, the fingers are originally webbed during development of the hand. The cells of the webbing later undergo apoptosis, resulting in separation of each individual finger and toe. Apoptosis may occur via apoptotic signals or preprogramming.

During the process of apoptosis, the cell undergoes changes in morphology and divides into many self-contained pieces called **apoptotic blebs**, which can then be digested by other cells, as shown in Figure 3.9. This allows for recycling of materials. Because the blebs are contained by a membrane, this also prevents the release of potentially harmful substances into the extracellular environment. This is different from **necrosis**, which is a process of cell death in which a cell dies as a result of injury. In necrosis, internal substances can be leaked, causing irritation of nearby tissues, or even an immune response.

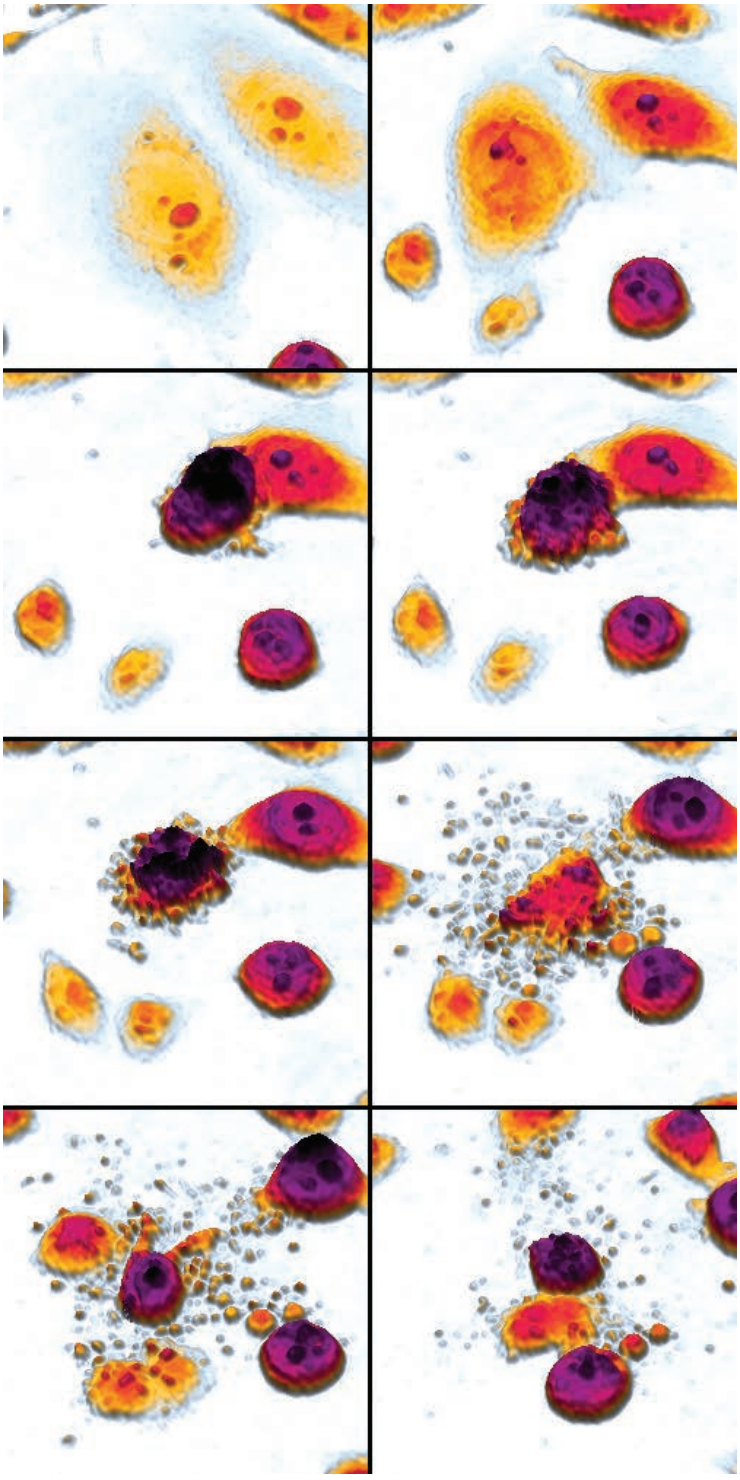


Figure 3.9. Apoptosis
An apoptotic cell disintegrates into blebs, which can be absorbed and digested by other cells.

Regeneration

Regenerative capacity, or the ability of an organism to regrow certain parts of the body, varies from species to species. Some species, such as salamanders and newts, have an enhanced capacity to regenerate because they retain extensive clusters of stem cells within their bodies. When regeneration is required, these stem cells can then migrate to the necessary part of the body to initiate regrowth. These species are said to undergo **complete regeneration**, in that the lost or damaged tissues are replaced with identical tissues. In contrast, **incomplete regeneration** implies that the newly formed tissue is not identical in structure or function to the tissue that has been injured or lost.

Humans typically exhibit incomplete regeneration in response to injury. However, in humans, regenerative capacity varies by the tissue type. Liver tissue has a high regenerative capacity, often able to undergo extensive regeneration following injury or loss. For example, living donors are often able to donate up to 50 percent of their liver tissue because their own livers will regenerate the missing portion. Unfortunately, the heart has little, if any, regenerative capacity, and scarring often results following an injury such as a heart attack. The kidneys have moderate regenerative capacity and are able to repair nephrons after injury to the tubules; however, this regenerative capacity is easily overwhelmed, and kidney failure may result.

SENESCENCE AND AGING

As organisms age, changes occur in both molecular and cellular structure. This results in disruption of metabolism and, eventually, death of the organism. **Senescence**, or biological aging, occurs as these changes accumulate and can occur at the cellular and organismal level. At the cellular level, senescence results in the failure of cells to divide, normally after approximately 50 divisions *in vitro*. Research has demonstrated that this may be due to shortened **telomeres**, or the ends of chromosomes. Telomeres reduce the loss of genetic information from the ends of chromosomes and help prevent the DNA from unraveling—their high concentration of guanine and cytosine enables telomeres to "knot off" the end of the chromosome. Telomeres are difficult to replicate, however, so they shorten during each round of DNA synthesis. Eventually, the telomeres become too short, and the cell is no longer able to replicate. Some cells, including germ cells, fetal cells, and tumor cells, express an enzyme known as *telomerase*. This enzyme is a reverse transcriptase that is able to synthesize the ends of chromosomes, preventing senescence. Telomerase allows for cells to divide indefinitely and may play a role in the survival of cancer cells.

At the organismal level, senescence represents changes in the body's ability to respond to a changing environment. Aging is complex and often involves not only cellular senescence but also the accumulation of chemical and environmental insults over time.

MCAT Concept Check 3.2:
Before you move on, assess your understanding of the material with these questions.

1. What is the difference between determination and differentiation?
   - Determination:

     _____
   - Differentiation:

     _____

2. What are the three types of potency? What lineages can a cell of each type differentiate into?

Type of Potency	Cell Lineages

3. What are the four types of cell–cell communication?
   - _____
   - _____
   - _____
   - _____

4. What is the difference between apoptosis and necrosis?
   - Apoptosis:

     _____
   - Necrosis:

     _____

3.3 Fetal Circulation ★

Recall that the placenta, shown in Figure 3.10, is the organ where nutrient, gas, and waste exchanges occur. It is crucial that maternal and fetal blood do not mix because they may have different blood types. The simplest method to move nutrients and waste products is by diffusion, and this is the preferred method for water, glucose, amino

Key Concept
Although the embryo obtains its nutrients and oxygen from the mother, there is no actual mixing of the blood. Instead, the placenta allows for the close proximity of the embryonic and maternal bloodstreams so that diffusion can occur between them.

acids, and inorganic salts. Diffusion requires a gradient, so this implies that there is a higher partial pressure of oxygen in maternal blood than fetal blood. In addition to an oxygen gradient, fetal blood cells contain **fetal hemoglobin (HbF)**, which exhibits a greater affinity for oxygen than does maternal (adult) hemoglobin (primarily HbA). This also assists with the transfer (and retention) of oxygen into the fetal circulatory system. Waste material and carbon dioxide move in the opposite direction.

Key Concept

Remember, gas exchange in the fetus occurs across the placenta. Fetal lungs do not function until birth.

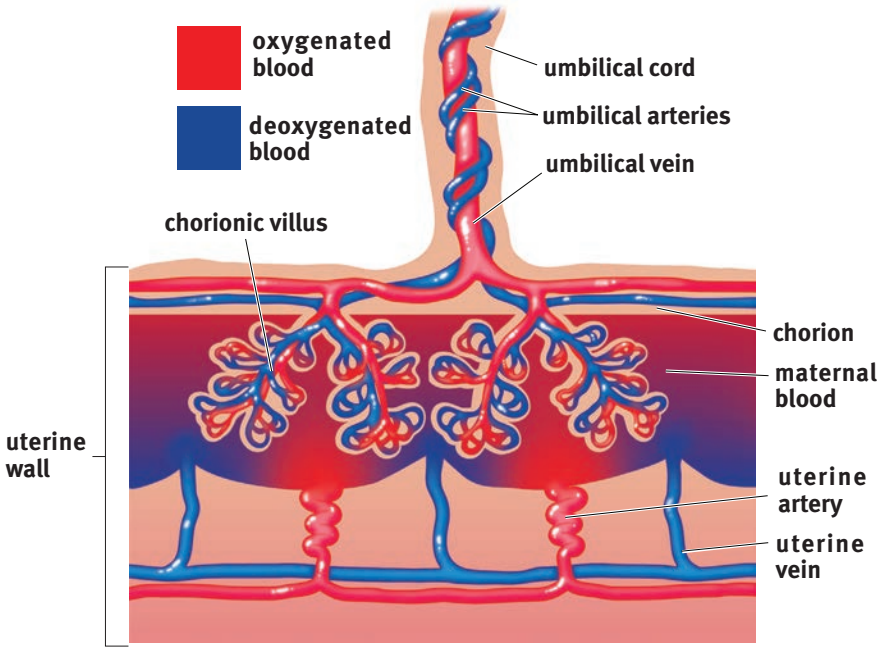

Figure 3.10. Placental Structure

The placental barrier also serves another function: immune protection. The fetus is immunologically naïve because it has not yet been exposed to any pathogens; however, accidental exposure can happen *in utero*. Thus, the crossing of antibodies across the placental membrane serves a protective function. The placenta also qualifies as an endocrine organ because it produces progesterone, estrogen, and human chorionic gonadotropin (hCG), all of which are essential for maintaining pregnancy.

Real World

Many pathogens are too large to cross the placental barrier by diffusion, but a set of pathogens called TORCHES infections can cross this barrier and cause significant birth defects. Therefore, screening for (and sometimes immunization against) these infections is recommended in pregnancy. TORCHES stands for ***TO****xoplasma gondii*, **R**ubella, **C**ytomegalovirus, **HE**rpes or **H**IV, and **S**yphilis.

The umbilical vessels are commonly tested on the MCAT because they demonstrate the need to understand the proper biological definitions of artery and vein. Like all other arteries that carry blood away from the heart, the **umbilical arteries** carry blood away from the fetus toward the placenta. And, like all of the other veins that carry blood toward the heart, the **umbilical vein** carries blood toward the fetus from the placenta. Remember that oxygenation occurs at the placenta, rather than in the fetal lungs. Therefore, the umbilical arteries carry deoxygenated blood and the umbilical vein carries oxygenated blood.

Key Concept

Unlike most other arteries, the umbilical arteries carry deoxygenated blood with waste products. Unlike most other veins, the umbilical vein carries oxygenated blood with nutrients.

There are several key differences between fetal and adult circulation that demonstrate important characteristics of the developing organism. The lungs and liver both do not serve significant functions prior to birth. Gas exchange does not occur at the lungs, but rather at the placenta. Detoxification and metabolism are primarily controlled by the mother's liver, and nutrient and waste exchange occurs at the placenta, as well. Thus, the fetus needs not depend on its own lungs and liver. Notably, these two organs are both underdeveloped and sensitive to the high blood pressures they will receive in postnatal life; thus, the fetus constructs three **shunts** to actively direct blood away from these organs while they develop, as shown in Figure 3.11.

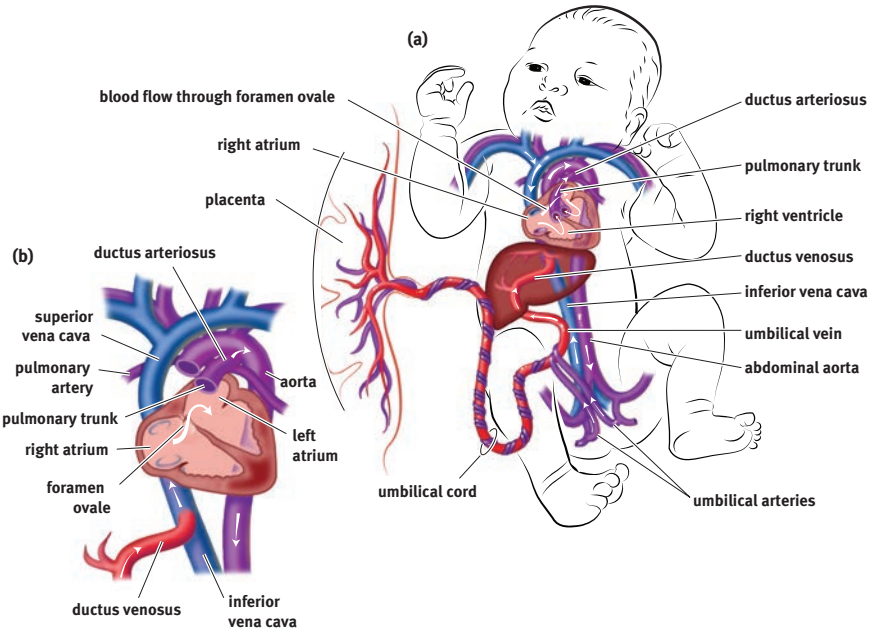

Figure 3.11. Fetal Circulation
(a) Systemic fetal circulation; (b) Enlarged view of fetal circulation highlighting the three fetal shunts.

Two different shunts are used to reroute blood from the lungs. The first, called the **foramen ovale**, is a one-way valve that connects the right atrium to the left atrium. This allows blood entering the right atrium from the inferior vena cava to flow into the left atrium, instead of the right ventricle, and thereby be pumped through the aorta into systemic circulation directly. Unlike in adult circulation, the right side of the heart is at a higher pressure in the developing fetus than the left side, which pushes blood through the opening. After birth, this pressure differential reverses, shutting the foramen ovale. Second, the **ductus arteriosus** shunts leftover blood from the pulmonary artery to the aorta. Again, the pressure differential between the right and left sides of the heart pushes blood through this opening and into systemic circulation.

The liver is bypassed using the **ductus venosus**, which shunts blood returning from the placenta via the umbilical vein directly to the inferior vena cava. The liver still receives some blood supply from smaller hepatic arteries in the systemic circulation.

MCAT Concept Check 3.3:
Before you move on, assess your understanding of the material with these questions.

1. What is the oxygenation status of the blood in the umbilical arteries? In the umbilical vein?
   - Umbilical arteries: _____
   - Umbilical vein: _____
2. What are the three fetal shunts? What vessels or heart chambers do they connect? What organ does each shunt bypass?

Shunt	Connected Vessels or Chambers	Organ Bypassed

3.4 Gestation and Birth

Human gestation lasts an estimated 280 days, which are divided into three trimesters. As a general rule, the larger the animal, the longer the gestational period and the fewer the offspring per pregnancy. For example, elephants usually have one calf and gestate for 22 months. In contrast, mice have 10 to 12 offspring per litter and gestate for only 20 days. Although you don't need to know every detail of gestation for the MCAT, there are some key developmental events in each trimester with which you should be familiar.

FIRST TRIMESTER

During the first weeks, the major organs begin to develop. The heart begins to beat at approximately 22 days, and soon afterward, the eyes, gonads, limbs, and liver start to form. By five weeks, the embryo is 10 mm in length, and by week six, it has grown to 15 mm. The cartilaginous skeleton begins to harden into bone by the seventh week. By the end of eight weeks, most of the organs have formed, the brain is fairly developed, and the embryo becomes known as a **fetus**. At the end of the third month, the fetus is about 9 cm long.

SECOND TRIMESTER

During the second trimester, the fetus undergoes a tremendous amount of growth. It begins to move within the amniotic fluid, its face takes on a human appearance, and its toes and fingers elongate. By the end of the sixth month, the fetus measures 30 to 36 cm long.

THIRD TRIMESTER

The seventh and eighth months are characterized by continued rapid growth and further brain development. Antibodies are transported by highly selective active transport from the mother to the fetus for protection against foreign matter in preparation for life outside the womb; this transfer begins earlier in the pregnancy, but it is highest in the ninth month, just before birth. The growth rate slows and the fetus becomes less active, as it has less room to move about.

BIRTH

Vaginal childbirth, or **parturition**, is accomplished by rhythmic contractions of uterine smooth muscle, coordinated by **prostaglandins** and the peptide hormone **oxytocin**. Birth consists of three basic phases. First, the cervix thins out and the amniotic sac ruptures, which is commonly called *water breaking*. Next, strong uterine contractions result in the birth of the fetus. Finally, the placenta and umbilical cord are expelled; these are often referred to as the **afterbirth**.

Real World

Advances in medicine have allowed premature babies born as early as 24 weeks to survive—far short of the normal 40 weeks. While these neonates may survive, there are often severe complications because fetal development is not complete at 24 weeks. These problems are most apparent in the respiratory, gastrointestinal, and nervous systems.

MCAT Concept Check 3.4:

Before you move on, assess your understanding of the material with these questions.

1. What are some of the key developmental features of each trimester?
   - First trimester:

     _____

     _____
   - Second trimester:

     _____

     _____
   - Third trimester:

     _____

     _____

2. What occurs in each of the three phases of birth?
   - _____
   - _____
   - _____

Conclusion

In this chapter, we have seen a just-fertilized ovum (zygote) become an embryo. As organs develop and the body organizes into complex organ systems, that embryo will turn into a newborn baby. Development certainly does not stop there, however—humans nurture their young for years (sometimes decades!)—as they undergo physical, cognitive, and sexual development. Embryonic development is extremely important because it lays the foundation for further development to be able to proceed correctly. Most of the time, the process goes exactly as planned; however, this is not always the case. In medical school, you will learn all about the wide spectrum of teratology—the study of birth defects.

Adult structures that arise from embryonic germ layers are of special importance to us because they are commonly tested on the MCAT. For the remainder of embryology—from the first cleavage event to the last uterine contraction—focus on the main terminology and highlights of each stage, in addition to the differences between fetal and adult physiology. Now that we have seen from where the organ systems derive, we begin our survey of anatomy and physiology. For the next eight chapters (Chapters 4 to 11 of *MCAT Biology Review*), we will explore the cells, tissues, organs, and interactions of each of the major organ systems. Our discussion begins with the nervous system.

CONCEPT SUMMARY

Early Developmental Stages

- **Fertilization** is the joining of a sperm and an ovum.
  - It usually occurs in the **ampulla** of the fallopian tube.
  - The sperm uses acrosomal enzymes to penetrate the corona radiata and zona pellucida.
  - Once it contacts the oocyte's plasma membrane, the sperm establishes the **acrosomal apparatus** and injects its pronucleus.
  - When the first sperm penetrates, it causes a release of calcium ions, which prevents additional sperm from fertilizing the egg and increases the metabolic rate of the resulting diploid **zygote**. This is called the **cortical reaction**.
- **Fraternal (dizygotic) twins** result from the fertilization of two eggs by two different sperm. **Identical (monozygotic) twins** result from the splitting of a zygote in two. Monozygotic twins can be classified by the placental structures they share (mono- *vs*. diamniotic, mono- *vs*. dichorionic).
- **Cleavage** is defined as the early divisions of cells in the embryo. These mitotic divisions result in a larger number of smaller cells, as the overall volume does not change.
  - The zygote becomes an embryo after the first cleavage because it is no longer unicellular.
  - **Indeterminate cleavage** results in cells that are capable of becoming any cell in the organism, while **determinate cleavage** results in cells that are committed to differentiating into a specific cell type.
- The **morula** is a solid mass of cells seen in early development.
- The **blastula** (**blastocyst**) has a fluid-filled center called a **blastocoel** and has two different cell types, including **trophoblasts** (which become placental structures) and the **inner cell mass** (which becomes the developing organism).
  - The blastula implants in the endometrial lining and forms the **placenta**.
  - The **chorion** contains **chorionic villi**, which penetrate the endometrium and create the interface between maternal and fetal blood.
  - Before the placenta is established, the embryo is supported by the **yolk sac**.
  - The **allantois** is involved in early fluid exchange between the embryo and the yolk sac.
  - The **amnion** lies just inside the chorion and produces amniotic fluid.
  - The developing organism is connected to the placenta via the **umbilical cord**.

- During **gastrulation**, the **archenteron** is formed with a **blastopore** at the end. As the archenteron grows through the blastocoel, it contacts the opposite side, establishing three primary germ layers.
  - The **ectoderm** becomes epidermis, hair, nails, and the epithelia of the nose, mouth, and anal canal, as well as the nervous system (including adrenal medulla) and lens of the eye.
  - The **mesoderm** becomes much of the the musculoskeletal, circulatory, and excretory systems. Mesoderm also gives rise to the gonads and the muscular and connective tissue layers of the digestive and respiratory systems, as well as the adrenal cortex.
  - The **endoderm** becomes much of the epithelial linings of the respiratory and digestive tracts, and parts of the pancreas, thyroid, bladder, and distal urinary tracts.
- **Neurulation**, or development of the nervous system, begins after the formation of the three germ layers.
  - The **notochord** induces a group of overlying ectodermal cells to form **neural folds** surrounding a **neural groove**.
  - The neural folds fuse to form the **neural tube**, which becomes the central nervous system.
  - The tip of each neural fold contains **neural crest cells**, which become the peripheral nervous system (sensory ganglia, autonomic ganglia, adrenal medulla, and Schwann cells) as well as specific cell types in other tissues (calcitonin-producing cells of the thyroid, melanocytes in the skin, and others).
- Teratogens are substances that interfere with development, causing defects or even death of the developing embryo. Teratogens include alcohol, certain prescription drugs, viruses, bacteria, and environmental chemicals.
- Maternal health can affect development, including diabetes (increased fetal size and hypoglycemia after birth) and folic acid deficiency (neural tube defects).

Mechanisms of Development

- Cell specialization occurs as a result of determination and differentiation.
  - **Determination** is the commitment to a specific cell lineage, which may be accomplished by uneven segregation of cellular material during mitosis or by **morphogens**, which promote development down a specific cell line. To respond to a specific morphogen, a cell must have **competency**.
  - **Differentiation** refers to the changes a cell undergoes due to **selective transcription** to take on characteristics appropriate to its cell line.
- Stem cells are cells that are capable of developing into various cell types. They can be classified by potency.

  - **Totipotent cells** are able to differentiate into all cell types, including the three germ layers and placental structures.
  - **Pluripotent cells** are able to differentiate into all three of the germ layers and their derivatives.
  - **Multipotent cells** are able to differentiate only into a specific subset of cell types.
- Cells communicate through a number of different signaling methods. An **inducer** releases factors to promote the differentiation of a competent **responder**.
  - **Autocrine** signals act on the same cell that released the signal.
  - **Paracrine** signals act on cells in the local area.
  - **Juxtacrine** signals act through direct stimulation of the adjacent cells.
  - **Endocrine** signals act on distant tissues after traveling through the bloodstream.
  - These are often **growth factors**, which are peptides that promote differentiation and mitosis in certain tissues.
  - If two tissues both induce further differentiation in each other, this is termed **reciprocal induction**.
  - Signaling often occurs via gradients.
- Cells may need to migrate to arrive at their anatomically correct location.
- **Apoptosis** is programmed cell death via the formation of **apoptotic blebs** that can subsequently be absorbed and digested by other cells. Apoptosis can be used for sculpting certain anatomical structures, such as removing the webbing between digits.
- **Regenerative capacity** is the ability of an organism to regrow certain parts of the body. The liver has high regenerative capacity, while the heart has low regenerative capacity.
- Senescence is the result of multiple molecular and metabolic processes; most notably, the shortening of telomeres during cell division.

Fetal Circulation

- Nutrient, gas, and waste exchange occurs at the placenta.
- Oxygen and carbon dioxide are passively exchanged due to concentration gradients.
- **Fetal hemoglobin** (**HbF**) has a higher affinity for oxygen than adult hemoglobin (primarily HbA), which also assists in the transfer (and retention) of oxygen into the fetal circulatory system.

- The placental barrier also serves as immune protection against many pathogens, and antibodies are transferred from mother to child.
- The placenta serves endocrine functions, secreting estrogen, progesterone, and human chorionic gonadotropin (hCG).
- The **umbilical arteries** carry deoxygenated blood from the fetus to the placenta; the **umbilical vein** carries oxygenated blood from the placenta back to the fetus.
- The fetal circulatory system differs from its adult version by having three shunts:
  - The **foramen ovale** connects the right atrium to the left atrium, bypassing the lungs.
  - The **ductus arteriosus** connects the pulmonary artery to the aorta, bypassing the lungs.
  - The **ductus venosus** connects the umbilical vein to the inferior vena cava, bypassing the liver.

Gestation and Birth

- In the first trimester, organogenesis occurs (development of heart, eyes, gonads, limbs, liver, brain).
- In the second trimester, tremendous growth occurs, movement begins, the face becomes distinctly human, and the digits elongate.
- In the third trimester, rapid growth and brain development continue, and there is transfer of antibodies to the fetus.
- During birth, the cervix thins out and the amniotic sac ruptures. Then, uterine contractions, coordinated by prostaglandins and oxytocin, result in birth of the fetus. Finally, the placenta and umbilical cord are expelled.

ANSWERS TO CONCEPT CHECKS

3.1

1. Determinate cleavage refers to cell division that results in cells having definitive lineages; that is, at least one daughter cell is already programmed to differentiate into a particular cell type. Indeterminate cleavage refers to cell division that results in cells that can differentiate into any cell type (or a whole organism).
2. Zygote → 2-, 4-, 8-, and 16-cell embryo → morula → blastula (blastocyst) → gastrula
3. Implantation occurs during the blastula (blastocyst) stage.
4.

Germ Layer	Organs
Ectoderm	Integument (including the epidermis, hair, nails, and epithelia of the nose, mouth, and anal canal), lens of the eye, nervous system (including adrenal medulla), inner ear
Mesoderm	Musculoskeletal system, circulatory system, excretory system, gonads, muscular and connective tissue layers of the digestive and respiratory systems, adrenal cortex
Endoderm	Epithelial linings of digestive and respiratory tracts, and parts of the liver, pancreas, thyroid, bladder, and distal urinary and reproductive tracts

5. Induction is the process by which nearby cells influence the differentiation of adjacent cells. This ensures proper spatial location and orientation of cells that share function or have complementary functions.
6. Neural crest cells become the peripheral nervous system (including the sensory ganglia, autonomic ganglia, adrenal medulla, and Schwann cells) as well as specific cell types in other tissues (such as calcitonin-producing cells of the thyroid, melanocytes in the skin, and others).

3.2

1. Determination is the commitment of a cell to a particular lineage. Differentiation refers to the actual changes that occur in order for the cell to assume the structure and function of the determined cell type.
2.

Type of Potency	Cell Lineages
Totipotency	Any cell type in the developing embryo (primary germ layers) or in extraembryonic tissues (amnion, chorion, placenta)
Pluripotency	Any cell type in the developing embryo (primary germ layers)
Multipotency	Any cell type within a particular lineage (for example, hematopoietic stem cells)

3. Autocrine (the signal acts on the same cell that secreted it), paracrine (the signal acts on local cells), juxtacrine (a cell triggers adjacent cells through direct receptor stimulation), endocrine (the signal travels via the bloodstream to act at distant sites)
4. Apoptosis is programmed cell death and results in contained blebs of the dead cell that can be picked up and digested by other cells. Necrosis is cell death due to injury and results in spilling of cytoplasmic contents.

3.3

1. The umbilical arteries carry deoxygenated blood. The umbilical vein carries oxygenated blood.
2.

Shunt	Connected Vessels or Chambers	Organ Bypassed
Foramen ovale	Right atrium to left atrium	Lungs
Ductus arteriosus	Pulmonary artery to aorta	Lungs
Ductus venosus	Umbilical vein to inferior vena cava	Liver

3.4

1. In the first trimester, organogenesis occurs (development of heart, eyes, gonads, limbs, liver, brain). In the second trimester, tremendous growth occurs, movement begins, the face becomes distinctly human, and the digits elongate. In the third trimester, rapid growth and brain development continue, and there is transfer of antibodies to the fetus.

2. In the first phase of birth, the cervix thins out and the amniotic sac ruptures. In the second phase, uterine contractions, coordinated by prostaglandins and oxytocin, result in birth of the fetus. In the third phase, the placenta and umbilical cord are expelled.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following developmental stages has the greatest nuclear-to-cytoplasmic ratio?

A. Eight-cell embryo
B. Morula
C. Blastula
D. Zygote

2. Which of the following associations of a primary germ layer and an adult organ is correct?

A. Endoderm—cardiac muscle
B. Endoderm—lens of the eye
C. Ectoderm—fingernails
D. Mesoderm—lining of digestive tract

3. From which of the following layers does the notochord form?

A. Ectoderm
B. Mesoderm
C. Endoderm
D. Archenteron

4. The influence of a specific group of cells on the differentiation of another group of cells is called:

A. competence.
B. senescence.
C. determination.
D. induction.

5. Which of the following is likely to be found in maternal blood during pregnancy?

A. Immunoglobulins produced by the fetus
B. Fetal hemoglobin released from fetal red blood cells
C. Progesterone produced by placental cells
D. Carbon dioxide exhaled from fetal lungs

6. A cell releases a substance that diffuses through the environment, resulting in differentiation of a nearby cell. This is an example of what type of cell–cell communication?

A. Autocrine
B. Juxtacrine
C. Paracrine
D. Endocrine

7. A cancer cell is removed from a patient and cultured. The cells in this culture seem to be able to divide indefinitely with no cellular senescence. Which protein is likely activated in these cells that accounts for this characteristic?

A. Epidermal growth factor
B. Sonic hedgehog
C. Transforming growth factor beta
D. Telomerase

8. A tumor is removed from a patient, and when investigated by pathologists, appears to contain tissue resembling placenta, hair, thyroid tissue, and cardiac muscle. What was the likely potency of the cells from which this tumor originated?

A. Nonpotent
B. Multipotent
C. Pluripotent
D. Totipotent

9. Which of the following is FALSE with regard to adult stem cells?

A. They retain inherent pluripotency if harvested from selected organs.
B. They are less controversial than embryonic stem cells.
C. They require treatment with various transcription factors.
D. There is a reduced risk of rejection if patient's own stem cells are used.

10. A child is born with an imperforate anus, in which the anal canal fails to form correctly and the rectum is not connected to the outside world. This pathology is most likely accounted for by a failure of:

A. cell differentiation.
B. cell determination.
C. apoptosis.
D. neurulation.

11. Following a myocardial infarction, the heart often heals by the creation of a scar by fibroblasts. This is an example of:

A. complete regeneration.
B. incomplete regeneration.
C. competency.
D. multipotency.

12. Neurofibromatosis type I, or von Recklinghausen's disease, is a disorder that causes formation of tumors in multiple nervous system structures as well as the skin. While all cells carry the same mutation on chromosome 17, selective transcription of the genome appears to cause the most significant tumorigenesis in which of the following primary germ tissue layers?

A. Ectoderm
B. Mesoderm
C. Endoderm
D. Notochord

13. Which of the following shows the correct order of early developmental milestones during embryogenesis?

A. Blastula → gastrula → morula
B. Morula → gastrula → blastula
C. Morula → blastula → gastrula
D. Gastrula → blastula → morula

14. A pregnant women is accidentally given a single dose of a teratogenic drug late in the third trimester. The baby is born three days later. Which of the following is the most likely outcome?

A. Complete failure of organ development and death of the fetus
B. Partial failure of organ development with survival of the fetus
C. Serious disfigurement of the fetus
D. Respiratory distress at birth, but no long-term effects

15. Which of the following statements regarding fetal circulation is FALSE?

A. In the umbilical cord, there are more arteries than veins.
B. The foramen ovale is the only shunt that connects two chambers of the heart.
C. Blood flow in the ductus arteriosus is from the aorta to the pulmonary artery.
D. The ductus venosus is the only shunt that bypasses the liver.

Explanations to Discrete Practice Questions

1. C

The question is asking us to determine the developmental stage with the greatest nuclear-to-cytoplasmic material ratio. During the series of rapid mitotic divisions known as cleavage, the number of cells increases dramatically, but the overall volume of the embryo does not change. In fact, the volume of the embryo does not significantly increase until after the blastula has already implanted. As such, a high ratio of nuclear to cytoplasmic material will be found at the stage with the greatest amount of cells during early development. From the given choices, the stage with the greatest number of cells is the blastula. This is further supported by the fact that the cells are displaced from the center by the blastocoel.

2. C

To answer this question, it could be useful to review quickly the embryonic layers. The ectoderm gives rise to the integument (the epidermis, hair, nails, and the epithelia of the nose, mouth, and anal canal), the lens of the eye, and the nervous system (including the adrenal medulla). The endoderm gives rise to the epithelial linings of the digestive and respiratory tracts and parts of the liver, pancreas, thyroid, and bladder. Finally, from the mesoderm arise the musculoskeletal system, the circulatory system, the excretory system, the gonads, and the adrenal cortex. Therefore, the only correct association can be found in **choice (C)** because the fingernails are derived from ectoderm.

3. B

A rod of mesodermal cells called the notochord develops along the longitudinal axis just under the dorsal layer of ectoderm. Through inductive effects from the notochord, the overlying ectoderm starts bending inward and forms a groove on the dorsal surface of the embryo. The dorsal ectoderm will eventually pinch off and develop into the spinal cord and brain. While the neural tube forms from ectoderm, the notochord itself is mesodermal.

4. D

The influence of a specific group of cells on the differentiation of another group of cells is termed induction. For example, the eyes are formed through a constant back-and-forth of reciprocal development between the brain and the ectoderm. Competence refers to the ability of a cell to respond to a given inducer, but not the influence of the group of organizing cells, eliminating **choice (A)**. Senescence is a term for biological aging, eliminating **choice (B)**. Determination may be the result of induction, but this term does not refer to the general concept of the effect of one group of cells on the differentiation on another group of cells, eliminating **choice (C)**.

5. C

During pregnancy, the placenta produces estrogen and progesterone to maintain the endometrium. These hormones are necessary for proper gestation of the fetus and should be measurable in maternal blood because they act on maternal organs. Prior to birth, the fetus is immunologically naïve and does not yet produce immunoglobulins, eliminating **choice (A)**. It is worth noting, though, that maternal immunoglobulins cross the placenta to enter fetal blood. Fetal hemoglobin is a large protein and, thus, cannot easily cross the placenta. Further, red blood cells are much too large to cross the barrier themselves, eliminating **choice (B)**. Carbon dioxide from fetal metabolism can be found in maternal blood, but the

lungs are nonfunctional prior to birth as the fetus is suspended in amniotic fluid. Carbon dioxide is transferred across the placenta directly from the fetal bloodstream, eliminating **choice (D)**.

6. C

The question stem states that a cell releases a substance that diffuses through the environment and causes differentiation of a nearby cell. Because the cell is acting on another nearby cell, and the molecule spreads by diffusion, this is an example of paracrine signaling. Autocrine signaling, **choice (A)**, occurs when a molecule secreted by a cell results in an effect on the same cell. Juxtacrine signaling, **choice (B)**, occurs between adjacent cells, but the signal does not spread by diffusion. In endocrine signaling, **choice (D)**, a molecule is secreted that travels via the bloodstream to a distant target.

7. D

Cells that are able to divide indefinitely with no senescence are not exhibiting normal cell behavior. Normally, somatic cells divide a limited number of times until the telomeres become too short to be effective protectors of genomic material. When this occurs, the cells stop dividing. However, in this case, the cells have continued to divide indefinitely. It is likely that the enzyme telomerase has been activated, which allows for synthesis of telomeres to counteract shortening during mitosis.

8. D

This question stem describes a tumor composed of multiple types of embryonic tissues as well as tissues derived from the three germ cell layers. Because this tumor contains placental tissue, the tumor must have originated from a cell that was able to produce those types of tissues. Cells capable of producing placental tissue as well as ectoderm, mesoderm, and endoderm are, by definition, totipotent.

9. A

Embryonic stem cells are controversial because they require destruction of an embryo to harvest, eliminating **choice (B)**. Adult stem cells are significantly less controversial, but require treatment with various transcription factors in order to induce an increased level of potency, eliminating **choice (C)**. Rejection is a concern when foreign cells are introduced into an individual; using one's own stem cells should remove this risk, eliminating **choice (D)**. Adult stem cells are rarely pluripotent unless pluripotency has been induced by strategic use of transcription factors. Therefore, **choice (A)** is the correct answer.

10. C

During development, programmed cell death occurs in multiple locations in order to ensure development of the correct adult structures. One of the places in which this occurs is between fingers and toes; another is the digestive tract, where a central lumen is formed. If apoptosis does not occur correctly in the digestive tract, an imperforate anus could result. Failure of determination or differentiation would likely result in the absence of anorectal structures altogether, eliminating **choices (A)** and **(B)**. Failure of neurulation would lead to an absence of a nervous system and would not be compatible with life, eliminating **choice (D)**.

11. B

After an injury, healing occurs by some sort of regenerative process. In humans, some tissues, such as the liver, are capable of regenerating tissue with much the same function and structure as the previous tissue. However, the heart is not capable of this sort of regeneration, often forming a fibrous scar in an area of injury. This is an example of incomplete regeneration, in which newly formed tissues are not identical in structure or function to the tissues that have been injured or lost.

12. A

Here, the mutation affects the skin and the nervous system, both of which are derived from ectoderm. The other germ tissue layers do not lead to skin or nervous system formation, eliminating **choices (B)** and **(C)**. The notochord is not actually a primary germ tissue layer, and thus cannot be an answer to the question, eliminating **choice (D)**.

13. C

After the first cell divisions occur, the embryo consists of a solid ball of cells known as a morula. Then a hollow center forms, creating the blastula. Finally, as the cells begin to differentiate into the three germ layers, the embryo is considered a gastrula. **Choice (C)** is therefore the correct answer.

14. D

The question stem states that the pregnant woman was given the drug three days before the baby was born. It is important to remember that organogenesis occurs during the first trimester. The last structure to become fully functional is the lungs. Because the organs were already largely formed prior to the administration of the teratogenic drug, it is likely that there was no major effect on the development of any organ as a result of exposure to the teratogen, eliminating **choices (A)**, **(B)**, and **(C)**. However, because lung tissues are so sensitive and because they mature so late, it is likely that the infant may have some respiratory distress at birth.

15. C

Blood flow in the ductus arteriosus is from the pulmonary artery to the aorta. The direction of flow is determined by the pressure differential between the right side of the heart (and pulmonary circulation) *vs.* the left side of the heart (and systemic circulation). Unlike in adults, the right side of the heart is at a higher pressure during prenatal life than the left side, so blood will shunt from the pulmonary circulation to the systemic circulation through both the foramen ovale and ductus arteriosus.

Concept Summary 146

Introduction

For generations, the indigenous peoples of South America used blow darts laced with a paralytic plant extract to hunt their prey. In the 1800s, English physicians who interacted with these indigenous South Americans recognized the possible uses of this paralytic agent, now known as *tubocurarine*, as an anesthetic agent for surgeries. Physicians noticed that animals under the influence of *tubocurarine* would become temporarily immobilized but would recover after a period of paralysis. According to these physicians, this discovery would revolutionize surgery as an anesthetic agent. So confident were they in their discovery that one of the physicians volunteered to undergo surgery under the influence of *tubocurarine* to demonstrate its effectiveness. Unfortunately, he failed to realize that, although the drug was an effective paralyzing agent, it did not have any effect on the sensory receptors of the body, so he felt every cut of the surgery without being able to move or do anything about it.

It is through the nervous system that organisms sense pain, temperature, and all aspects of their environment. It also serves to coordinate this sensory information and respond to stimuli. Specifically, the nervous system is responsible for the control of muscular movement, neuromuscular reflexes, and glandular secretions (such as salivation and lacrimation). In addition, the nervous system is responsible for higher-level thinking and mental function.

Despite all of its complex functions, the nervous system operates through basic electrical and chemical signals. Biomedical scientists have discovered so much about the nervous system: its anatomical and functional divisions, the nature of the action potential, and its histological features under the microscope. However, there is so much more that we do not know. It is an inspirational challenge for future physicians to realize that the brain continues to be a vast frontier for human exploration and discovery.

4.1 Cells of the Nervous System ★★★★

Neurons are specialized cells capable of transmitting electrical impulses and then translating those electrical impulses to chemical signals. In this section, we will consider the structure of the neuron as well as how neurons communicate with other parts of the nervous system.

NEURONS

Each neuron has a shape that matches its function, as dictated by the other cells with which that neuron interacts. There are a variety of different types of neurons in the body, but they all share some specific features.

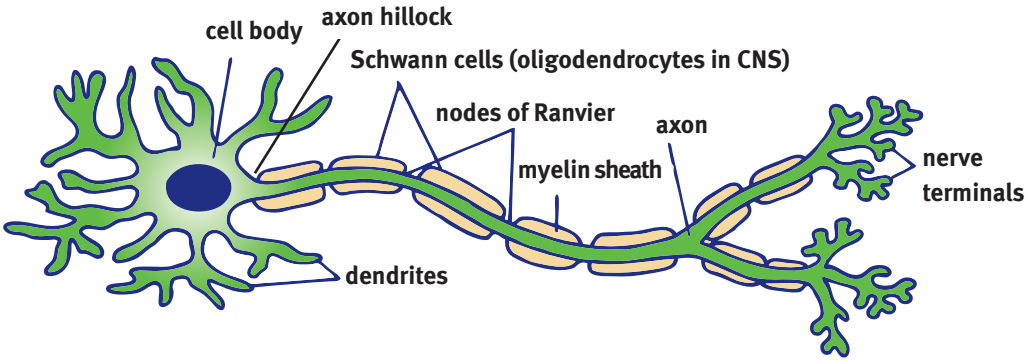

Figure 4.1. Structure of a Neuron

The anatomy of a neuron is shown in Figure 4.1. Like all other cells (besides mature red blood cells), neurons have nuclei. The nucleus is located in the **cell body**, also called the **soma**. The soma is also the location of the endoplasmic reticulum and ribosomes. The cell has many appendages emanating directly from the soma called **dendrites**, which receive incoming messages from other cells. The information received from the dendrites is transmitted through the cell body before it reaches the **axon hillock**, which integrates the incoming signals. The axon hillock plays an important role in **action potentials**, or the transmission of electrical impulses down the axon. Signals arriving from the dendrites can be either excitatory or inhibitory; the axon hillock sums these signals, and if the result is excitatory enough (reaching threshold, as discussed later in this chapter), it will initiate an action potential. The **axon** is a long appendage that terminates in close proximity to a target structure (a muscle, a gland, or another neuron). Most mammalian nerve fibers are insulated by **myelin** to prevent signal loss or crossing of signals. Just like insulation prevents wires next to each other from accidentally discharging each other, the **myelin sheath** maintains the electric signal within one neuron. In addition, myelin increases the speed of conduction in the axon. Myelin is produced by **oligodendrocytes** in the central

Real World

Sometimes the body mounts an immune response against its own myelin, leading to the destruction of this insulating substance (demyelination). Because myelin speeds the conduction of impulses along a neuron, the absence of myelin results in the slowing of information transfer. A common demyelinating disorder is multiple sclerosis (MS). In MS, the myelin of the brain and spinal cord is selectively targeted. Because so many different kinds of neurons are demyelinated, MS patients experience a wide variety of symptoms including weakness, lack of balance, vision problems, and incontinence.

nervous system and **Schwann cells** in the peripheral nervous system. At certain intervals along the axon, there are small breaks in the myelin sheath with exposed areas of axon membrane called **nodes of Ranvier**. As will be explored in the discussion of action potentials to follow, nodes of Ranvier are critical for rapid signal conduction. Finally, at the end of the axon is the **nerve terminal** or **synaptic bouton** (**knob**). This structure is enlarged and flattened to maximize neurotransmission to the next neuron and ensure proper release of **neurotransmitters**, the chemicals that transmit information between neurons.

Neurons are not physically connected to each other. Between the neurons, there is a small space into which the terminal portion of the axon releases neurotransmitters, which bind to the dendrites of the postsynaptic neuron. This space is known as the **synaptic cleft**; together, the nerve terminal, synaptic cleft, and postsynaptic membrane are known as a **synapse**. Neurotransmitters released from the axon terminal traverse the synaptic cleft and bind to receptors on the postsynaptic neuron.

Multiple neurons may be bundled together to form a **nerve** in the peripheral nervous system. These nerves may be **sensory**, **motor**, or **mixed**, which refers to the type(s) of information they carry; mixed nerves carry both sensory and motor information. The cell bodies of neurons of the same type are clustered together into ganglia.

In the central nervous system, axons may be bundled together to form **tracts**. Unlike nerves, tracts only carry one type of information. The cell bodies of neurons in the same tract are grouped into **nuclei**.

OTHER CELLS IN THE NERVOUS SYSTEM

Neurons are not the only cells in the nervous system. Neurons must be supported and myelinated by other cells. These cells are often called **glial cells**, or **neuroglia**. Glial cells play both structural and supportive roles, as shown in Figure 4.2.

Mnemonic

Axons carry neural signals **a**way from the soma; dendrites carry signals toward the soma.

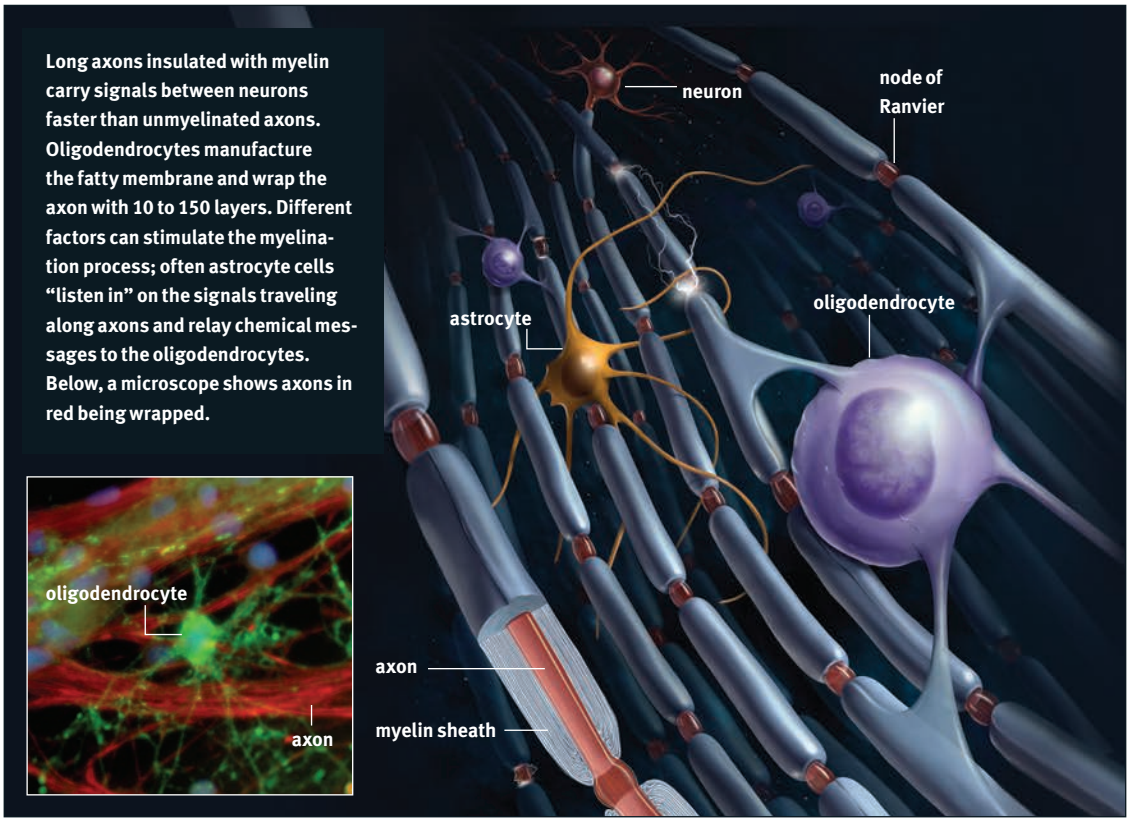

Figure 4.2. Glial Cells: Astrocytes and Oligodendrocytes

A detailed knowledge of these cell types is not necessary for the MCAT, so a familiarity with their basic functions will suffice:

- **Astrocytes** nourish neurons and form the blood–brain barrier, which controls the transmission of solutes from the bloodstream into nervous tissue.
- **Ependymal cells** line the ventricles of the brain and produce cerebrospinal fluid, which physically supports the brain and serves as a shock absorber.
- **Microglia** are phagocytic cells that ingest and break down waste products and pathogens in the central nervous system.
- **Oligodendrocytes** (CNS) and **Schwann cells** (PNS) produce myelin around axons.

MCAT Concept Check 4.1:

Before you move on, assess your understanding of the material with these questions.

1. For each of the following neuron structures, provide a brief description of its purpose:
   - Axon:

     _____
   - Axon hillock:

     _____
   - Dendrite:

     _____
   - Myelin sheath:

     _____
   - Soma:

     _____
   - Synaptic bouton:

     _____
2. What is a collection of cell bodies called in the CNS? In the PNS?
   - CNS: _____
   - PNS: _____
3. For each of the following glial cells, provide a brief description of its purpose:
   - Astrocyte:

     _____
   - Ependymal cell:

     _____
   - Microglia:

     _____
   - Oligodendrocyte:

     _____
   - Schwann cell:

     _____

4.2 Transmission of Neural Impulses

Now that we have discussed the basic anatomy of the neuron, we can turn to the physiology that underlies neuronal signaling.

THE ACTION POTENTIAL

Neurons use all-or-nothing messages called **action potentials** to relay electrical impulses down the axon to the synaptic bouton. As we will explore in the following section, action potentials ultimately cause the release of neurotransmitters into the synaptic cleft.

Resting Potential

All neurons exhibit a **resting membrane potential**. This means that there is an electrical potential difference (voltage) between the inside of the neuron and the extracellular space. Usually, this is about –70 mV, with the inside of the neuron being negative relative to the outside. Neurons use selective permeability to ions and the **Na^+/K^+ ATPase** to maintain this negative internal environment, as shown in Figure 4.3.

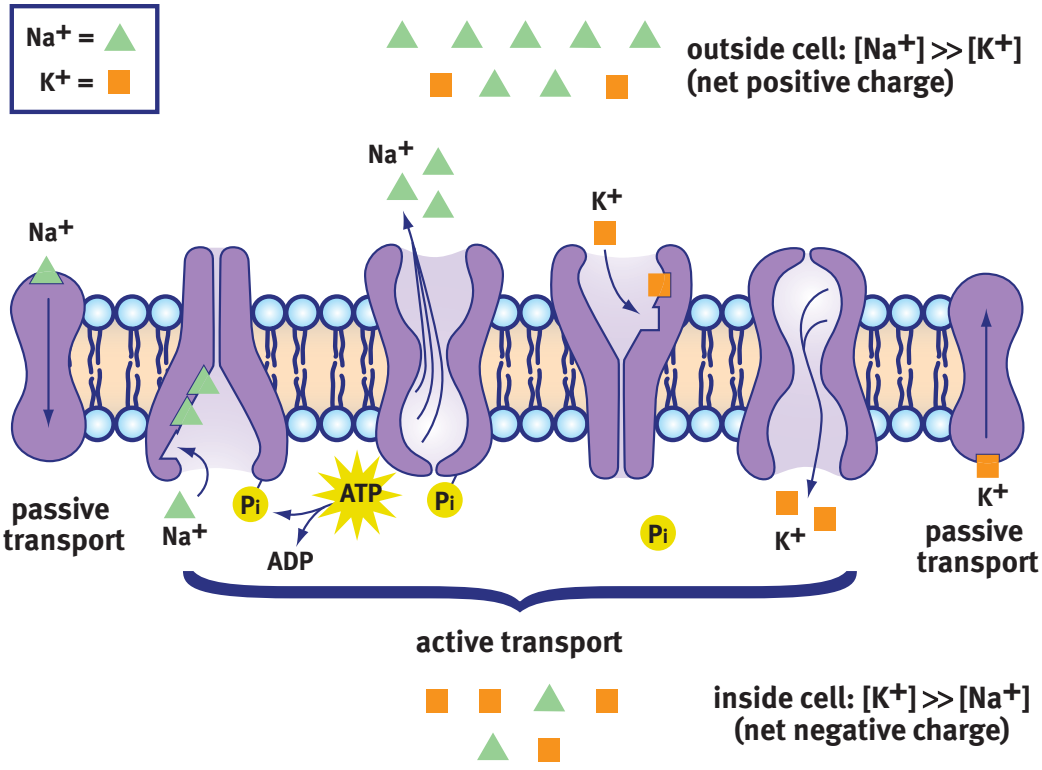

Figure 4.3. Maintenance of Resting Membrane Potential
The Na^+/K^+ ATPase maintains a resting membrane potential of –70 mV by moving 3 Na^+ ions out of the cell for every 2 K^+ ions moved into the cell.

Like any other cell, the neuronal plasma membrane is fairly impermeable to charged species. Because the plasma membrane contains a thick nonpolar barrier (fatty acid tails), it is not energetically favorable for ions to cross this barrier. Inside the neuron, $[K^+]$ is high and $[Na^+]$ is low. Outside of the neuron, $[Na^+]$ is high, whereas $[K^+]$ is low. The negative resting potential is generated by both negatively charged proteins within the cell and the relatively greater permeability of the membrane to K^+ compared with Na^+. If the cell membrane is more permeable to K^+ and the ion's concentration is higher inside, K^+ will diffuse down its gradient out of the cell. What does this mean in terms of charge movement? K^+ is positively charged, so its movement out of the cell results in a cell interior that is negative. Put another way, if we assume that the membrane starts at zero, and we take away a positive charge, we end up with a negative charge inside the cell: $0 - (+1) = -1$. Na^+ cannot readily enter at rest, so the negative potential is maintained.

The Na^+/K^+ ATPase is important for restoring this gradient after action potentials have been fired. It transports three Na^+ out of the cell for every two K^+ into the cell at the expense of one ATP. ATP is necessary because both Na^+ and K^+ are moved against their gradients by this process; thus, this qualifies as primary active transport. Each time the pump works, it results in the inside of the cell becoming relatively more negative, as only two positive charges are moved in for every three that are moved out.

The Axon Hillock

Neurons can receive both excitatory and inhibitory input. Excitatory input causes **depolarization** (raising the membrane potential, V_m, from its resting potential) and thus makes the neuron more likely to fire an action potential. Inhibitory input causes **hyperpolarization** (lowering the membrane potential from its resting potential) and thus makes the neuron less likely to fire an action potential. If the axon hillock receives enough excitatory input to be depolarized to the **threshold** value (usually in the range of –55 to –40 mV), an action potential will be triggered.

This implies that not every stimulus necessarily generates a response. A small excitatory signal may not be sufficient to bring the axon hillock to threshold. Further, a postsynaptic neuron may receive information from several different presynaptic neurons, some of which are excitatory and some of which are inhibitory. The additive effect of multiple signals is known as **summation**.

There are two types of summation: temporal and spatial. In **temporal summation**, multiple signals are integrated during a relatively short period of time. A number of small excitatory signals firing at nearly the same moment could bring a postsynaptic cell to threshold, enabling an action potential. In **spatial summation**,

Bridge

The resting membrane potential is dependent on the intra- and extracellular ion concentrations, relative permeability of the membrane to these different ions, and charges of these ions. The Goldman–Hodgkin–Katz voltage equation brings together these different factors into one equation that predicts the resting membrane potential. This equation is discussed in Chapter 8 of *MCAT Biochemistry Review*.

the additive effects are based on the number and location of the incoming signals. A large number of inhibitory signals firing directly on the soma will cause more profound hyperpolarization of the axon hillock than the depolarization caused by a few excitatory signals firing on the dendrites of a neuron.

Ion Channels and Membrane Potential

A graph of membrane potential *vs*. time during an action potential is shown in Figure 4.4.

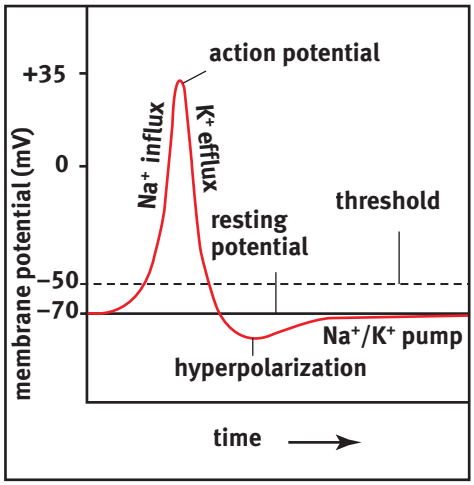

Figure 4.4. Action Potential Generation
Sufficient depolarization across the cell membrane to threshold leads to the generation of an action potential, followed by repolarization and hyperpolarization before returning to the resting membrane potential.

If the cell is brought to threshold, voltage-gated sodium channels open in the membrane. As the name implies, these ion channels open in response to the change in potential of the membrane (depolarization) and permit the passage of sodium ions. There is a strong **electrochemical gradient** that promotes the migration of sodium into the cell. From an electric standpoint, the interior of the cell is more negative than the exterior of the cell, which favors the movement of positively charged sodium cations into the cell. From a chemical standpoint, there is a higher concentration of sodium outside the cell than inside, which also favors the movement of sodium into the cell. As sodium passes through these ion channels, the membrane potential becomes more positive; that is, the cell rapidly depolarizes. Sodium channels not only open in response to changes in membrane potential, but are also inactivated by them. When V_m approaches +35 mV, the sodium channels are **inactivated** and will have to be brought back near the resting potential to be **deinactivated**. Thus, these sodium channels can exist in three states: **closed** (before the cell reaches threshold, and after inactivation has been reversed), **open** (from threshold to approximately +35 mV), and **inactive** (from approximately +35 mV to the resting potential).

Key Concept

Na^+ wants to go into the cell because the cell is more negative inside (electrical gradient) and has a lower concentration of Na^+ inside (chemical gradient).

The positive potential inside the cell not only triggers the voltage-gated sodium channels to inactivate, but also triggers the voltage-gated potassium channels to open. Once sodium has depolarized the cell, there is an electrochemical gradient favoring the efflux of potassium from the neuron. As positively charged potassium cations are driven out of the cell, there will be a restoration of the negative membrane potential called **repolarization**. The efflux of K^+ causes an overshoot of the resting membrane potential, hyperpolarizing the neuron. This hyperpolarization serves an important function: it makes the neuron refractory to further action potentials. There are two types of **refractory periods**. During the **absolute refractory period**, no amount of stimulation can cause another action potential to occur. During the **relative refractory period**, there must be *greater than normal* stimulation to cause an action potential because the membrane is starting from a potential that is more negative than its resting value.

The Na^+/K^+ ATPase acts to restore not only the resting potential, but also the sodium and potassium gradients that have been partially dissipated by the action potential.

Impulse Propagation

So far, we have discussed the movements of ions at one small segment of the axon. For a signal to be conveyed to another neuron, the action potential must travel down the axon and initiate neurotransmitter release. This movement is called **impulse propagation** and is shown in Figure 4.5. As sodium rushes into one segment of the axon, it will cause depolarization in the surrounding regions of the axon. This depolarization will bring subsequent segments of the axon to threshold, opening the sodium channels in those segments. Each of these segments then continues through the rest of the action potential in a wavelike fashion until the action potential reaches the nerve terminal. After the action potential has fired in one segment of axon, that segment becomes momentarily refractory, as described previously. The functional consequence of this is that information can only flow in one direction.

Key Concept

Action potentials rely on both electrical and chemical gradients. The neuron starts at the resting potential, around −70 mV. At the resting potential, potassium is high inside the cell and low outside the cell, while sodium is high outside the cell and low inside the cell. Once the cell reaches threshold, sodium channels open and sodium floods the cell, making it more positive inside (depolarization). Then, sodium channels are inactivated and the potassium channels open. This allows potassium to flow out of the cell, bringing the potential to the negative range (repolarization), and actually overshooting the resting potential (hyperpolarization). The Na^+/K^+ ATPase then works to restore the resting potential.

Real World

A toxin called *tetrodotoxin* (TTX) is found in the pufferfish, a delicacy in Japan. TTX blocks the voltage-gated Na^+ channels, thereby blocking neuronal transmission. This can rapidly cause death because the phrenic nerves innervating the diaphragm can no longer depolarize, leading to paralysis of the muscle and a cessation of breathing. For this reason, chefs who prepare pufferfish must be specially trained and licensed.

Real World

Local anesthetics work by blocking voltage-gated Na^+ channels. These drugs work particularly well on sensory neurons and therefore block the transmission of pain. They favor pain neurons because these neurons have small axonal diameters and little or no myelin, allowing easy access to the sodium channels. Anesthetic concentrations are kept sufficiently low to block pain neurons without significant effects on other sensory modalities or motor function.

Real World

This insulation by myelin is extremely effective. A human spinal cord is about the thickness of a finger. Without this insulation, the cord would have to be almost as wide as a telephone pole to prevent signal loss.

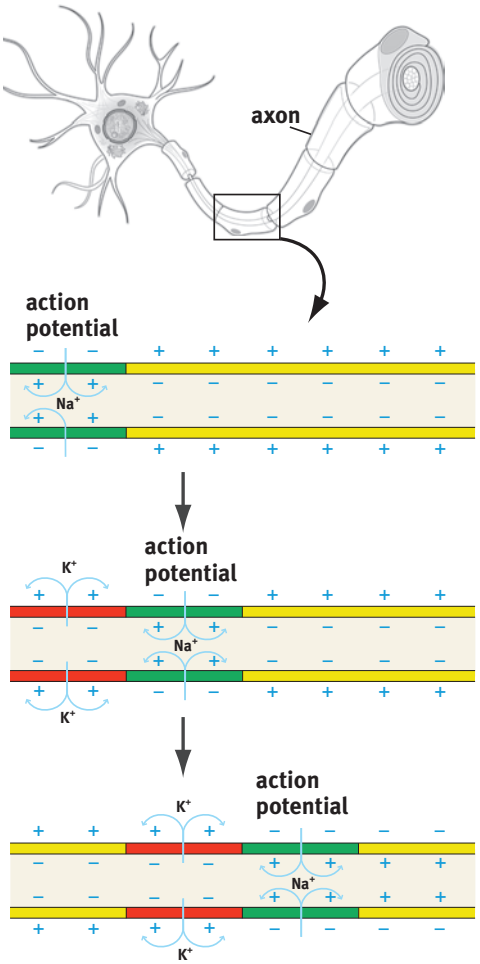

Figure 4.5. Action Potential Propagation
Action potentials are propagated down the axon when proximal sodium channels open and depolarize the membrane, inducing neighboring sodium channels to open as well; because of the refractory character of these channels, the action potential can move in only one direction.

The speed at which action potentials move depends on the length and cross-sectional area of the axon. Increased length of the axon results in higher resistance and slower conduction. Greater cross-sectional areas allow for faster propagation due to decreased resistance. The effect of cross-sectional area is more significant than the effect of length. In order to maximize the speed of transmission, mammals have myelin. Myelin is an extraordinarily good insulator, preventing the dissipation of the electric signal. The insulation is so effective that the membrane is only permeable to ion movement at the nodes of Ranvier. Thus, the signal "hops" from node to node—what is called **saltatory conduction**.

It is important to note that all action potentials within the same type of neuron have the same potential difference during depolarization. Increased intensity of a

stimulus does not result in an increased potential difference of the action potential, but rather an increased frequency of firing.

THE SYNAPSE

As discussed previously, neurons are not actually in direct physical contact. There is a small space between neurons called the synaptic cleft into which neurotransmitters are secreted, as shown in Figure 4.6. To clarify the terminology, the neuron preceding the synaptic cleft is called the **presynaptic neuron**; the neuron after the synaptic cleft is called the **postsynaptic neuron**. If a neuron signals to a gland or muscle, rather than another neuron, the postsynaptic cell is termed an **effector**. Most synapses are **chemical** in nature; they use small molecules referred to as **neurotransmitters** to send messages from one cell to the next.

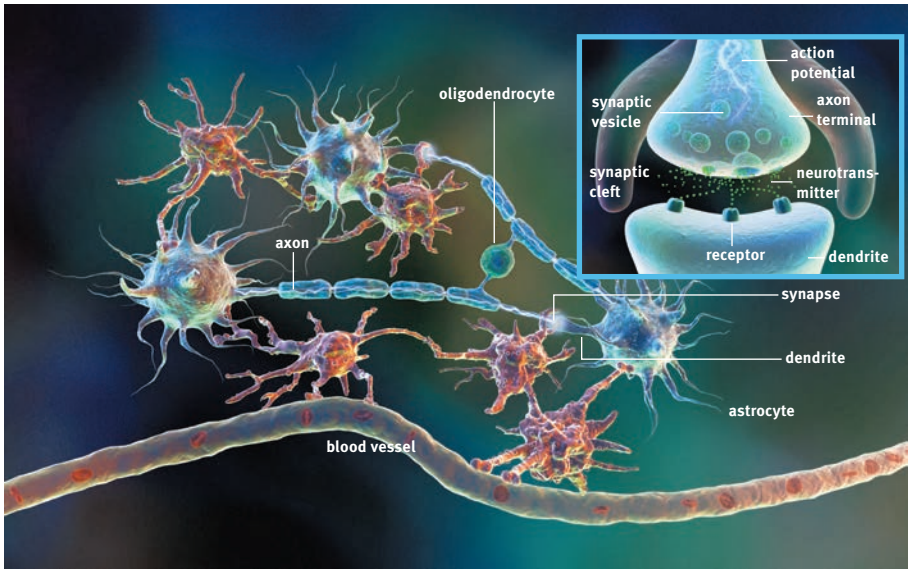

Figure 4.6. The Synapse
Synaptic vesicles are released from the presynaptic neuron and diffuse across the synaptic cleft to activate receptors on the postsynaptic neuron (or gland or muscle).

Neurotransmitters

Prior to release, neurotransmitter molecules are stored in membrane-bound vesicles in the nerve terminal. When the action potential reaches the nerve terminal, voltage-gated calcium channels open, allowing calcium to flow into the cell. This sudden increase in intracellular calcium triggers fusion of the membrane-bound vesicles with the cell membrane at the synapse, causing exocytosis of the neurotransmitter.

Once released into the synapse, the neurotransmitter molecules diffuse across the cleft and bind to receptors on the postsynaptic membrane. This allows the message to be passed from one neuron to the next. As we stated earlier, neurons

Key Concept

It is critical to understand the difference between electrical and chemical transmission. Within a neuron, electricity is used to pass signals down the length of the axon. Between neurons, chemicals (neurotransmitters) are used to pass signals to the subsequent neuron (or gland or muscle).

may be either excitatory or inhibitory; this distinction truly comes at the level of the neurotransmitter receptors, which tend to be either ligand-gated ion channels or G protein-coupled receptors. If the receptor is a ligand-gated ion channel, the postsynaptic cell will either be depolarized or hyperpolarized. If it is a G protein-coupled receptor, it will cause either changes in the levels of cyclic AMP (cAMP) or an influx of calcium. Note that the physiology of receptors is further discussed in Chapter 3 of *MCAT Biochemistry Review*.

Neurotransmission must be regulated—there are almost no circumstances under which constant signaling to the postsynaptic cell would be desirable. Therefore, the neurotransmitter must be removed from the synaptic cleft. There are three main mechanisms to accomplish this goal. First, neurotransmitters can be broken down by enzymatic reactions. The breakdown of **acetylcholine** (**ACh**) by *acetylcholinesterase* (AChE), shown in Figure 4.7, is a classic example.

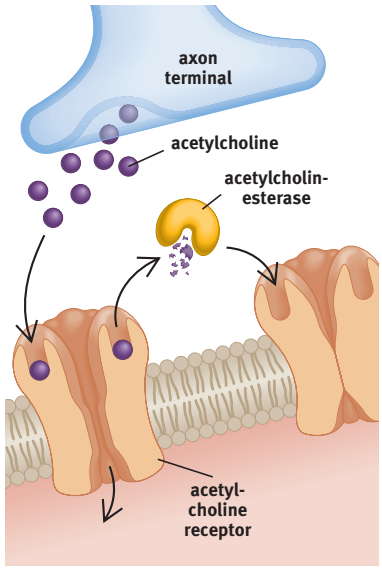

Figure 4.7. Breakdown of a Neurotransmitter by an Enzyme
Acetylcholine (ACh) can be broken down by acetylcholinesterase (AChE).

Second, neurotransmitters can be brought back into the presynaptic neuron using **reuptake carriers**. The reuptake of **serotonin** (**5-HT**), shown in Figure 4.8, is a classic example of this mechanism. **Dopamine** (**DA**) and **norepinephrine** (**NE**) also use reuptake carriers.

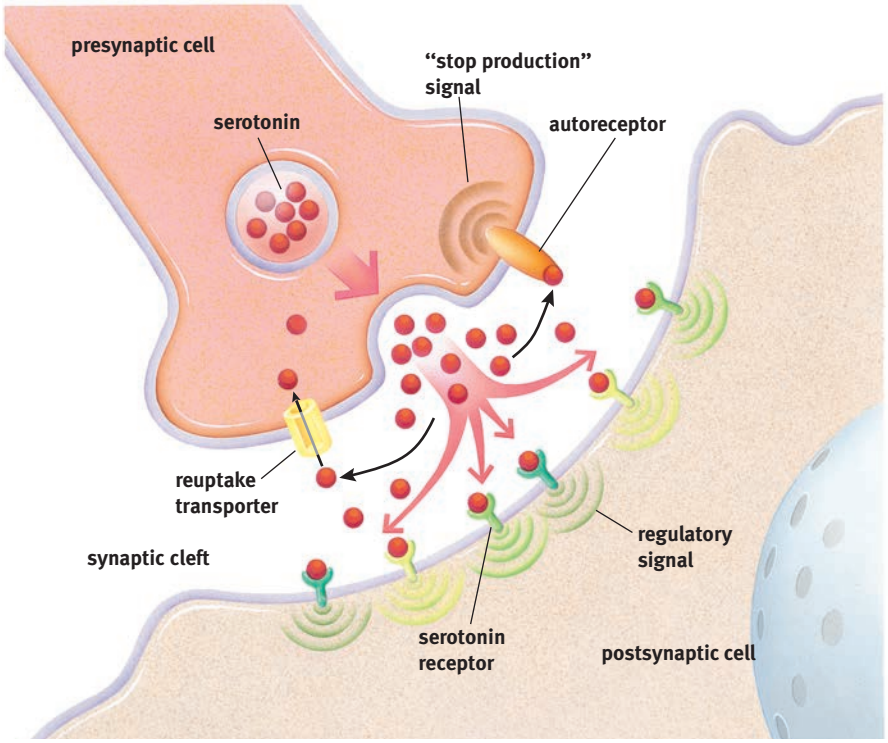

Figure 4.8. Reuptake of a Neurotransmitter
Serotonin (5-HT) can be taken back up by the presynaptic cell; an autoreceptor will signal the presynaptic cell to stop releasing serotonin and start the reuptake process.

Third, neurotransmitters may simply diffuse out of the synaptic cleft. **Nitric oxide** (**NO**), a gaseous signaling molecule, fits into this category.

MCAT Concept Check 4.2:
Before you move on, assess your understanding of the material with these questions.

1. What neural structure initiates the action potential?

_____

2. What entity maintains the resting membrane potential? What is the approximate voltage of the resting membrane potential?

_____

3. What is the difference between temporal and spatial summation?
   - Temporal summation:

_____

Real World

Many common drugs (either in clinical use or street drugs) modify processes that occur in the synapse. For instance, cocaine acts by blocking neuronal reuptake carriers, thus prolonging the action of neurotransmitters in the synapse. There are clinically useful drugs (some of which are used to treat Alzheimer's disease, glaucoma, and myasthenia gravis) that inhibit acetylcholinesterase, thereby elevating synaptic levels of acetylcholine. Nerve gases, which have been used in warfare and terrorism, are extremely potent acetylcholinesterase inhibitors. Nerve gas causes rapid death by preventing the relaxation of skeletal muscle (most importantly, the diaphragm), leading to respiratory arrest.

- Spatial summation:

_____

4. During the action potential, which ion channel opens first? How is this ion channel regulated? What effect does the opening of this channel have on the polarization of the cell?
   - Ion channel:

   _____

   - Regulation:

   _____

   - Effect on polarization:

   _____

5. During the action potential, which ion channel opens second? How is this ion channel regulated? What effect does the opening of this channel have on the polarization of the cell?
   - Ion channel:

   _____

   - Regulation:

   _____

   - Effect on polarization:

   _____

6. What is the difference between the absolute and relative refractory period?
   - Absolute refractory period:

   _____

   - Relative refractory period:

   _____

7. What ion is primarily responsible for the fusion of neurotransmitter-containing vesicles with the nerve terminal membrane?

_____

8. What are the three main methods by which a neurotransmitter's action can be stopped?
   - _____
   - _____
   - _____

4.3 Organization of the Human Nervous System

The nervous system is a remarkable collection of cells that governs both involuntary and voluntary behavior, while also maintaining **homeostasis**. Functions of the nervous system include:

- Sensation and perception
- Motor function
- Cognition (thinking) and problem-solving
- Executive function and planning
- Language comprehension and creation
- Memory
- Emotion and emotional expression
- Balance and coordination
- Regulation of endocrine organs
- Regulation of heart rate, breathing rate, vascular resistance, temperature, and exocrine glands

The human nervous system is a complex web of over 100 billion cells that communicate, coordinate, and regulate signals for the rest of the body. Mental and physical action occurs when the body can react to external stimuli using the nervous system. In this section, we will look at the nervous system and its basic organization.

Note: Much of the information contained in this section is also discussed in Chapter 1 of MCAT Behavioral Sciences Review.

CENTRAL AND PERIPHERAL NERVOUS SYSTEMS

Generally speaking, there are three kinds of nerve cells in the nervous system: sensory neurons, motor neurons, and interneurons. **Sensory neurons** (also known as **afferent neurons**) transmit sensory information from receptors to the spinal cord and brain. **Motor neurons** (also known as **efferent neurons**) transmit motor information from the brain and spinal cord to muscles and glands. **Interneurons** are found between other neurons and are the most numerous of the three types. Interneurons are located predominantly in the brain and spinal cord and are often linked to reflexive behavior.

Mnemonic

Afferent neurons **a**scend in the spinal cord toward the brain; **e**fferent neurons **e**xit the spinal cord on their way to the rest of the body.

Different types of information require different types of processing. Processing of stimuli and response generation may happen at the level of the spinal cord, or may require input from the brainstem or cerebral cortex. Reflexes, discussed later in this section, only require processing at the level of the spinal cord. For example, when a reflex hammer hits the patellar tendon, the sensory information goes to the spinal cord, where a motor signal is sent to the quadriceps muscles, causing the leg to jerk forward at the knee. No input from the brain is required. However, some scenarios require input from the brain or brainstem. When this happens, **supraspinal** circuits are used.

Let's turn to the overall structure of the human nervous system, which is diagrammed in Figure 4.9.

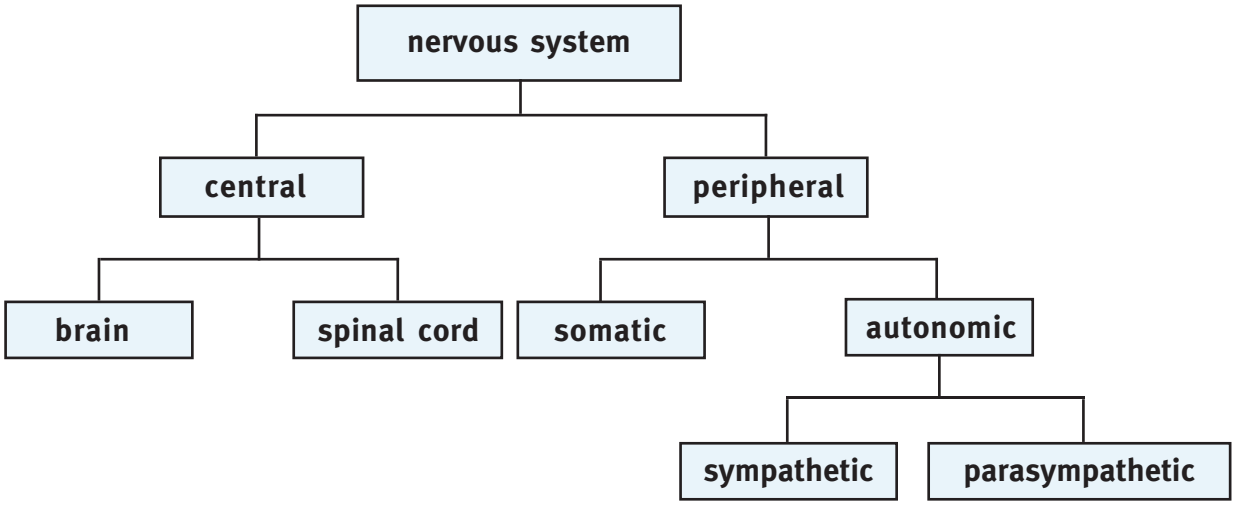

Figure 4.9. Major Divisions of the Nervous System

The nervous system can be broadly divided into two primary components: the central and peripheral nervous systems. The **central nervous system** (**CNS**) is composed of the brain and spinal cord. The brain consists of white matter and grey matter. The **white matter** consists of axons encased in myelin sheaths. The **grey matter** consists of unmyelinated cell bodies and dendrites. In the brain, the white matter lies deeper than the grey matter. At the base of the brain is the brainstem, which is largely responsible for basic life functions such as breathing. Note that the lobes of the brain and major brain structures are discussed in Chapter 1 of *MCAT Behavioral Sciences Review*.

The spinal cord extends downward from the brainstem and can be divided into four divisions: **cervical**, **thoracic**, **lumbar**, and **sacral**. Almost all of the structures below the neck receive sensory and motor innervation from the spinal cord. The spinal

cord is protected by the **vertebral column**, which transmits nerves at the space between adjacent vertebrae. Like the brain, the spinal cord also consists of white and grey matter. The white matter lies on the outside of the cord, and the grey matter is deep within it. The axons of motor and sensory neurons are in the spinal cord. The sensory neurons bring information in from the periphery and enter on the dorsal (back) side of the spinal cord. The cell bodies of these sensory neurons are found in the **dorsal root ganglia**. Motor neurons exit the spinal cord ventrally, or on the side closest to the front of the body. The structure of the spinal cord can be seen in Figure 4.10.

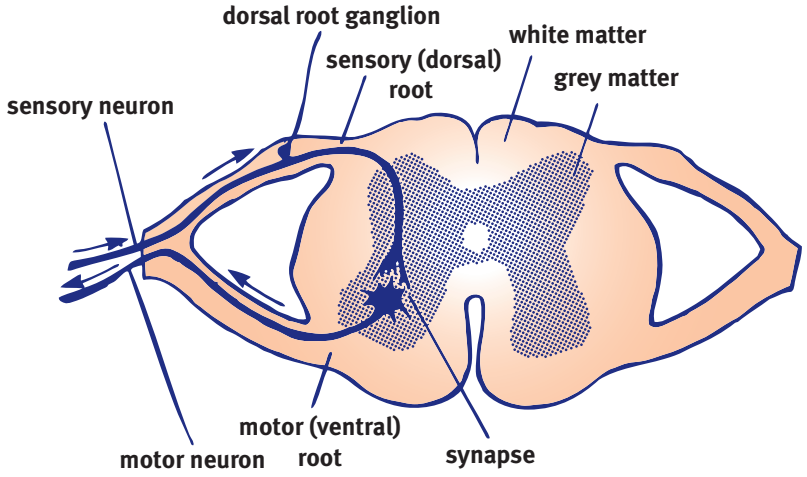

Figure 4.10. The Spinal Cord
Sensory neurons transmit information about pain, temperature, and vibration up to the brain and have cell bodies in the dorsal root ganglia toward the back of the spinal cord; the motor neurons run from the brain along the opposite side of the spinal cord and in the ventral root to control movements of skeletal muscle and glandular secretions.

The **peripheral nervous system** (**PNS**), in contrast, is made up of nerve tissue and fibers outside the brain and spinal cord, including all 31 pairs of spinal nerves and 10 of the 12 pairs of cranial nerves (the olfactory and optic nerves are technically outgrowths of the central nervous system). The PNS thus connects the CNS to the rest of the body and can itself be subdivided into the somatic and autonomic nervous systems.

The **somatic nervous system** consists of sensory and motor neurons distributed throughout the skin, joints, and muscles. Sensory neurons transmit information through afferent fibers. Motor impulses, in contrast, travel along efferent fibers.

The **autonomic nervous system** (**ANS**) generally regulates heartbeat, respiration, digestion, and glandular secretions. In other words, the ANS manages the involuntary muscles associated with many internal organs and glands. The ANS also

helps regulate body temperature by activating sweating or piloerection, depending on whether we are too hot or too cold. The main thing to understand about these functions is that they are automatic, or independent of conscious control. Note the similarity between the words autonomic and automatic. This association makes it easy to remember that the autonomic nervous system manages automatic functions such as heartbeat, respiration, digestion, and temperature control.

One primary difference between the somatic and autonomic nervous systems is that the peripheral component of the autonomic nervous system contains two neurons. A motor neuron in the somatic nervous system goes directly from the spinal cord to the muscle without synapsing. In the autonomic nervous system, two neurons work in series to transmit messages from the spinal cord. The first neuron is known as the **preganglionic neuron**, whereas the second is the **postganglionic neuron**. The soma of the preganglionic neuron is in the CNS, and its axon travels to a ganglion in the PNS. Here it synapses on the cell body of the postganglionic neuron, which then affects the target tissue.

Key Concept

The first neuron in the autonomic nervous system is called the preganglionic neuron. The second neuron is the postganglionic neuron.

THE AUTONOMIC NERVOUS SYSTEM

The ANS has two subdivisions: the sympathetic nervous system and the parasympathetic nervous system. These two branches often act in opposition to one another, meaning that they are antagonistic. For example, the sympathetic nervous system acts to accelerate heart rate and inhibit digestion, while the parasympathetic nervous system, in contrast, decelerates heart rate and increases digestion.

The main role of the **parasympathetic nervous system** is to conserve energy. It is associated with resting and sleeping states and acts to reduce heart rate and constrict the bronchi. The parasympathetic nervous system is also responsible for managing digestion by increasing peristalsis and exocrine secretions. Acetylcholine is the neurotransmitter responsible for parasympathetic responses in the body and is released by both preganglionic and postganglionic neurons. The vagus nerve (cranial nerve X), is responsible for much of the parasympathetic innervation of the thoracic and abdominal cavity. The functions of the parasympathetic nervous system are summarized in Figure 4.11.

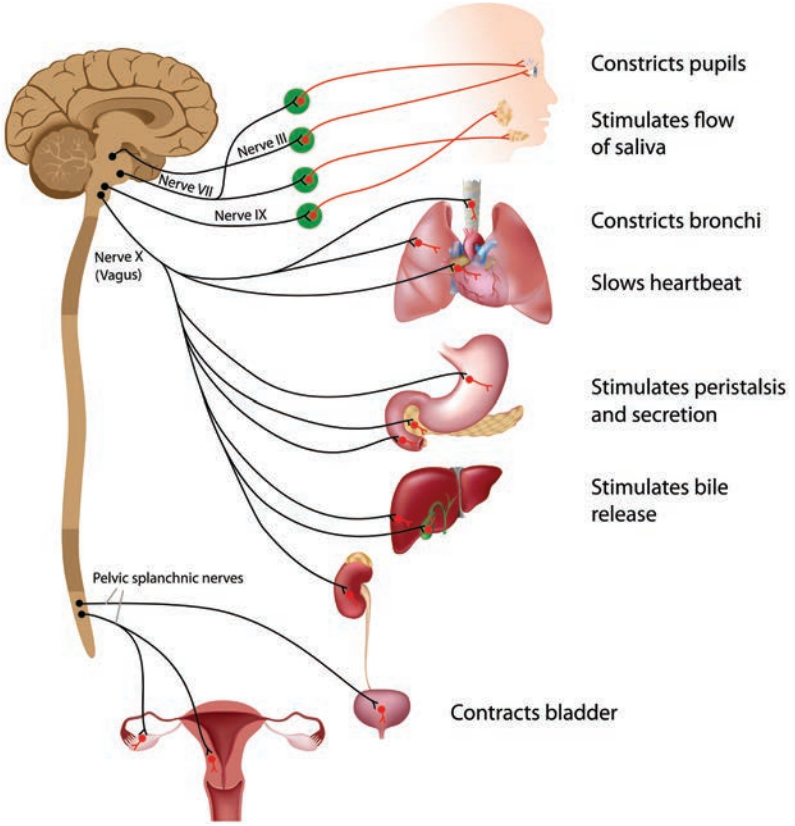

Figure 4.11. Functions of the Parasympathetic Nervous System

In contrast, the **sympathetic nervous system** is activated by stress. This can include everything from a mild stressor, such as keeping up with schoolwork, to emergencies that mean the difference between life and death. The sympathetic nervous system is closely associated with rage and fear reactions, also known as "fight-or-flight" reactions. When activated, the sympathetic nervous system:

- Increases heart rate
- Redistributes blood to muscles of locomotion
- Increases blood glucose concentration
- Relaxes the bronchi
- Decreases digestion and peristalsis
- Dilates the eyes to maximize light intake
- Releases epinephrine into the bloodstream

The functions of the sympathetic nervous system are summarized in Figure 4.12. In the sympathetic nervous system, preganglionic neurons release acetylcholine, while most postganglionic neurons release norepinephrine.

Mnemonic

Sympathetic and parasympathetic nervous systems:

- Sympathetic: **"fight**-or-**flight"**
- Parasympathetic: **"rest**-and-**digest"**

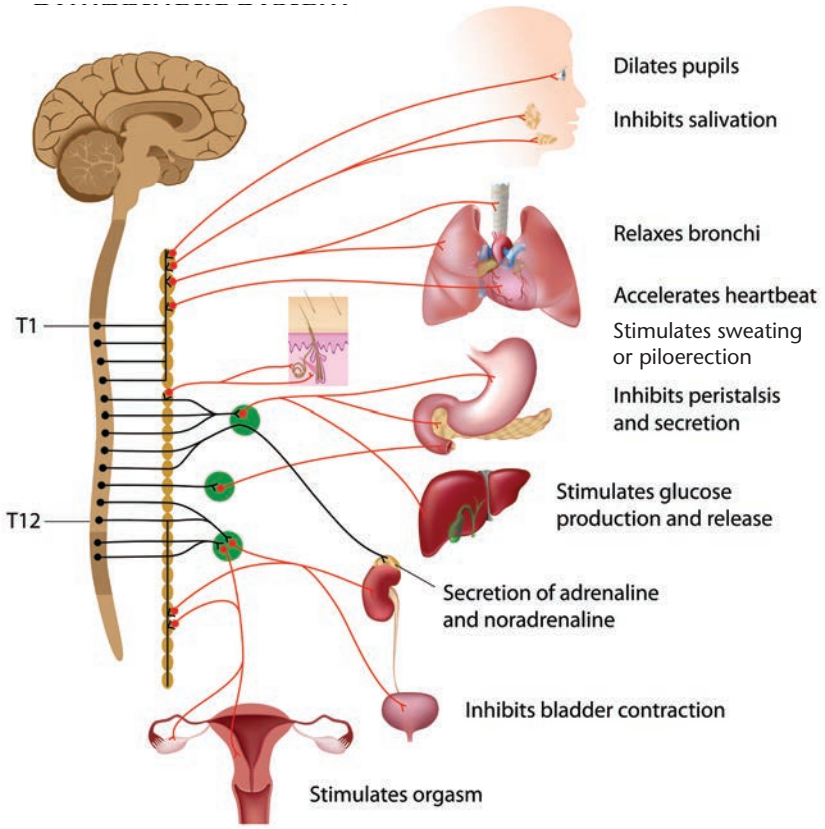

Figure 4.12. Functions of the Sympathetic Nervous System

REFLEXES

Key Concept

Consider the purpose of reflexes. Although it may be amusing to make your friends' legs jump when you tap them, there is a more functional reason why this response occurs. The stretch on the patellar tendon makes the body think that the muscle may be getting overstretched. In response, the muscle contracts in order to prevent injury.

Neural circuits called **reflex arcs** control reflexive behavior. For example, consider what occurs when someone steps on a nail. Receptors in the foot detect pain, and the pain signal is transmitted by sensory neurons up to the spinal cord. At that point, the sensory neurons connect with interneurons, which can then relay pain impulses up to the brain. Rather than wait for the brain to send out a signal, interneurons in the spinal cord can also send signals to the muscles of both legs directly, causing the individual to withdraw the foot with pain while supporting with the other foot. The original sensory information still makes its way up to the brain; however, by the time it arrives there, the muscles have already responded to the pain, thanks to the reflex arc. There are two types of reflex arcs: monosynaptic and polysynaptic.

Monosynaptic

In a **monosynaptic reflex arc**, there is a single synapse between the sensory neuron that receives the stimulus and the motor neuron that responds to it. A classic example is the **knee-jerk reflex**, shown in Figure 4.13. When the patellar tendon is stretched, information travels up the sensory (afferent, presynaptic) neuron to

the spinal cord, where it interfaces with the motor (efferent, postsynaptic) neuron that contracts the quadriceps muscles. The net result is extension of the leg, which lessens the tension on the patellar tendon. Note that the reflex is simply a feedback loop and a response to potential injury. If the patellar tendon or quadriceps muscles are stretched too far, they may tear, damaging the knee joint. Thus, the reflex serves to protect the muscles.

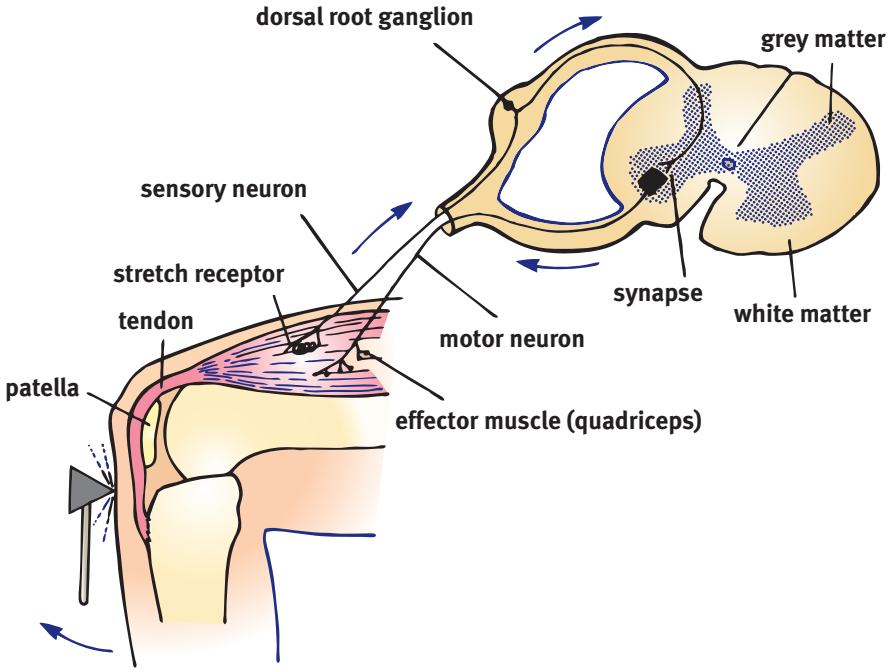

Figure 4.13. The Knee-Jerk Reflex
The knee-jerk or knee extension reflex may be elicited by swiftly stretching the patellar tendon with a reflex hammer.

Polysynaptic

In a **polysynaptic reflex arc**, there is at least one interneuron between the sensory and motor neurons. A real-life example is the reaction to stepping on a nail described earlier, which involves the **withdrawal reflex**. The extremity with which one steps on the nail will be stimulated to flex, using the hip muscles and hamstring muscles, pulling the foot away from the nail. This is a monosynaptic reflex, similar to the knee-jerk reflex described previously. However, if the person is to maintain balance, the other foot must be planted firmly on the ground. For this to occur, the motor neuron that controls the quadriceps muscles in the opposite limb must be stimulated, extending it. Interneurons in the spinal cord provide the connections from the incoming sensory information to the motor neurons in the supporting limb.

MCAT Concept Check 4.3:

Before you move on, assess your understanding of the material with these questions.

1. What parts of the nervous system are in the central nervous system (CNS)? Peripheral nervous system (PNS)?
   - CNS:

     _____

   - PNS:

     _____

2. What do afferent neurons do? Efferent neurons?
   - Afferent:

     _____

   - Efferent:

     _____

3. What functions are accomplished by the somatic nervous system? The autonomic nervous system?
   - Somatic:

     _____

   - Autonomic:

     _____

4. What are the effects of the sympathetic nervous system? The parasympathetic nervous system?
   - Sympathetic:

     _____

   - Parasympathetic:

     _____

5. What is the pathway of neural impulses in a monosynaptic reflex? In a polysynaptic reflex?
   - Monosynaptic reflex:

     _____

   - Polysynaptic reflex:

     _____

Conclusion

The nervous system is one of the most fascinating and complex of the human body; millions upon millions of cells allow for our appropriate interactions in the everyday world. It is the seat of personality and, ultimately, the system that makes you *you*. In medical school, your courses on neuroscience will go into astounding detail about the nervous system, including the circuits that govern sensations such as pain and temperature, and circuits that allow your body to move and function.

In this chapter, we explored the nervous system at both a cellular and organizational level. Neurons are the primary cells of the nervous system, propagating impulses through both electrical and chemical means—action potentials and synaptic transmission, respectively. Neurons can be grouped together to form nerves, which are the primary organizational structures in one major branch of the nervous system, the peripheral nervous system. This is in contrast to the central nervous system, which consists of the brain and spinal cord. The peripheral nervous system can be subdivided into the somatic and autonomic nervous systems, the latter of which can be further subdivided into the sympathetic and parasympathetic nervous systems.

The nervous system is heavily tested on the MCAT because it plays a role in the function of almost every other major organ system. Neurons cause muscles to move and digestive structures to carry food along through peristalsis, and they regulate breathing rate, heart rate, and glandular secretions. The nervous system is not the only system that has such a profound effect throughout the body, however. The endocrine system, which we will explore in the next chapter, serves a similar role—but through chemical messengers carried in the blood called hormones.

CONCEPT SUMMARY

Cells of the Nervous System

- **Neurons** are highly specialized cells responsible for the conduction of impulses.
- Neurons communicate using both electrical and chemical forms of communication.
  - Electrical communication occurs via ion exchange and the generation of membrane potentials down the length of the axon.
  - Chemical communication occurs via neurotransmitter release from the presynaptic cell and the binding of these neurotransmitters to the postsynaptic cell.
- Neurons consist of many different parts.
  - **Dendrites** are appendages that receive signals from other cells.
  - The cell body or **soma** is the location of the nucleus as well as organelles such as the endoplasmic reticulum and ribosomes.
  - The **axon hillock** is where the cell body transitions to the axon, and where action potentials are initiated.
  - The **axon** is a long appendage down which an action potential travels.
  - The **nerve terminal** or **synaptic bouton** is the end of the axon from which neurotransmitters are released.
  - **Nodes of Ranvier** are exposed areas of myelinated axons that permit saltatory conduction.
  - The **synapse** consists of the nerve terminal of the presynaptic neuron, the membrane of the postsynaptic cell, and the space between the two, called the **synaptic cleft**.
- Many axons are coated in **myelin**, an insulating substance that prevents signal loss.
  - Myelin is created by **oligodendrocytes** in the central nervous system and **Schwann cells** in the peripheral nervous system.
  - Myelin prevents dissipation of the neural impulse and crossing of neural impulses from adjacent neurons.
- Individual axons are bundled into **nerves** or **tracts**.
  - A single nerve may carry multiple types of information, including sensory, motor, or both. Tracts contain only one type of information.
  - Cell bodies of neurons of the same type within a nerve cluster in **ganglia** in the peripheral nervous system.
  - Cell bodies of the individual neurons within a tract cluster in **nuclei** in the central nervous system.

- **Neuroglia** or **glial cells** are other cells within the nervous system in addition to neurons.
  - **Astrocytes** nourish neurons and form the blood–brain barrier, which controls the transmission of solutes from the bloodstream into nervous tissue.
  - **Ependymal cells** line the ventricles of the brain and produce cerebrospinal fluid, which physically supports the brain and serves as a shock absorber.
  - **Microglia** are phagocytic cells that ingest and break down waste products and pathogens in the central nervous system.
  - Oligodendrocytes (CNS) and Schwann cells (PNS) produce myelin around axons.

Transmission of Neural Impulses

- All neurons exhibit a **resting membrane potential** of approximately –70 mV.
  - Resting potential is maintained using selective permeability of ions as well as the Na^+/K^+ ATPase.
  - The **Na^+/K^+ ATPase** pumps three sodium ions out of the cell for every two potassium ions pumped in.
- Incoming signals can be either excitatory or inhibitory.
  - Excitatory signals cause depolarization of the neuron.
  - Inhibitory signals cause hyperpolarization of the neuron.
  - **Temporal summation** refers to the addition of multiple signals near each other in time.
  - **Spatial summation** refers to the addition of multiple signals near each other in space.
- An **action potential** is used to propagate signals down the axon.
  - When enough excitatory stimulation occurs, the cell is **depolarized** to the **threshold voltage** and voltage-gated sodium channels open.
  - Sodium flows into the neuron due to its strong **electrochemical gradient**. This continues depolarizing the neuron.
  - At the peak of the action potential (approximately +35 mV), sodium channels are inactivated and potassium channels open.
  - Potassium flows out of the neuron due to its strong electrochemical gradient, **repolarizing** the cell. Potassium channels stay open long enough to overshoot the action potential, resulting in a **hyperpolarized** neuron; then, the potassium channels close.
  - The Na^+/K^+ ATPase brings the neuron back to the resting potential and restores the sodium and potassium gradients.

- While the axon is hyperpolarized, it is in its **refractory period**. During the **absolute refractory period**, the cell is unable to fire another action potential. During the **relative refractory period**, the cell requires a larger than normal stimulus to fire an action potential.
- The impulse propagates down the length of the axon because the influx of sodium in one segment of the axon brings the subsequent segment of the axon to threshold. The fact that the preceding segment of the axon is in its refractory period means that the action potential can only travel in one direction.

- At the nerve terminal, neurotransmitters are released into the synapse.
  - When the action potential arrives at the nerve terminal, voltage-gated calcium channels open.
  - The influx of calcium causes fusion of vesicles filled with neurotransmitter with the presynaptic membrane, resulting in exocytosis of neurotransmitter into the synaptic cleft.
  - The neurotransmitters bind to receptors on the postsynaptic cell, which may be ligand-gated ion channels or G protein-coupled receptors.
- Neurotransmitters must be cleared from the postsynaptic receptors to stop the propagation of the signal.
  - The neurotransmitter can be enzymatically broken down.
  - The neurotransmitter can be absorbed back into the presynaptic cell by **reuptake channels**.
  - The neurotransmitter can diffuse out of the synaptic cleft.

Organization of the Human Nervous System

- There are three types of neurons in the nervous system: **motor** (**efferent**) neurons, **interneurons**, and **sensory** (**afferent**) neurons.
- The nervous system is made up of the **central nervous system** (**CNS**; brain and spinal cord) and **peripheral nervous system** (**PNS**; cranial and spinal nerves).
  - In the CNS, **white matter** consists of myelinated axons, and **grey matter** consists of unmyelinated cell bodies and dendrites. In the brain, white matter is deeper than grey matter. In the spinal cord, grey matter is deeper than white matter.
  - The PNS is divided into the **somatic** (voluntary) and **autonomic** (automatic) nervous systems.
  - The autonomic nervous system is further divided into the **parasympathetic** (rest-and-digest) and **sympathetic** (fight-or-flight) branches.

- **Reflex arcs** use the ability of interneurons in the spinal cord to relay information to the source of a stimulus while simultaneously routing it to the brain.
  - In a **monosynaptic reflex arc**, the sensory (afferent, presynaptic) neuron fires directly onto the motor (efferent, postsynaptic) neuron.
  - In a **polysynaptic reflex arc**, the sensory neuron may fire onto a motor neuron as well as interneurons that fire onto other motor neurons.

ANSWERS TO CONCEPT CHECKS

4.1

1. The axon transmits an electrical signal (the action potential) from the soma to the synaptic knob. The axon hillock integrates excitatory and inhibitory signals from the dendrites and fires an action potential if the excitatory signals are strong enough to reach threshold. Dendrites receive incoming signals and carry them to the soma. The myelin sheath acts as insulation around the axon and speeds conduction. The soma is the cell body and contains the nucleus, endoplasmic reticulum, and ribosomes. The synaptic bouton lies at the end of the axon and releases neurotransmitters.
2. A collection of cell bodies in the central nervous system is called a nucleus. In the peripheral nervous system, it is called a ganglion.
3. Astrocytes nourish neurons and form the blood–brain barrier. Ependymal cells produce cerebrospinal fluid. Microglia ingest and break down waste products and pathogens. Oligodendrocytes produce myelin in the central nervous system. Schwann cells produce myelin in the peripheral nervous system.

4.2

1. The action potential is initiated at the axon hillock.
2. The resting membrane potential is maintained by the Na^+/K^+ ATPase at approximately –70 mV.
3. Temporal summation is the integration of multiple signals close to each other in time. Spatial summation is the integration of multiple signals close to each other in space.
4. The sodium channel opens first at threshold (around –50 mV). It is regulated by inactivation, which occurs around +35 mV. Inactivation can only be reversed by repolarizing the cell. The opening of the sodium channel causes depolarization.
5. The potassium channel opens second at approximately +35 mV. It is regulated by closing at low potentials (slightly below –70 mV). The opening of the potassium channel causes repolarization and—eventually—hyperpolarization.
6. During the absolute refractory period, the cell is unable to fire an action potential regardless of the intensity of a stimulus. During the relative refractory period, the cell can fire an action potential only with a stimulus that is stronger than normal.
7. Calcium is responsible for fusion of neurotransmitter vesicles with the nerve terminal membrane.
8. A neurotransmitter's action can be stopped by enzymatic degradation, reuptake, or diffusion.

4.3

1. The central nervous system includes the brain and spinal cord. The peripheral nervous system includes cranial and spinal nerves and sensors.
2. Afferent (sensory) neurons bring signals from a sensor to the central nervous system. Efferent (motor) neurons bring signals from the central nervous system to an effector.
3. The somatic nervous system is responsible for voluntary actions—most notably, moving muscles. The autonomic nervous system is responsible for involuntary actions, like heart rate, bronchial dilation, dilation of the pupils, exocrine gland function, and peristalsis.
4. The sympathetic nervous system promotes a "fight-or-flight" response, with increased heart rate and bronchial dilation, redistribution of blood to locomotor muscles, dilation of the pupils, and slowing of digestive and urinary function. The parasympathetic nervous system promotes "rest-and-digest" functions, slowing heart rate and constricting the bronchi, redistributing blood to the gut, promoting exocrine secretions, constricting the pupils, and promoting peristalsis and urinary function.
5. In a monosynaptic reflex, a sensory (afferent, presynaptic) neuron fires directly onto a motor (efferent, postsynaptic) neuron. In a polysynaptic reflex, a sensory neuron may fire directly onto a motor neuron, but interneurons are used as well. These interneurons fire onto other motor neurons.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Resting membrane potential depends on:

I. differential distribution of ions across the axon membrane.

II. the opening of voltage-gated calcium channels.

III. active transport of ions across the membrane.

A. I only
B. I and II only
C. I and III only
D. II and III only

2. All of the following are associated with the myelin sheath EXCEPT:

A. faster conduction of nerve impulses.
B. nodes of Ranvier forming gaps along the axon.
C. increased magnitude of the potential difference during an action potential.
D. saltatory conduction of action potentials.

3. Which of the following is true with regard to the action potential?

A. All hyperpolarized stimuli will be carried to the axon terminal without a decrease in size.
B. The size of the action potential is proportional to the size of the stimulus that produced it.
C. Increasing the intensity of the depolarization increases the size of the impulse.
D. Once an action potential is triggered, an impulse of a given magnitude and speed is produced.

4. Which of the following correctly describes a difference between nerves and tracts?

A. Nerves are seen in the central nervous system; tracts are seen in the peripheral nervous system.
B. Nerves have cell bodies in nuclei; tracts have cell bodies in ganglia.
C. Nerves may carry more than one type of information; tracts can only carry one type of information.
D. Nerves contain only one neuron; tracts contain many neurons.

5. Which of the following accurately describes sensory neurons?

A. Sensory neurons are afferent and enter the spinal cord on the dorsal side.
B. Sensory neurons are efferent and enter the spinal cord on the dorsal side.
C. Sensory neurons are afferent and enter the spinal cord on the ventral side.
D. Sensory neurons are efferent and enter the spinal cord on the ventral side.

6. When a sensory neuron receives a stimulus that brings it to threshold, it will do all of the following EXCEPT:

A. become depolarized.
B. transduce the stimulus to an action potential.
C. inhibit the spread of the action potential to other sensory neurons.
D. cause the release of neurotransmitters onto cells in the central nervous system.

7. When the potential across the axon membrane is more negative than the normal resting potential, the neuron is said to be in a state of:

A. depolarization.
B. hyperpolarization.
C. repolarization.
D. polarization.

8. Which of the following statements concerning the somatic division of the peripheral nervous system is INCORRECT?

A. Its pathways innervate skeletal muscle.
B. Its pathways are usually voluntary.
C. Some of its pathways are referred to as reflex arcs.
D. Its pathways always involve more than two neurons.

9. Which of the following is a function of the parasympathetic nervous system?

A. Increasing blood sugar during periods of stress
B. Dilating the pupils to enhance vision
C. Increasing oxygen delivery to muscles
D. Decreasing heart rate and blood pressure

10. Which of the following neurotransmitters is used in the ganglia of both the sympathetic and parasympathetic nervous systems?

A. Acetylcholine
B. Dopamine
C. Norepinephrine
D. Serotonin

11. In which neural structure are ribosomes primarily located?

A. Dendrites
B. Soma
C. Axon hillock
D. Axon

12. An autoimmune disease attacks the voltage-gated calcium channels in the nerve terminal. What is a likely symptom of this condition?

A. Spastic paralysis (inability to relax the muscles)
B. Flaccid paralysis (inability to contract the muscles)
C. Inability to reuptake neurotransmitters once released
D. Retrograde flow of action potentials

13. A neuron only fires an action potential if multiple presynaptic cells release neurotransmitter onto the dendrites of the neuron. This is an example of:

A. saltatory conduction.
B. summation.
C. a feedback loop.
D. inhibitory transmission.

14. A disease results in the death of Schwann cells. Which portion of the nervous system is NOT likely to be affected?

A. Central nervous system
B. Somatic nervous system
C. Autonomic nervous system
D. Parasympathetic nervous system

15. A surgeon accidentally clips a dorsal root ganglion during a spinal surgery. What is a likely consequence of this error?

I. Loss of motor function at that level
II. Loss of sensation at that level
III. Loss of cognitive function

A. I only
B. II only
C. I and II only
D. I, II, and III

Explanations to Discrete Practice Questions

1. C

The polarization of the neuron at rest is the result of an uneven distribution of ions between the inside and outside of the cell. This difference is achieved through the active pumping of ions into and out of the neuron (using the Na^+/K^+ ATPase). Voltage-gated calcium channels are important in the nerve terminal, where the influx of calcium triggers the fusion of vesicles containing neurotransmitter with the membrane, but not in maintaining resting membrane potential.

2. C

Myelin is a white lipid-containing material surrounding the axons of many neurons in the central and peripheral nervous systems. It is arranged on the axon discontinuously; the gaps between the segments of myelin are called nodes of Ranvier, eliminating **choice (B)**. Myelin increases the conduction velocity by insulating segments of the axon so that the membrane is permeable to ions only at the nodes of Ranvier, eliminating **choice (A)**. The action potential jumps from node to node, a process known as saltatory conduction, eliminating **choice (D)**. Action potentials are often described as being "all-or-nothing"; the magnitude of the potential difference in an action potential is constant, regardless of the intensity of the stimulus. Thus, myelin does not affect the magnitude of the potential difference in an action potential, making **choice (C)** the correct answer.

3. D

As in the previous question, the action potential is often described as an all-or-nothing response. This means that, whenever the threshold membrane potential is reached, an action potential with a consistent size and duration is produced. Neuronal information is coded by the frequency and number of action potentials, not the size of the action potential, eliminating **choices (B)** and **(C)** and making **choice (D)** the correct answer. Hyperpolarizing (inhibitory) signals are not transmitted to the nerve terminal, eliminating **choice (A)**.

4. C

Nerves are collections of neurons in the peripheral nervous system and may contain multiple types of information (sensory or motor); they contain cell bodies in ganglia. Tracts are collections of neurons in the central nervous system and contain only one type of information; they contain cell bodies in nuclei.

5. A

Sensory neurons are considered afferent (carrying signals from the periphery to the central nervous system) and enter the spinal cord on the dorsal side. Motor neurons are considered efferent (carrying signals from the central nervous system to the periphery) and exit the spinal cord on the ventral side.

6. C

When a sensory neuron receives a signal that is strong enough to bring it to threshold, one can assume that the receptor becomes depolarized, allowing it to transduce the stimulus to an action potential. The action potential will then be carried by sensory neurons to the central nervous system, where the cell will release neurotransmitters. Therefore, among the given choices, the only incorrect statement is found in **choice (C)**. If a receptor is stimulated, it will promote the spread of the action potential to postsynaptic sensory neurons in the spinal cord, which can send the signal toward the brain.

7. B

When the potential across the axon membrane is more negative than the normal resting potential, the neuron is referred to as hyperpolarized. Hyperpolarization occurs right after an action potential and is caused by excess potassium exiting the neuron.

8. D

The somatic division of the peripheral nervous system innervates skeletal muscles and is responsible for voluntary movement. Some of the pathways in this part of the nervous system are reflex arcs, which are reflexive responses to certain stimuli that involve only a sensory and a motor neuron. These neurons synapse in the spinal cord and do not require signaling from the brain. The pathways of the somatic division can involve two, three, or more neurons, depending on the type of signal. The correct answer therefore is **choice (D)**.

9. D

The parasympathetic nervous system governs the "rest-and-digest" response. The parasympathetic nervous system slows the heart rate, decreases blood pressure, promotes blood flow to the GI tract, and constricts the pupils, among other functions. The sympathetic nervous system governs the fight-or-flight response, including increased heart rate and blood pressure, decreased bloodflow to the digestive tract, and increased bloodflow to the muscles. **Choice (D)** is the only answer choice that represents a function of the parasympathetic nervous system.

10. A

Acetylcholine is the neurotransmitter released by the preganglionic neuron in both the sympathetic and parasympathetic nervous systems. The postganglionic neuron in the sympathetic nervous system usually releases norepinephrine, while the postganglionic neuron in the parasympathetic nervous system releases acetylcholine.

11. B

Neurons contain very specialized structures, including dendrites, axons, and the axon hillock. However, neurons are still cells and must carry out cellular functions including protein synthesis. The cell body or soma contains the nucleus, endoplasmic reticulum, and ribosomes.

12. B

First, consider the function of voltage-gated calcium channels. When the nerve terminal depolarizes, voltage-gated calcium channels open, allowing for influx of calcium. This influx of calcium triggers fusion of the synaptic vesicles containing neurotransmitters with the membrane of the neuron at the nerve terminal. This allows for exocytosis of the neurotransmitters into the synapse. If a disease blocked the influx of calcium, there would be no release of neurotransmitters. A lack of neurotransmitters means that the neuron cannot send signals. Thus, any symptoms resulting from this disease would be due to an inability of neurons to communicate. If neurons cannot communicate, flaccid paralysis may be one of the results.

13. B

Some neurons require multiple instances of excitatory transmission to be brought to threshold. These excitatory signals may be close to each other in time (temporal) or in space (spatial); either way, this pattern of excitation is termed summation.

14. A

Schwann cells are responsible for myelination of cells in the peripheral nervous system. Thus, the central nervous system is unlikely to be affected. The peripheral nervous system includes the somatic nervous system and the autonomic nervous system. The autonomic nervous system is composed of both the parasympathetic and sympathetic nervous systems. Thus, **choice (A)** is the right answer.

15. B

The dorsal root ganglion contains cell bodies of sensory neurons only. If a dorsal root ganglion is disrupted at a certain level, there will be a loss of sensation at that level.

Introduction

Human beings consist of many trillions of cells that must work together to sustain life. Fuel resources must be conserved or used appropriately, such as during responses to stressful situations. In addition, organs must be able to communicate with the brain to cause a change in behavior and physiology to maintain homeostasis. Hormones, as the messengers in the endocrine system, play an essential role in this communication. For example, the pancreas produces both insulin and glucagon. Insulin favors the transport of glucose into organs as well as the storage of excess glucose when blood glucose concentrations are high. Conversely, glucagon triggers the release of sugar stores and raises blood glucose concentration. Working together, these hormones ensure that there is enough glucose available for organ function, but that glucose levels are not so high as to cause damage to organ systems.

This is no inconsequential fact. Diabetes mellitus is one of the most common diagnoses in the United States and a major cause of morbidity and mortality. Type 1 diabetes mellitus is an autoimmune disease in which insulin-producing cells in the islets of Langerhans are destroyed; type 2 diabetes mellitus is caused by end-organ insensitivity to insulin. In both cases, blood glucose concentrations rise to dangerous levels (sometimes up to ten times the normal concentration) and can cause significant damage to multiple organs, including the retina of the eye, the glomeruli of the kidneys, the coronary vessels of the heart and cerebral vessels of the brain, and nerves in the extremities. Left untreated (or, to be frank, even if treated in many cases), diabetes can lead to blindness, kidney failure, heart attacks, strokes, and

amputation. Regardless of the field you enter, you will spend a significant amount of time working with diabetic patients and will have to think about the effects of this diagnosis on other diagnoses and their treatment.

In this chapter, we will explore the different types of hormones and how they work. We'll survey the various endocrine organs and discuss the hormones each one produces. This is an extremely high-yield chapter: the MCAT frequently tests not only the content of the endocrine system (the hormones and their functions), but also the reasoning of the endocrine system (feedback loops and their regulation). Return to this chapter frequently during studying; a thorough knowledge of this system will assuredly pay off in points on Test Day.

5.1 Mechanisms of Hormone Action

The endocrine system consists of organs, known as **glands**, that secrete hormones. **Hormones** are signaling molecules that are secreted directly into the bloodstream to travel to a distant target tissue. At that tissue, hormones bind to receptors, inducing a change in gene expression or cellular functioning. Not all hormones share the same structure and function. In order to understand how each hormone functions, it is first important to understand basic hormone structure.

CLASSIFICATION OF HORMONES BY CHEMICAL STRUCTURE

Hormones can be subdivided into categories based on different criteria. First, hormones can be classified by their chemical identities. Hormones can be **peptides**, **steroids**, or **amino acid derivatives**.

Peptide Hormones

Peptide hormones are made up of amino acids, ranging in size from quite small (such as ADH) to relatively large (such as insulin). Peptide hormones are all derived from larger precursor polypeptides that are cleaved during posttranslational modification. These smaller units are transported to the Golgi apparatus for further modifications that activate the hormone and direct it to the correct location in the cell. Such hormones are released by exocytosis after being packaged into vesicles.

Because peptide hormones are charged and cannot pass through the plasma membrane, these hormones must bind to an extracellular receptor. The peptide hormone is considered the **first messenger**; it binds to the receptor and triggers the transmission of a second signal, known as the **second messenger**. There are many different receptor subtypes, and the type of receptor determines what happens once the hormone has stimulated the receptor.

The connection between the hormone at the surface and the effect brought about by second messengers within the cell is known as a **signaling cascade**. At each step, there is the possibility of **amplification**. For example, one hormone molecule may bind to multiple receptors before it is degraded. Also, each receptor may activate multiple enzymes, each of which will trigger the production of large quantities of second messengers. Thus, each step can result in an increase in the intensity of the signal. Some common second messengers are **cyclic adenosine monophosphate** (**cAMP**), **inositol triphosphate** (**IP_3**), and calcium. The activation of a G protein-coupled receptor is shown in Figure 5.1. In this system, the binding of a peptide hormone triggers the receptor to either activate or inhibit an enzyme called ***adenylate cyclase***, raising or lowering the levels of cAMP accordingly. cAMP can bind to intracellular targets, such as *protein kinase A*, which phosphorylates transcription factors like cAMP response element-binding protein (CREB) to exert the hormone's ultimate effect. Keep in mind that protein kinase A can modify other enzymes as well as transcription factors, thus it can have a rapid or slow effect on the cell.

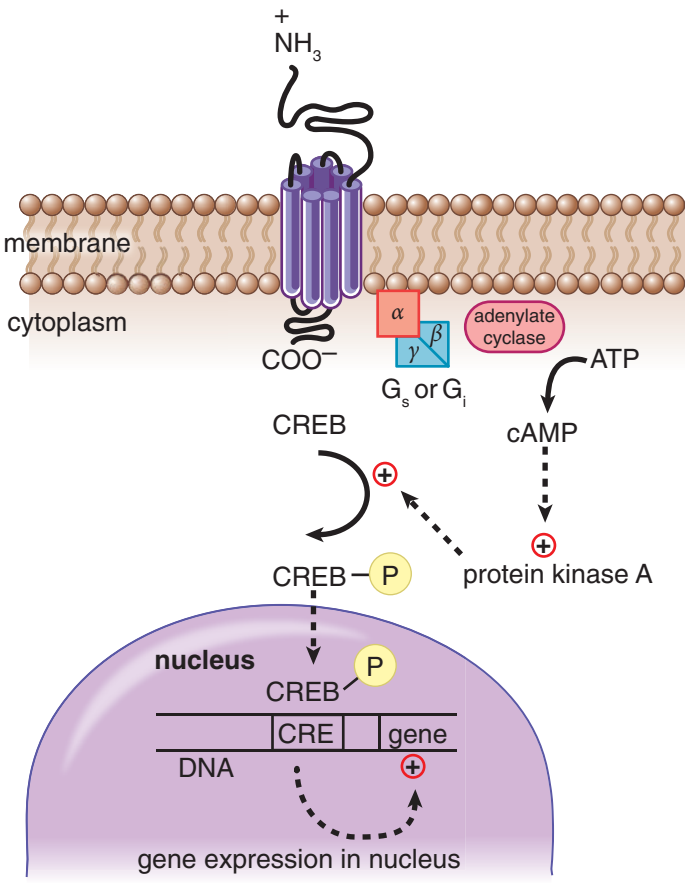

Figure 5.1. Mechanism of Action of a Peptide Hormone
Peptide hormones bind to membrane-bound receptors to intiate a signal cascade, using second messengers like cAMP.

The effects of peptide hormones are usually rapid but short-lived because these hormones act through transient second messenger systems. It is quicker to turn them on and off, compared with steroid hormones, but their effects do not last without relatively constant stimulation.

Because peptides are generally water-soluble, peptide hormones can travel freely in the bloodstream and usually do not require carriers. This is in stark contrast to steroid hormones, as we will explore in the next section.

Steroid Hormones

Steroid hormones are derived from cholesterol and are produced primarily by the gonads and adrenal cortex. Because steroid hormones are derived from nonpolar molecules, they can easily cross the cell membrane. In fact, their receptors are usually intracellular (in the cytosol) or intranuclear (in the nucleus). Upon binding to the receptor, steroid hormone–receptor complexes undergo conformational changes. The receptor can then bind directly to DNA, resulting in either increased or decreased transcription of particular genes, depending on the identity of the hormone, as shown in Figure 5.2. One common form of conformational change is **dimerization**, or pairing of two receptor–hormone complexes. The effects of steroid hormones are slower but longer-lived than peptide hormones because steroid hormones cause alterations in the amount of mRNA and protein present in a cell by direct action on DNA.

Key Concept

Peptide hormones have surface receptors and act via second messenger systems. Steroid hormones bind to intracellular receptors and function by binding to DNA to alter gene transcription.

Mnemonic

Insulin is a peptide hormone, and it has to be released at every meal in order to be active. Thus, it has fast onset but is short-acting (like most peptide hormones). Estrogen and testosterone are steroid hormones that promote sexual maturation. This is a slower, but longer-lasting change (as is true for most steroid hormones).

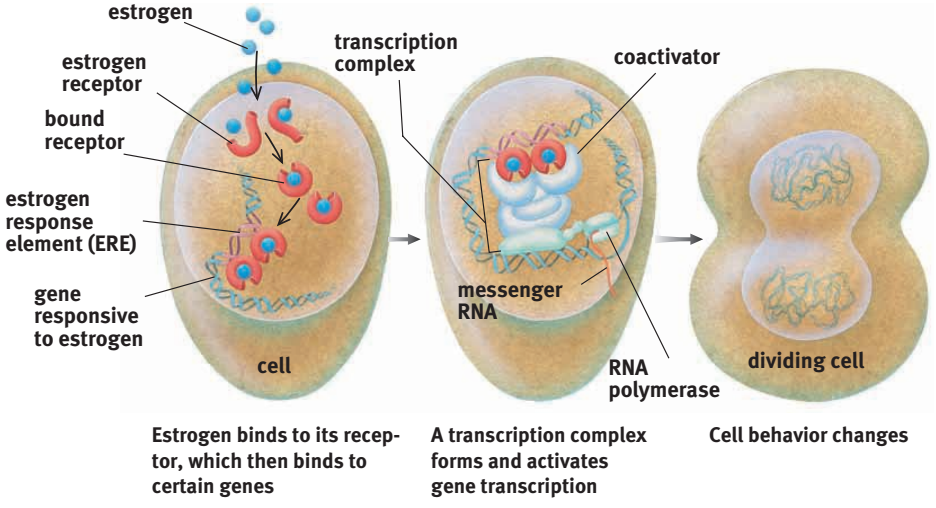

Figure 5.2. Mechanism of Action of a Steroid Hormone
Estrogen, like all steroid hormones, influences cell behavior by modifying transcription.

Steroid hormones are not water-soluble and, thus, must be carried by proteins in the bloodstream to be able to travel around the body. Some of these proteins are very specific, and carry only one hormone (such as *sex hormone-binding globulin*), while

other proteins are nonspecific (such as ***albumin***). Note that hormones are generally inactive while attached to a carrier protein and must dissociate from the carrier to function. Levels of carrier proteins can change the levels of active hormone. For example, some conditions increase the quantity of a protein that carries thyroid hormones, *thyroxine-binding globulin* (TBG). This causes the body to perceive a lower level of thyroid hormone because the increased quantity of TBG binds a larger proportion of the hormone, meaning there is less free hormone available.

Amino Acid-Derivative Hormones

Finally, **amino acid-derivative hormones** are less common than peptide and steroid hormones, but include some of the most important hormones discussed in this chapter, including epinephrine, norepinephrine, triiodothyronine, and thyroxine. These hormones are derived from one or two amino acids, usually with a few additional modifications. For example, thyroid hormones are made from tyrosine with the addition of several iodine atoms.

This chemistry of this family of hormones is considerably less predictable and is one of the few instances where overt memorization may be the best strategy. The **catecholamines** (epinephrine and norepinephrine) bind to G protein-coupled receptors while the thyroid hormones bind intracellularly.

CLASSIFICATION OF HORMONES BY TARGET TISSUE

Some hormones, known as **direct hormones**, are secreted and then act directly on a target tissue. For example, insulin released by the pancreas causes increased uptake of glucose by muscles. Other hormones, known as **tropic hormones**, require an intermediary to act. For example, as discussed in Chapter 2 of *MCAT Biology Review*, gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH then acts on the gonads to stimulate testosterone production in the male and estrogen production in the female. GnRH and LH do not cause direct changes in the physiology of muscle, bone, and hair follicles; rather, they stimulate the production of another hormone by another endocrine gland that acts on these target tissues. Tropic hormones usually originate in the brain and anterior pituitary gland, as these structures are involved in coordination of multiple processes within the body.

Real World

During pregnancy, high levels of estrogen and progesterone cause increased production of TBG, thyroxine-binding globulin. In order to compensate, pregnant women secrete much higher levels of the thyroid hormones. Thus, in order to diagnose thyroid disease in a pregnant woman, different reference values must be used.

MCAT Expertise

The mechanism of action of the amino acid-derivative hormones should be memorized because it is so unpredictable. Epinephrine and norepinephrine have extremely fast onset but are short-lived, like peptide hormones—think of an *adrenaline rush*. Thyroxine and triiodothyronine, on the other hand, have slower onset but a longer duration, like steroid hormones—they regulate metabolic rate over a long period of time.

Mnemonic

Most peptide and amino acid-derivative hormones have names that end in ***–in*** or ***–ine*** (insul***in***, vasopress***in***, thyrox***ine***, triiodothyron***ine***, and so on). Most steroid hormones have names that end in ***–one***, ***–ol***, or ***–oid*** (testoster***one***, aldoster**one** and other mineralocortic***oid***s, cortis***ol*** and other glucocortic***oid***s, and so on). This is not exhaustive, but may help you identify the chemistry of a hormone on Test Day.

MCAT Concept Check 5.1:
Before you move on, assess your understanding of the material with these questions.

1. Compare and contrast peptide and steroid hormones based on the following criteria:

Criterion	Peptide Hormones	Steroid Hormones
Chemical precursor		
Location of receptor		
Mechanism of action		
Method of travel in the bloodstream		
Rapidness of onset		
Duration of action		

2. How are amino acid-derivative hormones synthesized?

_____

_____

3. What is the difference between a direct and a tropic hormone?
   - Direct hormone:

     _____
   - Tropic hormone:

     _____

5.2 Endocrine Organs and Hormones ★★

The hypothalamus, the pituitary, the thyroid, the parathyroid glands, the adrenal glands, the pancreas, the gonads (testes and ovaries), and the pineal gland are all endocrine glands, as shown in Figure 5.3. Each of these organs is capable of synthesizing and secreting one or more hormones. Furthermore, there are collections of cells within organs, such as the kidneys, gastrointestinal glands, heart, and thymus that serve important endocrine roles. The organs in this second group are traditionally not called endocrine organs because hormone production is not their main function.

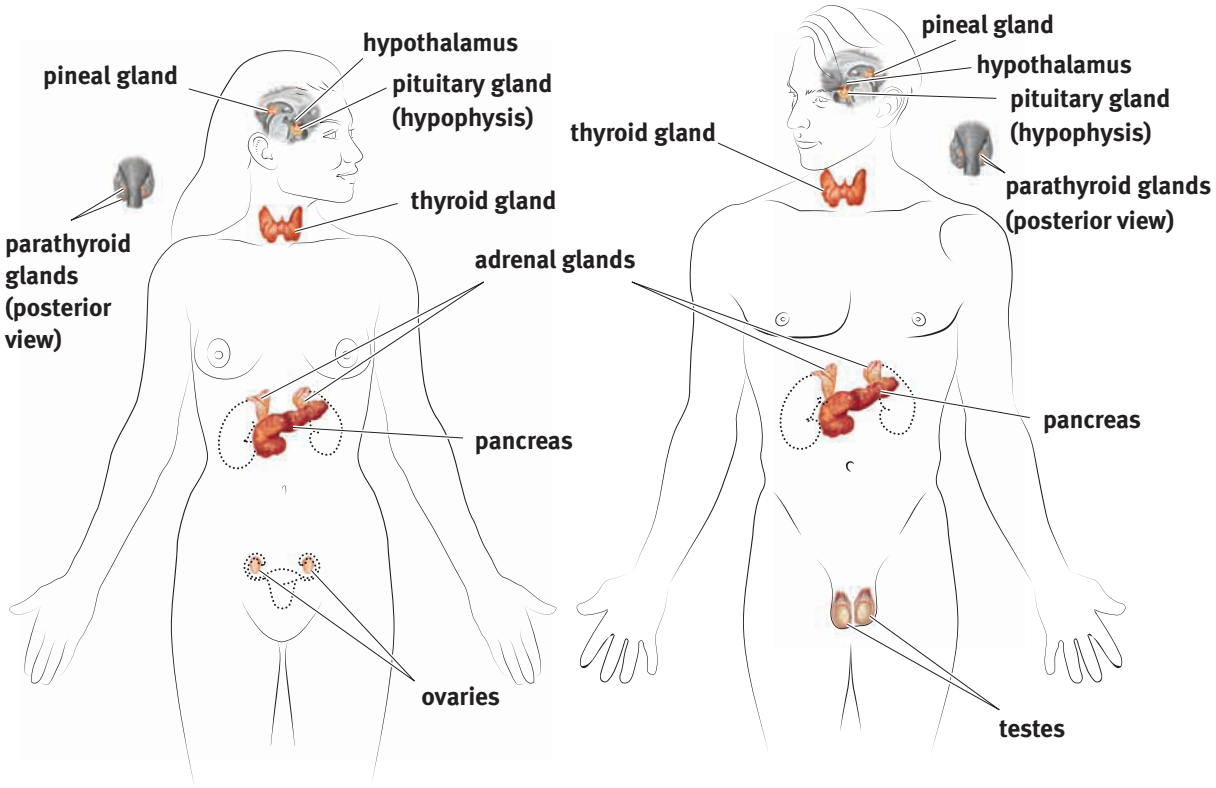

Figure 5.3. Organs of the Endocrine System
Endocrine organs produce hormones that are secreted into the bloodstream to act on distant target tissues.

Now that we have discussed the mechanisms through which hormones act and their classification, we can discuss the individual endocrine organs and the hormones secreted by each.

HYPOTHALAMUS

Let's begin with the **hypothalamus**, the bridge between the nervous and endocrine systems. By regulating the pituitary gland through tropic hormones, the hypothalamus is capable of having organism-wide effects. The hypothalamus is located in the forebrain, directly above the pituitary gland and below the thalamus (hence the name *hypothalamus*). Because the hypothalamus and the pituitary are close to each other, the hypothalamus controls the pituitary through paracrine release of hormones into a portal system that directly connects the two organs. The hypothalamus receives input from a wide variety of sources. For example, a part of the hypothalamus called the *suprachiasmatic nucleus* receives some of the light input from the retinae and helps to control sleep–wake cycles. Other parts of the hypothalamus respond to increases in blood osmolarity. Still other parts of the hypothalamus regulate appetite and satiety.

Bridge

The hypothalamus contains a number of nuclei in its three sections, called the lateral, ventromedial, and anterior hypothalamus. These nuclei play roles in emotional experience, aggressive behavior, sexual behavior, metabolism, temperature regulation, and water balance. The parts of the hypothalamus are discussed in Chapter 1 of *MCAT Behavioral Sciences Review*.

The release of hormones by the hypothalamus is regulated by negative feedback. **Negative feedback** occurs when a hormone (or product) later in the pathway inhibits hormones (or enzymes) earlier in the pathway. This type of feedback maintains homeostasis and prevents wasted energy by restricting production of substances that are already present in sufficient quantities. The hypothalamus and pituitary gland are inextricably linked. The pituitary gland has an anterior and posterior component, each with a unique interaction with the hypothalamus. We will discuss each in turn.

Interactions with the Anterior Pituitary

The hypothalamus secretes compounds into the **hypophyseal portal system**, which is a blood vessel system that directly connects the hypothalamus with the anterior pituitary, as shown in Figure 5.4. Thus, hormones released from the hypothalamus travel directly to the anterior pituitary and cannot be found in appreciable concentrations in the systemic circulation. Note that the term **hypophysis** is an alternative term for the pituitary. Once hormones have been released from the hypothalamus into this portal bloodstream, they travel down the pituitary stalk and bind to receptors in the anterior pituitary, stimulating the release of other hormones.

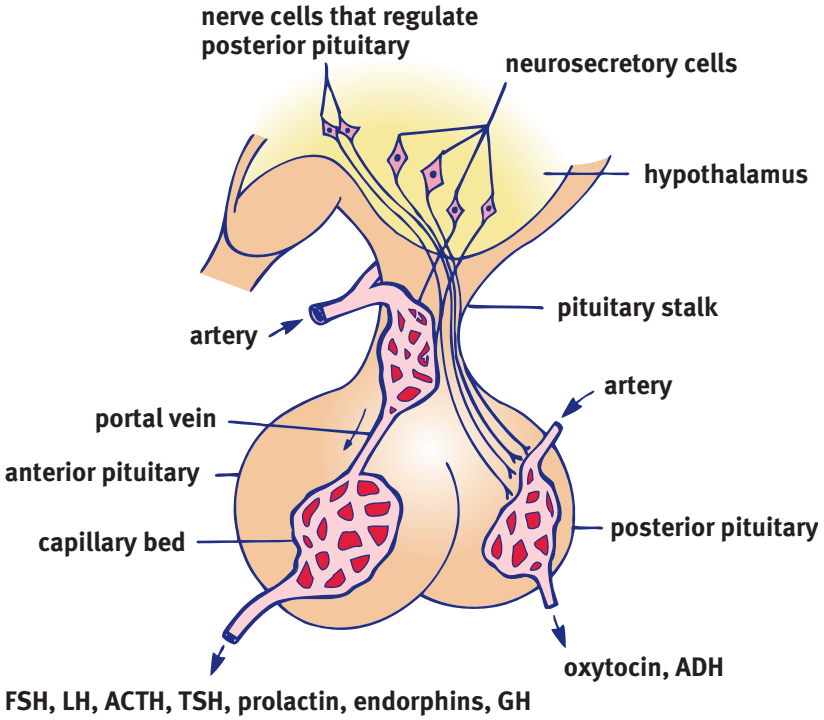

Figure 5.4. The Hypophyseal Portal System
A system of blood vessels connects the hypothalamus to the pituitary.

The hypothalamus secretes several different tropic hormones. The following indicates each hormone released by the hypothalamus and the hormone(s) released by the anterior pituitary in response:

- Gonadotropin-releasing hormone (GnRH) → follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
- Growth hormone-releasing hormone (GHRH) → growth hormone (GH)
- Thyroid-releasing hormone (TRH) → thyroid-stimulating hormone (TSH)
- Corticotropin-releasing factor (CRF) → adrenocorticotropic hormone (ACTH)

There is one exception to this pattern—prolactin-inhibiting factor (PIF), which is actually dopamine, is released by the hypothalamus and causes a *decrease* in prolactin secretion.

Each of the tropic hormones then causes the release of another hormone from an endocrine gland that has negative feedback effects. For example, release of CRF from the hypothalamus will stimulate the anterior pituitary to secrete ACTH. ACTH will then cause the adrenal cortex to increase the level of **cortisol** being secreted into the blood. However, cortisol is detrimental when levels become too high. To prevent excess cortisol secretion, cortisol can inhibit the hypothalamus and anterior pituitary from releasing CRF and ACTH, respectively, as shown in Figure 5.5. This makes sense because CRF and ACTH have already accomplished their desired effect: getting more cortisol into the blood. What does this mean in terms of receptors in the hypothalamus and pituitary? Cortisol receptors must be present in these organs; otherwise, they wouldn't be able to recognize that cortisol levels had increased. Three-organ systems like these are commonly referred to as **axes**; for example, the hypothalamic–pituitary–adrenal (HPA) axis, the hypothalamic–pituitary–ovarian (HPO) axis, and so on.

Key Concept

Whereas most of the hormones in the anterior pituitary require a factor from the hypothalamus to be released, prolactin is the exception. As long as the hypothalamus releases PIF (which is actually dopamine), no prolactin will be released. It is the absence of PIF that allows for prolactin to be released.

Key Concept

Although it seems as if the pituitary has all the power in the endocrine system, the anterior pituitary is controlled by the hypothalamus, which is located directly above it.

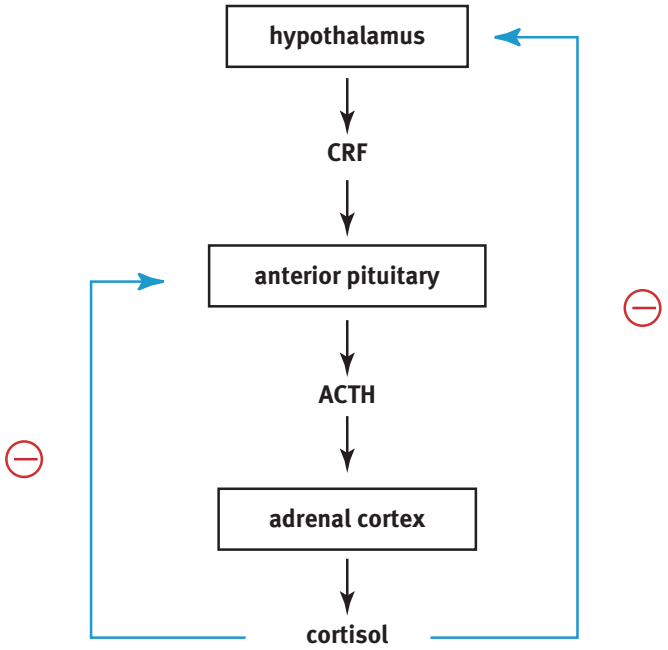

Figure 5.5. Hypothalamic Negative Feedback Mechanism

Interactions with the Posterior Pituitary

The posterior pituitary does not receive tropic hormones through the hypophyseal portal system. Rather, neurons in the hypothalamus send their axons down the pituitary stalk directly into the posterior pituitary, which can then release oxytocin and antidiuretic hormone. **Oxytocin** is a hormone that stimulates uterine contractions during labor, as well as milk letdown during lactation. There is evidence that oxytocin is also involved in bonding behavior. **Antidiuretic hormone** (**ADH**, also called **vasopressin**) increases reabsorption of water in the collecting ducts of the kidneys. ADH is secreted in response to increased plasma osmolarity, or increased concentration of solutes within the blood.

Real World

A tumor of the pituitary gland may result in compression of the portal system that connects the pituitary to the hypothalamus. This will block the ability of PIF to reach the pituitary and exert its effect. Thus, more prolactin will be released. This may result in lactation (galactorrhea), even in males. Thus, milk production in a male or nonpregnant female should urge a physician to check for a pituitary tumor.

ANTERIOR PITUITARY

As described earlier, the pituitary gland is divided into anterior and posterior sections. Because this distinction has already been covered, our discussion of the pituitary gland here will focus on the hormones released by each section.

The **anterior pituitary** synthesizes and secretes seven different products. Four of these are tropic hormones, while the other three are direct hormones.

Tropic Hormones

We are going to mention the tropic hormones only briefly here. These hormones work by causing the release of another hormone at the organ level. Thus, we will discuss the tropic hormones in tandem with the endocrine organ on which they act. The release of both follicle-stimulating hormone (FSH) and luteinizing hormone

Mnemonic

Products of the anterior pituitary:
FLAT PEG
- **F**ollicle-stimulating hormone (FSH)
- **L**uteinizing hormone (LH)
- **A**drenocorticotropic hormone (ACTH)
- **T**hyroid-stimulating hormone (TSH)
- **P**rolactin
- **E**ndorphins
- **G**rowth hormone (GH)

Additionally, the four hormones in FLAT are all tropic hormones, while the three hormones in PEG are all direct hormones.

(LH) is stimulated by gonadotropin-releasing hormone (GnRH) from the hypothalamus. These two hormones act on the gonads (testes and ovaries). The release of adrenocorticotropic hormone (ACTH) is stimulated by corticotropin-releasing factor (CRF) from the hypothalamus; ACTH acts on the adrenal cortex. The release of thyroid-stimulating hormone (TSH) is stimulated by thyroid-releasing hormone (TRH) from the hypothalamus; TSH acts on the thyroid.

Direct Hormones

Prolactin is more important in females than in males; it stimulates milk production in the **mammary glands**. Milk production in the male is always pathologic. During pregnancy, estrogen and progesterone levels are high. In addition, prolactin, a hormone that increases milk production, is also secreted by the anterior pituitary. Prolactin is an unusual hormone in that the release of dopamine from the hypothalamus *decreases* its secretion. The high levels of estrogen and progesterone allow for the development of milk ducts in preparation for lactation, but it is not until shortly after the expulsion of the placenta, when estrogen, progesterone, and dopamine levels drop, that the block on milk production is removed and lactation actually begins.

Milk ejection occurs when the newborn infant latches on to the breast. Nipple stimulation causes activation of the hypothalamus, resulting in two different reactions. First, oxytocin is released from the posterior pituitary, resulting in contraction of the smooth muscle of the breast and ejection of milk through the nipple. Second, the hypothalamus stops releasing dopamine onto the anterior pituitary, which—as mentioned above—allows prolactin release, causing production of milk and regulation of the milk supply.

Endorphins decrease the perception of pain. For example, after completing a marathon, many people will say they are on an endorphin "high" or "rush." Endorphins mask the pain from just having run 26.2 miles and can even induce a sense of euphoria. Many pharmaceutical agents, such as morphine, mimic the effect of these naturally occuring painkillers.

Growth hormone (**GH**) is named for exactly what it does: it promotes the growth of bone and muscle. This sort of growth is energetically expensive and requires large quantities of glucose. Growth hormone prevents glucose uptake in certain tissues (those that are not growing) and stimulates the breakdown of fatty acids. This increases the availability of glucose overall, allowing the muscle and bone to use it. GH release is stimulated by growth hormone-releasing hormone (GHRH) from the hypothalamus.

Bone growth originates in special regions of the bone known as epiphyseal plates, which seal shut during puberty. An excess of GH released in childhood (before this closure) can cause **gigantism**, and a deficit results in **dwarfism**. In adults, the situation is slightly different. Because the long bones are sealed, GH still has an effect, but it is primarily in the smaller bones. The resulting medical condition is known as **acromegaly**. The bones most commonly affected are those in the hands, feet, and head. Patients with acromegaly tend to present to their doctors because they have had to buy larger shoes, cannot wear their rings, and can no longer fit into their hats.

POSTERIOR PITUITARY

The **posterior pituitary** contains the nerve terminals of neurons with cell bodies in the hypothalamus. As mentioned earlier, the posterior pituitary receives and stores two hormones produced by the hypothalamus: ADH and oxytocin.

ADH is secreted in response to low blood volume (as sensed by baroreceptors) or increased blood osmolarity (as sensed by osmoreceptors), as shown in Figure 5.6. Its action is at the level of the collecting duct, where it increases the permeability of the duct to water. The net effect is a greater reabsorption of water from the filtrate in the nephron. This results in greater retention of water, which results in increased blood volume and higher blood pressure.

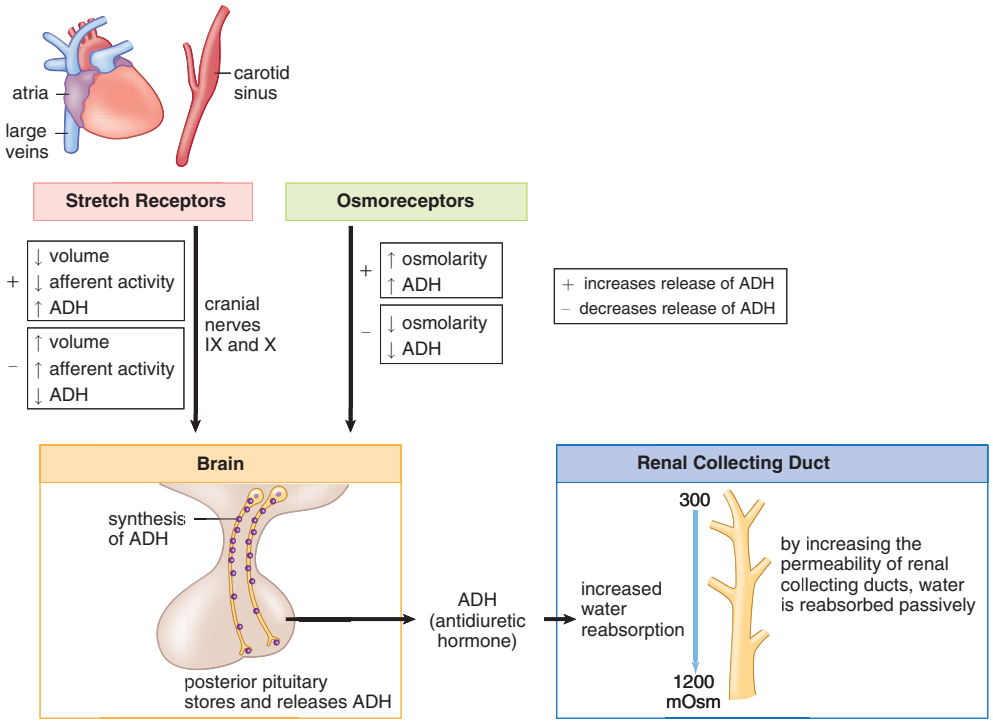

Figure 5.6. Antidiuretic Hormone (ADH)

Oxytocin is secreted during childbirth and allows for coordinated contraction of uterine smooth muscle. Its secretion may also be stimulated by suckling, as it promotes milk ejection through contraction of smooth muscle in the breast. Finally, oxytocin may be involved in bonding behavior. Oxytocin is unusual in that it has a **positive feedback** loop: the release of oxytocin promotes uterine contraction, which promotes more oxytocin release, which promotes stronger uterine contractions, and so on. Positive feedback loops can usually be identified by this theme of a "spiraling forward" process and usually have a definitive endpoint—in this case, delivery.

Key Concept

The two hormones released from the posterior pituitary are actually synthesized in the hypothalamus, and simply released from the posterior pituitary gland. The posterior pituitary does not synthesize any hormones itself.

THYROID

The **thyroid** is controlled by **thyroid-stimulating hormone** from the anterior pituitary. The thyroid is on the front surface of the trachea; it can be palpated (felt) as an organ near the base of the neck that moves up and down with swallowing. The thyroid has two major functions: setting basal metabolic rate and calcium homeostasis. It mediates the first effect by releasing triiodothyronine (T_3) and thyroxine (T_4), whereas calcium levels are controlled by calcitonin.

Triiodothyronine and Thyroxine

Triiodothyronine (**T_3**) and **thyroxine** (**T_4**) are both produced by the iodination of the amino acid tyrosine in the **follicular cells** of the thyroid. The numbers 3 and 4 refer to the number of iodine atoms attached to the tyrosine. Thyroid hormones are capable of resetting the basal metabolic rate of the body by making energy production more or less efficient, as well as altering the utilization of glucose and fatty acids. Increased amounts of T_3 and T_4 will lead to increased cellular respiration. This leads to a greater amount of protein and fatty acid turnover by speeding up both synthesis and degradation of these compounds. High plasma levels of thyroid hormones will lead to decreased TSH and TRH synthesis; negative feedback prevents excessive secretion of T_3 and T_4, as shown in Figure 5.7.

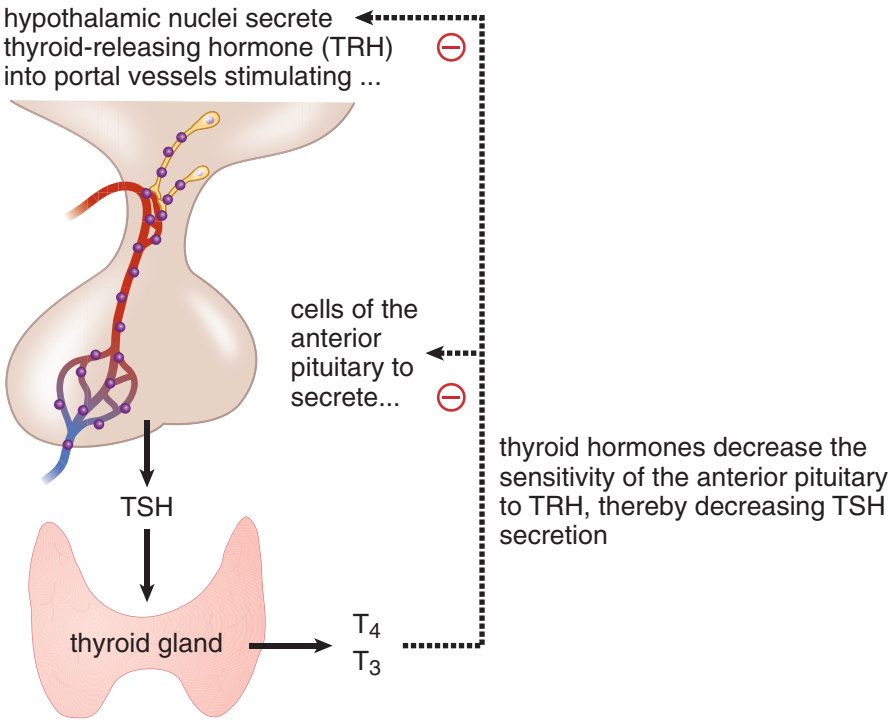

Figure 5.7. Thyroid Hormone Negative Feedback Mechanism

A deficiency of iodine or inflammation of the thyroid may result in **hypothyroidism**, in which thyroid hormones are secreted in insufficient amounts or not at all. The condition is characterized by lethargy, decreased body temperature, slowed respiratory and heart rate, cold intolerance, and weight gain. Thyroid hormones are required for appropriate neurological and physical development in children. Most children are tested at birth for appropriate levels because a deficiency will result in mental retardation and developmental delay (**cretinism**).

An excess of thyroid hormone, which may result from a tumor or thyroid overstimulation, is called **hyperthyroidism**. We can predict the clinical course of this syndrome by considering the opposite of each of the effects seen in hypothyroidism: heightened activity level, increased body temperature, increased respiratory and heart rate, heat intolerance, and weight loss.

Mnemonic

Calci**ton**in **tone**s down calcium levels in the blood.

Calcitonin

If we were to examine thyroid tissue under a light microscope, we would see two distinct cell populations within the gland. Follicular cells produce thyroid hormones and **C-cells** (also called **parafollicular cells**) produce **calcitonin**. Calcitonin acts to decrease plasma calcium levels in three ways: increased calcium excretion from the kidneys, decreased calcium absorption from the gut, and increased storage of calcium in the bone. High levels of calcium in the blood stimulate secretion of calcitonin from the C-cells.

PARATHYROID GLANDS

The parathyroids are four small pea-sized structures that sit on the posterior surface of the thyroid. The hormone produced by the parathyroid glands is aptly named **parathyroid hormone** (**PTH**). PTH serves as an antagonistic hormone to calcitonin, raising blood calcium levels; specifically, it decreases excretion of calcium by the kidneys, increases absorption of calcium in the gut (via vitamin D), and increases bone resorption, thereby freeing up calcium, as shown in Figure 5.8. Like the hormones we have already seen, PTH is also subject to feedback inhibition. As levels of plasma calcium rise, PTH secretion is decreased. Parathyroid hormone also affects phosphorus homeostasis by resorbing phosphate from bone and reducing reabsorption of phosphate in the kidney (thus promoting its excretion in the urine).

PTH also activates **vitamin D**, which is required for the absorption of calcium and phosphate in the gut. The overall effect of parathyroid hormone, therefore, is a significant increase in blood calcium levels with little effect on phosphate (the absorption of phosphate in the gut and its excretion in the kidney somewhat cancel each other).

Key Concept

Calcium is an exceptionally important ion. The critically important functions of calcium include:

- Bone structure and strength
- Release of neurotrasmitters from neurons
- Regulation of muscle contraction
- Clotting of blood (calcium is a cofactor)

In addition, calcium also plays a role in cell movement and exocytosis of cellular materials.

Key Concept

Just like glucagon and insulin, PTH and calcitonin are antagonistic to each other. We should think of these hormones as a pair with the primary function of regulating calcium levels in the blood. PTH increases calcium levels, whereas calcitonin decreases calcium levels.

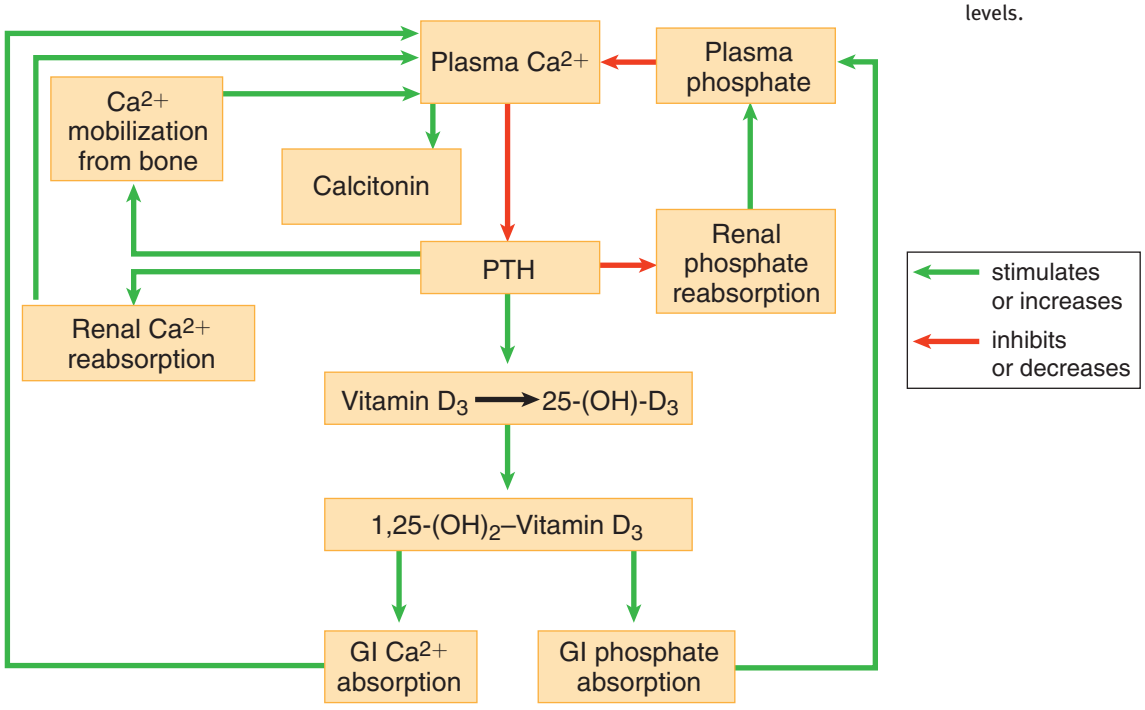

Figure 5.8. Calcium and Phosphorus Homeostasis

ADRENAL CORTEX

The **adrenal glands** are located on top of the kidneys. Adrenal actually translates to *near* or *next to the kidney*. Each adrenal gland consists of a cortex and a medulla. This distinction is more than anatomical. Each part of the gland is responsible for the secretion of different hormones. The **adrenal cortex** secretes **corticosteroids**. These are steroid hormones that can be divided into three functional classes: **glucocorticoids**, **mineralocorticoids**, and **cortical sex hormones**.

Glucocorticoids

Glucocorticoids are steroid hormones that regulate glucose levels. In addition, these hormones also affect protein metabolism. The two glucocorticoids most likely to be tested on the MCAT are **cortisol** and **cortisone**. These hormones raise blood glucose by increasing gluconeogenesis and decreasing protein synthesis. Cortisol and cortisone can also decrease inflammation and immunologic responses. Cortisol is also known as a stress hormone because it is released in times of physical or emotional stress. This increases blood sugar and provides a ready source of fuel in case the body must react quickly to a dangerous stimulus.

Glucocorticoid release is under the control of adrenocorticotropic hormone (ACTH) as described earlier. Corticotropin-releasing factor (CRF) from the hypothalamus promotes release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which promotes release of glucocorticoids from the adrenal cortex.

Real World

Many people who suffer from joint pain may be treated with glucocorticoid injections into the joint space. These injections decrease inflammation. In addition, glucocorticoids are used to treat systemic inflammation such as that which occurs due to allergies or autoimmune disease.

Mineralocorticoids

Mineralocorticoids are used in salt and water homeostasis; their most profound effects are on the kidneys. The most noteworthy mineralocorticoid is **aldosterone**, which increases sodium reabsorption in the distal convoluted tubule and collecting duct of the nephron. Water follows the sodium cations into the bloodstream, increasing blood volume and pressure. Note that, while the blood pressure increases, the plasma osmolarity remains unchanged—unlike with ADH. Aldosterone also decreases the reabsorption of potassium and hydrogen ions in these same segments of the nephron, promoting their excretion in the urine.

Unlike the glucocorticoids, aldosterone is primarily under the control of the **renin–angiotensin–aldosterone** system, as shown in Figure 5.9. Decreased blood pressure causes the **juxtaglomerular cells** of the kidney to secrete **renin**, which cleaves an inactive plasma protein, **angiotensinogen**, to its active form, **angiotensin I**. Angiotensin I is then converted to **angiotensin II** by **angiotensin-converting enzyme** (**ACE**) in the lungs. Angiotensin II stimulates the adrenal cortex to secrete aldosterone. Once blood pressure is restored, there is a decreased drive to stimulate renin release, thus serving as the negative feedback mechanism for this system.

Real World

In addition to stimulating the secretion of aldosterone, which increases blood volume and hence blood pressure, angiotensin II also increases blood pressure directly through a powerful vasoconstrictive effect and by increasing heart rate. Angiotensin-converting enzyme (ACE) inhibitors block the conversion of angiotensin I to angiotensin II, inhibiting vasoconstriction. Therefore, ACE inhibitors are frequently prescribed for the treatment of high blood pressure and congestive heart failure. In the latter case, vasodilation helps reduce the resistance against which the failing heart must pump. Most ACE inhibitors' names end with *–pril* (*lisinopril*, *enalapril*, *ramipril*).

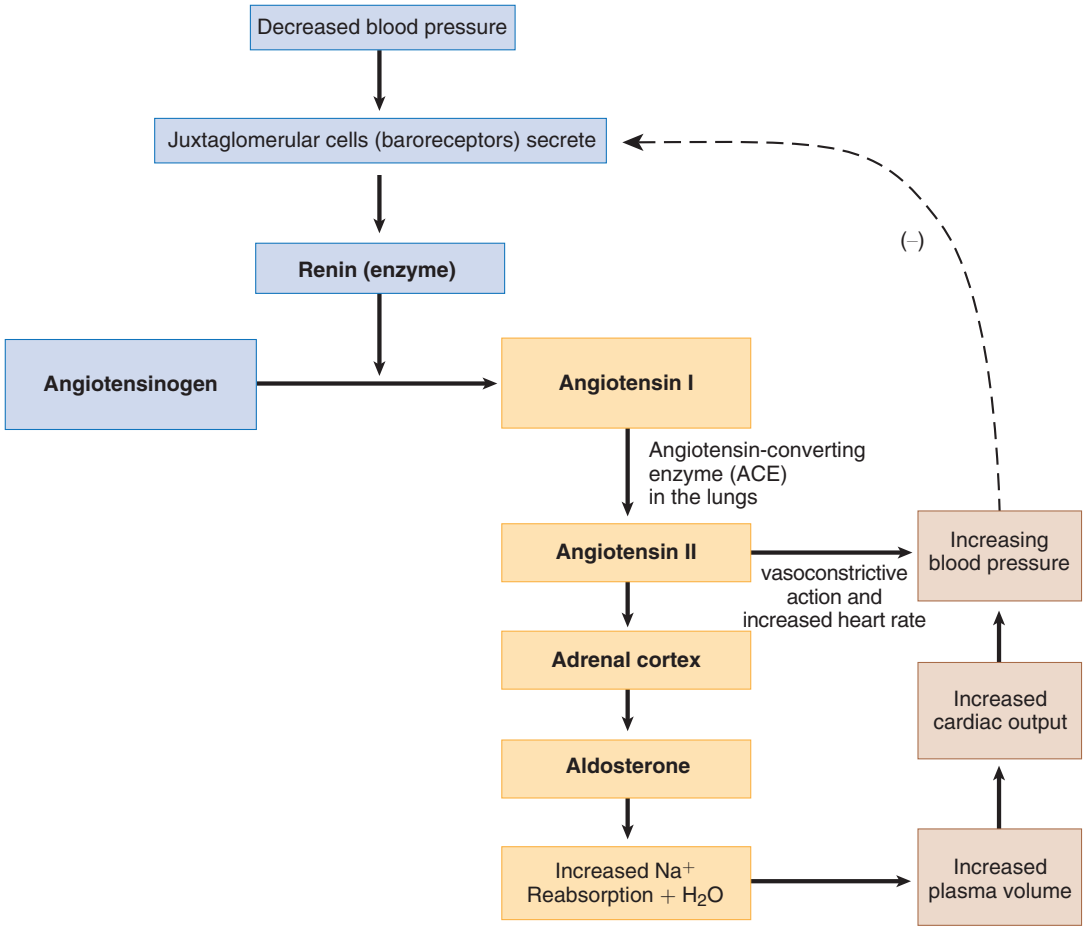

Figure 5.9. The Renin–Angiotensin–Aldosterone System

Cortical Sex Hormones

The adrenal glands also make **cortical sex hormones** (**androgens** and **estrogens**). Because males already secrete large quantities of androgens in the testes, adrenal testosterone plays a small role in male physiology. However, females are much more sensitive to disorders of cortical sex hormone production. For example, certain enzyme deficiencies in the synthetic pathways of other adrenal cortex hormones result in excess androgen production in the adrenal cortex. Such a deficiency would result in no obvious phenotypic effects in a male fetus; however, a genotypic female may be born with ambiguous or masculinized genitalia due to the presence of excess cortical sex hormones. Males can be affected by similar disorders if they lead to excessive production of estrogens.

Mnemonic

Functions of the corticosteroids:
The 3 **S**'s

- **S**alt (mineralocorticoids)
- **S**ugar (glucocorticoids)
- **S**ex (cortical sex hormones)

ADRENAL MEDULLA

Nestled inside the adrenal cortex is the adrenal medulla. A derivative of the nervous system, this organ is responsible for the production of the sympathetic hormones **epinephrine** and **norepinephrine**. The specialized nerve cells in the medulla are capable of secreting these compounds directly into the circulatory system. Both

epinephrine and norepinephrine are amino acid-derivative hormones that belong to a larger class of molecules known as **catecholamines**.

Much like the sympathetic component of the autonomic nervous system, the hormones released from the adrenal medulla affect a wide variety of systems in the body, and all of their effects are centered on the fight-or-flight response. Epinephrine can increase the breakdown of glycogen to glucose (glycogenolysis) in both liver and muscle, as well as increase the basal metabolic rate. Both hormones will increase heart rate, dilate the bronchi, and alter blood flow to supply the systems that would be used in a sympathetic response. That is, there is vasodilation of blood vessels leading to the skeletal muscle, heart, lungs, and brain, increasing bloodflow to these organs. Concurrently, vasoconstriction decreases bloodflow to the gut, kidneys, and skin. Note that the stress response involves both cortisol and epinephrine. Classically, cortisol is thought of as being important for long-term (slow) stress responses, while catecholamines are thought of as being important for short-term (fast) stress responses. Note, however, that cortisol actually increases the synthesis of catecholamines as well, resulting in an increase in catecholamine release.

PANCREAS

The pancreas has both exocrine and endocrine functions. Exocrine tissues secrete substances directly into ducts; the pancreas produces a number of digestive enzymes, as discussed in Chapter 9 of *MCAT Biology Review*. From an endocrine standpoint, small groups of hormone-producing cells are grouped together into **islets of Langerhans** throughout the pancreas, as shown in Figure 5.10. Islets contain three distinct types of cells: **alpha** (α), **beta** (β), and **delta** (δ) **cells**. Each cell type secretes a different hormone: α-cells secrete **glucagon**, β-cells secrete **insulin**, and δ-cells secrete **somatostatin**.

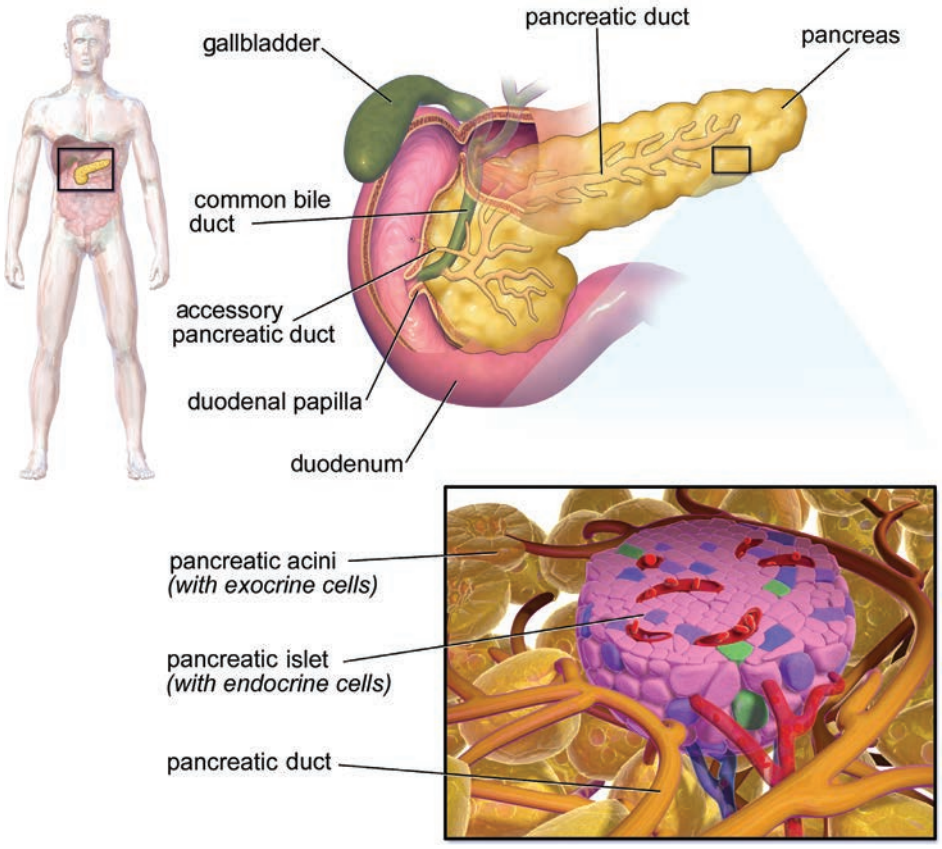

Figure 5.10. Gross and Microscopic Anatomy of the Pancreas
Islets of Langerhans are scattered throughout the pancreas and serve the endocrine function of the organ.

Glucagon

Glucagon is secreted during times of fasting. When glucose levels run low, the secretion of glucagon stimulates degradation of protein and fat, conversion of glycogen to glucose, and production of new glucose via gluconeogenesis. In addition to low blood glucose concentrations, certain gastrointestinal hormones (such as cholecystokinin and gastrin) increase glucagon release from α-cells. When blood glucose concentrations are high, glucagon release is inhibited.

Insulin

Insulin is antagonistic to glucagon and is therefore secreted when blood glucose levels are high, as shown in Figure 5.11. Insulin induces muscle and liver cells to take up glucose and store it as glycogen for later use. In addition, because it is active when glucose levels are high, insulin stimulates anabolic processes such as fat and protein synthesis.

Mnemonic

Glucagon levels are high when **glucose** is **gone.**

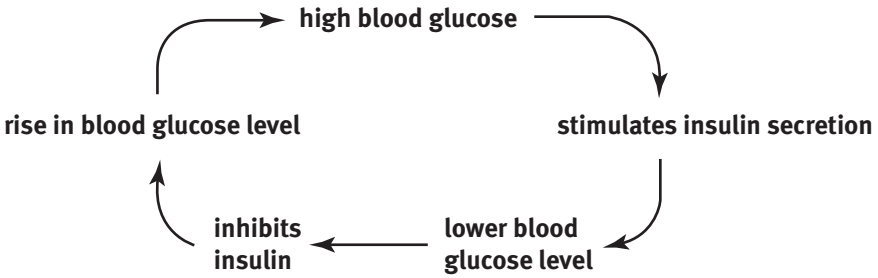

Figure 5.11. Insulin Has a Direct Relationship with Blood Glucose Concentration
When blood glucose levels are high, insulin levels rise, causing cells to take up glucose from the blood; when blood glucose levels are low, insulin levels remain low as well.

Key Concept

Insulin decreases plasma glucose. Glucagon increases plasma glucose. Growth hormone, glucocorticoids, and epinephrine are also capable of increasing plasma glucose. These hormones that raise blood glucose levels are commonly called counterregulatory hormones.

In excess, insulin will cause **hypoglycemia**, which is characterized by low blood glucose concentration. Underproduction, insufficient secretion, or insensitivity to insulin all can result in **diabetes mellitus**, which is clinically characterized by **hyperglycemia** (excess glucose in the blood). In the kidneys, excessive glucose in the filtrate will overwhelm the nephron's ability to reabsorb glucose, resulting in its presence in the urine. Because it is an osmotically active particle and does not readily cross the cell membrane, the presence of glucose in the filtrate leads to excess excretion of water and an increase—that is sometimes quite dramatic—of the urine volume. Diabetics often report **polyuria** (increased frequency of urination) and **polydipsia** (increased thirst). There are two types of diabetes mellitus. **Type I** (insulin-dependent) diabetes mellitus is caused by autoimmune destruction of the β-cells of the pancreas; these individuals produce little to no insulin because the majority of β-cells have been destroyed. Type I diabetics require regular injections of insulin to prevent hyperglycemia and to permit entry of glucose into cells. **Type II** (non-insulin-dependent) diabetes mellitus is the result of receptor-level resistance to the effects of insulin. Type II diabetes mellitus is partially inherited and partially due to environmental factors, such as high-carbohydrate diets and obesity. Certain pharmaceutical agents can be taken orally to help the body more effectively use the insulin it produces. These individuals require insulin only when their bodies can no longer control glucose levels, even when aided by these medications.

Somatostatin

Somatostatin is an inhibitor of both insulin and glucagon secretion. High blood glucose and amino acid concentrations stimulate its secretion. Somatostatin is also produced by the hypothalamus, where it functions to decrease growth hormone secretion in addition to its effects on insulin and glucagon.

GONADS

Because reproductive endocrinology is discussed in detail in Chapter 2 of *MCAT Biology Review*, we offer only a brief overview in this chapter. The **testes** secrete testosterone in response to stimulation by gonadotropins (LH and FSH). Testosterone

causes sexual differentiation of the male during gestation and also promotes the development and maintenance of secondary sex characteristics in males, such as axillary and pubic hair, deepening of the voice, and muscle growth.

The **ovaries** secrete estrogen and progesterone in response to gonadotropins. Estrogen is involved in development of the female reproductive system during gestation and also promotes the development and maintenance of secondary sex characteristics in females, such as axillary and pubic hair, breast growth, and body fat redistribution. These two steroid hormones also govern the menstrual cycle as well as pregnancy.

PINEAL GLAND

The **pineal gland** is located deep within the brain, where it secretes the hormone **melatonin**. The precise mechanism of this hormone is unclear, although it has been demonstrated to be involved in **circadian rhythms**. Blood levels of melatonin are at least partially responsible for the sensation of sleepiness. The pineal gland receives projections directly from the retina, but is not involved in vision; it is hypothesized that the pineal gland responds to decreases in light intensity by releasing melatonin.

Real World

Melatonin has enjoyed somewhat of a wonder drug status over the past decade as it is touted as a remedy for everything from jet lag to aging. Certainly, one effect of melatonin is to cause overwhelming drowsiness, supporting its utility for "resetting" one's daily rhythm. Melatonin is available over the counter in health food stores, but the long-term effects of melatonin therapy are currently unknown.

OTHER ORGANS

In addition to the organs listed above, specific cells and tissues in other organs are capable of endocrine signaling. In the gastrointestinal tract, endocrine tissue can be found in both the stomach and intestine. Many gastrointestinal peptides have been identified; important ones include secretin, gastrin, and cholecystokinin. The specific functions of these hormones are discussed in Chapter 9 of *MCAT Biology Review*, but as we might expect for the digestive system, the stimulus for release of most of these peptides is the presence of specific nutrients.

The kidneys play a role in water balance. As mentioned earlier, ADH increases water permeability in the collecting duct, and the renin–angiotensin–aldosterone system increases sodium and water reabsorption in the distal convoluted tubule and collecting duct. The kidneys also produce **erythropoietin**, which stimulates bone marrow to increase production of erythrocytes (red blood cells). It is secreted in response to low oxygen levels in the blood.

The heart releases **atrial natriuretic peptide** (**ANP**) to help regulate salt and water balance. When cells in the atria are stretched from excess blood volume, they release ANP. This hormone promotes excretion of sodium and therefore increases urine volume. This effect is functionally antagonistic to aldosterone because it lowers blood volume and pressure, and has no effect on blood osmolarity.

The thymus, located directly behind the sternum, releases **thymosin**, which is important for proper T-cell development and differentiation. The thymus atrophies by adulthood, and thymosin levels drop accordingly. The function of T-cells is discussed in Chapter 8 of *MCAT Biology Review*.

A full list of hormones and their actions can be found in Table 5.1 below.

Hormone	Source	Type	Action
Follicle-stimulating hormone (FSH)	Anterior pituitary	Peptide	Stimulates follicle maturation in females; spermatogenesis in males
Luteinizing hormone (LH)		Peptide	Stimulates ovulation in females; testosterone synthesis in males
Adrenocorticotropic hormone (ACTH)		Peptide	Stimulates the adrenal cortex to synthesize and secrete glucocorticoids
Thyroid-stimulating hormone (TSH)		Peptide	Stimulates the thyroid to produce thyroid hormones
Prolactin		Peptide	Stimulates milk production and secretion
Endorphins		Peptide	Decrease sensation of pain; can promote euphoria
Growth hormone (GH)		Peptide	Stimulates bone and muscle growth; raises blood glucose levels
Antidiuretic hormone (ADH; vasopressin)	Hypothalamus (released by posterior pituitary)	Peptide	Stimulates water reabsorption in kidneys by increasing permeability of collecting duct
Oxytocin		Peptide	Stimulates uterine contractions during labor and milk secretion during lactation; may promote bonding behavior
Triiodothyronine (T_3) and thyroxine (T_4)	Thyroid (follicular cells)	Amino acid-derivative	Stimulate metabolic activity
Calcitonin	Thyroid (parafollicular or C cells)	Peptide	Decreases blood calcium concentrations
Parathyroid hormone (PTH)	Parathyroids	Peptide	Increases blood calcium concentrations

Table 5.1. Major Hormones in Humans

Glucocorticoids (cortisol and cortisone)	Adrenal cortex	Steroid	Increase blood glucose concentrations; decrease protein synthesis; anti-inflammatory
Mineralo-corticoids (aldosterone)		Steroid	Increase water reab-sorption in the kidneys by increasing sodium reabsorption; promote potassium and hydrogen ion excretion
Epinephrine and norepi-nephrine	Adrenal medulla	Amino acid-derivative	Increase blood glucose concentrations and heart rate; dilate bronchi; alter blood flow patterns
Glucagon	Pancreas (α-cells)	Peptide	Stimulates glycogen breakdown (glycogen-olysis); increases blood glucose concentrations
Insulin	Pancreas (β-cells)	Peptide	Lowers blood glucose concentrations and increases anabolic pro-cesses
Somatostatin	Pancreas (δ-cells)	Peptide	Suppresses secretion of glucagon and insulin
Testosterone	Testis (and adrenal cortex)	Steroid	Develops and maintains male reproductive system and male secondary sex characteristics
Estrogen	Ovary (and placenta)	Steroid	Develops and maintains female reproductive sys-tem and female second-ary sex characteristics
Progesterone		Steroid	Promotes maintenance of the endometrium
Melatonin	Pineal gland	Peptide	Involved in circadian rhythms
Erythropoietin	Kidney	Peptide	Stimulates bone marrow to produce erythrocytes
Atrial natriuretic peptide (ANP)	Heart (atria)	Peptide	Promotes salt and water excretion
Thymosin	Thymus	Peptide	Stimulates T-cell develop-ment

Table 5.1. (Continued)

MCAT Concept Check 5.2:

Before you move on, assess your understanding of the material with these questions.

1. For each of the hypothalamic releasing hormones listed below, what hormone(s) does each affect in the anterior pituitary? On which organ does each pituitary hormone act? What hormone(s) are released by the target organs?

Hypothalamic Releasing Hormone	Hormone(s) from Anterior Pituitary	Target Organ	Hormone(s) Released by Target Organ
Gonadotropin-releasing hormone (GnRH)			
Corticotropin-releasing factor (CRF)			
Thyroid-releasing hormone (TRH)			
Dopamine			N/A
Growth hormone-releasing hormone (GHRH)			N/A

2. Which two hormones are primarily involved in calcium homeostasis? Where does each come from, and what effect does each have on blood calcium concentrations?

   - _____
     _____
   - _____
     _____

3. Which endocrine tissue synthesizes catecholamines? What are the two main catecholamines it produces?

   _____

4. Which two pancreatic hormones are the major drivers of glucose homeostasis? Where does each come from, and what effect does each have on blood glucose concentrations?

   - _____
     _____

- _____

_____

5. Which three hormones are primarily involved in water homeostasis? Where does each come from, and what effect does each have on blood volume and osmolarity?

- _____

_____

- _____

_____

- _____

_____

Conclusion

The endocrine system is unique because its organs are not anatomically related. Hormones are produced in a wide variety of locations and can have wide-reaching effects throughout the entire organism. The endocrine system allows for integration and execution of the homeostatic parameters that are necessary to ensure proper functioning of the body as a whole. For example, we learned that calcium is maintained within a narrow concentration range in the plasma by the antagonistic actions of calcitonin and parathyroid hormone (and vitamin D). Each hormone manipulates the steady state of the organism. As you continue your study of the human body, you will find that the endocrine system participates in every system of the body by regulating fuel metabolism, bloodflow, growth, and development.

In the last section of this chapter, there was a small note on erythropoietin, the hormone that stimulates the production of red blood cells in the bone marrow. Don't interpret the small amount of real estate afforded to this hormone as an indication that it is unimportant to the functioning of the body. In fact, every cell of the body (except red blood cells themselves) needs a constant supply of oxygen to accomplish its function. Our bodies acquire this oxygen through the respiratory system and then carry the oxygen to all of the tissues using the circulatory system. In the next two chapters, we will explore each of these systems separately. Recognize, however, that this division is artificial; indeed, like the body as a whole, the respiratory and circulatory systems are indivisible as they serve a common function: providing oxygen for every working cell in the body.

CONCEPT SUMMARY

Mechanisms of Hormone Action

- Endocrine signaling involves the secretion of **hormones** directly into the bloodstream. The hormones travel to distant target tissues, where they bind to receptors and induce a change in gene expression or cell function.
- **Peptide hormones** are composed of amino acids and are derived from larger precursor proteins that are cleaved during posttranslational modification.
  - Peptide hormones are polar and cannot pass through the plasma membrane.
  - These hormones bind to extracellular receptors, where they trigger the transmission of a **second messenger**.
  - Each step of the **signaling cascade** can demonstrate **amplification** of the signal.
  - Peptide hormones usually have rapid onset but are short-lived.
  - These hormones travel freely in the bloodstream and do not require a special carrier.
- **Steroid hormones** are derived from cholesterol.
  - Steroid hormones are minimally polar and can pass through the plasma membrane.
  - These hormones bind to and promote a conformational change of intracellular or intranuclear receptors; the hormone–receptor complex binds to DNA, affecting the transcription of a particular gene.
  - Steroid hormones usually have slow onset but are long-lived.
  - These hormones cannot dissolve in the bloodstream and must be carried by specific proteins.
- **Amino acid-derivative hormones** are modified amino acids.
  - Their chemistry shares some features with peptide hormones and some features with steroid hormones; different amino acid-derivative hormones share different features with these other hormone classes.
  - Common examples are epinephrine, norepinephrine, triiodothyronine, and thyroxine.
- Hormones can be classified by their target tissues.
  - **Direct hormones** have major effects in non-endocrine tissues.
  - **Tropic hormones** have major effects in other endocrine tissues.

Endocrine Organs and Hormones

- The hypothalamus is the bridge between the nervous and endocrine systems.
  - The release of hormones from the hypothalamus is mediated by a number of factors, including projections from other parts of the brain, chemo- and baroreceptors in the blood vessels, and negative feedback from other hormones.
  - In **negative feedback**, the final hormone (or product) of a pathway inhibits hormones (or enzymes) earlier in the pathway, maintaining **homeostasis**.
  - The hypothalamus stimulates the anterior pituitary gland through paracrine release of hormones into the hypophyseal portal system, which directly connects the two organs.
  - **Gonadotropin-releasing hormone** (**GnRH**) promotes the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
  - **Growth hormone-releasing hormone** (**GHRH**) promotes the release of growth hormone.
  - **Thyroid-releasing hormone** (**TRH**) promotes the release of thyroid-stimulating hormone (TSH).
  - **Corticotropin-releasing factor** (**CRF**) promotes the release of adrenocorticotropic hormone (ACTH).
  - **Prolactin-inhibiting factor** (**PIF** or **dopamine**) inhibits the release of prolactin.
  - Interactions with the posterior pituitary occur via the axons of nerves in the hypothalamus. Antidiuretic hormone (ADH or vasopressin) and oxytocin are synthesized in the hypothalamus and then travel down these axons to the posterior pituitary, where they are released into the bloodstream.
- The **anterior pituitary** releases hormones in response to stimulation from the hypothalamus. Four of these (FSH, LH, ACTH, and TSH) are tropic hormones, while three (prolactin, endorphins, and growth hormone) are direct hormones.
  - **Follicle-stimulating hormone** (**FSH**) promotes the development of ovarian follicles in females and spermatogenesis in males.
  - **Luteinizing hormone** (**LH**) promotes ovulation in females and testosterone production in males.
  - **Adrenocorticotropic hormone** (**ACTH**) promotes synthesis and release of glucocorticoids from the adrenal cortex.
  - **Thyroid-stimulating hormone** (**TSH**) promotes synthesis and release of triiodothyronine and thyroxine from the thyroid.
  - **Prolactin** promotes milk production.

- **Endorphins** decrease perception of pain and can cause euphoria.
- **Growth hormone** (**GH**) promotes growth of bone and muscle and shunts glucose to these tissues. It raises blood glucose concentrations.

- The **posterior pituitary** releases two hormones produced in the hypothalamus.
  - **Antidiuretic hormone** (**ADH** or **vasopressin**) is secreted in response to low blood volume or increased blood osmolarity and increases reabsorption of water in the collecting duct of the nephron, increasing blood volume and decreasing blood osmolarity.
  - **Oxytocin** is secreted during childbirth and promotes uterine contractions. It also promotes milk ejection and may be involved in bonding behavior. It is unusual in that it has a **positive feedback** loop, not negative.
- The **thyroid** is located at the base of the neck in front of the trachea; it produces three key hormones.
  - **Triiodothyronine** (**T_3**) and **thyroxine** (**T_4**) are produced by **follicular cells** and contain iodine. They increase basal metabolic rate and alter the utilization of glucose and fatty acids. Thyroid hormones are required for proper neurological and physical development in children.
  - **Calcitonin** is produced by **parafollicular** (**C**) **cells**. It decreases plasma calcium concentration by promoting calcium excretion in the kidneys, decreasing calcium absorption in the gut, and promoting calcium storage in bone.
- The **parathyroid glands** release **parathyroid hormone** (**PTH**), which increases blood calcium concentration.
  - PTH decreases excretion of calcium by the kidneys and increases bone resorption directly to increase blood calcium concentration.
  - PTH activates vitamin D, which is necessary for calcium and phosphate absorption from the gut.
  - PTH promotes resorption of phosphate from bone and reduces reabsorption of phosphate in the kidney, but vitamin D promotes absorption of phosphate from the gut; these two effects on phosphate concentration somewhat cancel each other.
- The **adrenal cortex** produces three classes of steroid hormones.
  - **Glucocorticoids** such as **cortisol** and **cortisone** increase blood glucose concentration, reduce protein synthesis, inhibit the immune system, and participate in the stress response. Glucocorticoid release is stimulated by ACTH.
  - **Mineralocorticoids** such as **aldosterone** promote sodium reabsorption in the distal convoluted tubule and collecting duct, thus increasing water reabsorption. Aldosterone also increases potassium and hydrogen ion excretion. It is regulated by the **renin–angiotensin–aldosterone system**, not ACTH.

- **Cortical sex hormones** include **androgens** (like **testosterone**) and **estrogens** in both males and females.

- The **adrenal medulla** is derived from the nervous system and secretes catecholamines into the bloodstream.
  - **Catecholamines** include **epinephrine** and **norepinephrine**, which are involved in the fight-or-flight (sympathetic) response.
  - These hormones promote glycogenolysis, increase the basal metabolic rate, increase heart rate, dilate the bronchi, and alter blood flow.
- The endocrine **pancreas** produces hormones that regulate glucose homeostasis.
  - **Glucagon** is produced by **α-cells** and raises blood glucose levels by stimulating protein and fat degradation, glycogenolysis, and gluconeogenesis.
  - **Insulin** is produced by **β-cells** and lowers blood glucose levels by stimulating glucose uptake by cells and anabolic processes, like glycogen, fat, and protein synthesis.
  - **Somatostatin** is produced by **δ-cells** and inhibits insulin and glucagon secretion.
- The gonads produce hormones that are involved in development and maintenance of the reproductive systems and secondary sex characteristics.
  - The **testes** secrete **testosterone**.
  - The **ovaries** secrete **estrogen** and **progesterone**.
- The **pineal gland** releases **melatonin**, which helps to regulate **circadian rhythms**.
- Other organs may release hormones, even if they are not primarily considered part of the endocrine system.
  - Cells in the stomach and intestine produce hormones like **secretin**, **gastrin**, and **cholecystokinin**.
  - The kidneys secrete **erythropoietin**, which stimulates bone marrow to produce erythrocytes (red blood cells) in response to low oxygen levels in the blood.
  - The atria of the heart secrete **atrial natriuretic peptide** (**ANP**), which promotes excretion of salt and water in the kidneys in response to stretching of the atria (high blood volume).
  - The thymus secretes **thymosin**, which is important for proper T-cell development and differentiation.

ANSWERS TO CONCEPT CHECKS

5.1

1.

Criterion	Peptide Hormones	Steroid Hormones
Chemical precursor	Amino acids (polypeptides)	Cholesterol
Location of receptor	Extracellular (cell membrane)	Intracellular or intranuclear
Mechanism of action	Stimulates a receptor (usually a G protein-coupled receptor), affecting levels of second messengers (commonly cAMP). Initiates a signal cascade.	Binds to a receptor, induces conformational change, and regulates transcription at the level of the DNA.
Method of travel in the bloodstream	Dissolves and travels freely	Binds to a carrier protein
Rapidness of onset	Quick	Slow
Duration of action	Short-lived	Long-lived

2. Amino acid-derivative hormones are made by modifying amino acids, such as the addition of iodine to tyrosine (in thyroid hormone production).
3. Direct hormones are secreted into the bloodstream and travel to a target tissue, where they have direct effects. Tropic hormones cause secretion of another hormone that then travels to the target tissue to cause an effect.

5.2

1.

Hypothalamic Releasing Hormone	Hormone(s) from Anterior Pituitary	Target Organ	Hormone(s) Released by Target Organ
Gonadotropin-releasing hormone (GnRH)	Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)	Gonads (testes or ovaries)	Testosterone (testes) or estrogen and progesterone (ovaries)
Corticotropin-releasing factor (CRF)	Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Glucocorticoids (cortisol and cortisone)
Thyroid-releasing hormone (TRH)	Thyroid-stimulating hormone (TSH)	Thyroid	Triiodothyronine (T_3), thyroxine (T_4)
Dopamine	Prolactin*	Breast tissue	N/A
Growth hormone-releasing hormone (GHRH)	Growth hormone	Bone, muscle	N/A

*Note that a *decrease* in dopamine from the hypothalamus promotes prolactin secretion.

2. Calcitonin from the parafollicular (C-) cells of the thyroid decreases blood calcium concentration. Parathyroid hormone from the parathyroid glands increases blood calcium concentration.
3. The adrenal medulla synthesizes catecholamines, including epinephrine and norepinephrine.
4. Glucagon from the α-cells of the pancreas increases blood glucose concentration. Insulin from the β-cells of the pancreas decreases blood glucose concentration.
5. Antidiuretic hormone (ADH or vasopressin) from the hypothalamus (released by the posterior pituitary) increases blood volume and decreases blood osmolarity. Aldosterone from the adrenal cortex increases blood volume with no effect on blood osmolarity. Atrial natriuretic peptide (ANP) from the heart decreases blood volume with no effect on blood osmolarity.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following associations between a hormone and its category is INCORRECT?

A. Aldosterone—mineralocorticoid
B. Testosterone—cortical sex hormone
C. ADH—mineralocorticoid
D. Cortisone—glucocorticoid

2. Which of the following hormones directly stimulates a target tissue that is NOT an endocrine organ?

A. ACTH
B. TSH
C. LH
D. GH

3. Increased synthetic activity of the parathyroid glands would lead to:

A. an increase in renal calcium reabsorption.
B. a decrease in the rate of bone resorption.
C. a decrease in basal metabolic rate.
D. a decrease in blood glucose concentration.

4. Which of the following statements concerning growth hormone is NOT true?

A. Overproduction of growth hormone in adults results in acromegaly.
B. It promotes growth of bone and muscle.
C. It is produced by the hypothalamus but secreted by the pituitary.
D. A childhood deficiency in growth hormone results in dwarfism.

5. Iodine deficiency may result in:

A. galactorrhea.
B. cretinism.
C. gigantism.
D. hyperthyroidism.

6. A patient has a very high TSH level. Which of the following would NOT cause a high TSH level?

A. Autoimmune destruction of thyroid cells that produce T_3 and T_4.
B. A tumor in the hypothalamus that secretes high levels of TRH.
C. High levels of T_4 from thyroid replacement medications.
D. Cancerous growth of parafollicular cells in the thyroid, destroying other cell types in the organ.

7. Which of the following hormones is NOT derived from cholesterol?

A. Aldosterone
B. Estrogen
C. Oxytocin
D. Progesterone

8. Which of the following is true regarding pancreatic somatostatin?

A. Its secretion is increased by low blood glucose.
B. It is always inhibitory.
C. It is regulated by cortisol levels.
D. It stimulates insulin and glucagon secretion.

9. Destruction of all β-cells in the pancreas would cause:

A. glucagon secretion to stop and an increase in blood glucose concentration.
B. glucagon secretion to stop and a decrease in blood glucose concentration.
C. insulin secretion to stop and an increase in blood glucose concentration.
D. insulin secretion to stop and a decrease in blood glucose concentration.

10. Which of the following is FALSE regarding aldosterone regulation?

A. Renin converts the plasma protein angiotensinogen to angiotensin I.
B. Angiotensin II stimulates the adrenal cortex to secrete aldosterone.
C. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme.
D. A decrease in blood oxygen concentrations stimulates renin production.

11. A scientist discovers a new hormone that is relatively large in size and triggers the conversion of ATP to cAMP. Which of the following best describes the type of hormone that was discovered?

A. Amino acid-derivative hormone
B. Peptide hormone
C. Steroid hormone
D. Tropic hormone

12. A patient presents with muscle weakness, slow movement, and calcium deposits in his tissues. A blood test reveals very low calcium levels in the blood. Administration of which the following would be an appropriate treatment for the blood test findings?

A. Calcitonin
B. Parathyroid hormone
C. Aldosterone
D. Thymosin

13. Oxytocin and antidiuretic hormone are:

A. peptide hormones produced and released by the pituitary.
B. steroid hormones produced and released by the pituitary.
C. peptide hormones produced by the hypothalamus and released by the pituitary.
D. steroid hormones produced by the hypothalamus and released by the pituitary.

14. Excessive levels of dopamine in the brain are associated with psychosis. Accordingly, many antipsychotic medications block dopamine receptors. Which of the following effects may be seen in an individual taking antipsychotics?

A. Increased secretion of growth hormone
B. Decreased secretion of growth hormone
C. Increased secretion of prolactin
D. Decreased secretion of prolactin

15. A genotypically female infant is born with ambiguous genitalia. Soon after birth, she suffers from hyponatremia, or low blood concentrations of sodium. Which endocrine organ is most likely to be affected?

A. Hypothalamus
B. Pituitary
C. Kidneys
D. Adrenal cortex

Explanations to Discrete Practice Questions

1. C

Unlike the other hormones listed here, ADH is not secreted by the adrenal cortex and is therefore not a *–corticoid*. Rather, ADH is a peptide hormone produced by the hypothalamus and released by the posterior pituitary that promotes water reabsorption. The other associations are all correct.

2. D

A hormone that directly stimulates a non-endocrine target tissue is referred to as a direct hormone. Glancing at the answer choices, we notice that all of the hormones are secreted by the anterior pituitary gland. The direct hormones secreted by the anterior pituitary are prolactin, endorphins, and growth hormone (GH). All of the other answer choices are tropic hormones; the tropic hormones of the anterior pituitary include follicle-stimulating hormone (FSH), luteinizing hormone (LH), adrenocorticotropic hormone (ACTH), and thyroid-stimulating hormone (TSH).

3. A

The parathyroid glands secrete parathyroid hormone (PTH), a hormone that functions to increase blood calcium levels. An increase in synthetic activity of the parathyroid glands would lead to an increase in PTH and, therefore, an increase in blood calcium levels through three mechanisms: increased calcium reabsorption in the kidneys (decreased excretion), increased bone resorption, and increased absorption of calcium from the gut (via activation of vitamin D).

4. C

Growth hormone is a direct hormone secreted by the anterior pituitary. Among its many functions, GH promotes growth in bone and muscle, eliminating **choice (B)**. An overproduction of growth hormone in children results in gigantism, whereas in adults it results in acromegaly (enlargement of the small bones in the extremities and of certain facial bones, such as the jaw), eliminating **choice (A)**. On the other hand, a childhood deficiency of growth hormone results in dwarfism, eliminating **choice (D)**. GH is synthesized and secreted in the anterior pituitary; **choice (C)** describes antidiuretic hormone and oxytocin, not GH.

5. B

Inflammation of the thyroid or iodine deficiency can cause hypothyroidism, in which the thyroid hormones are undersecreted or not secreted at all. Hypothyroidism in newborn infants causes cretinism, which is characterized by poor neurological and physical development (including mental retardation, short stature, and coarse facial features). While iodine deficiency can result in a swelling of the thyroid gland (called a goiter), which can also be seen in causes of hyperthyroidism, iodine deficiency does not cause hyperthyroidism, eliminating **choice (D)**. Galactorrhea, **choice (A)**, is associated with prolactin; gigantism, **choice (C)**, is associated with growth hormone.

6. C

The hypothalamic–pituitary–thyroid axis includes the secretion of thyroid-releasing hormone (TRH) from the hypothalamus stimulating the secretion of thyroid-stimulating hormone (TSH) from the anterior pituitary, which stimulates the secretion of triiodothyronine (T_3) and thyroxine (T_4) from the thyroid. Overproduction of TRH would promote overproduction of TSH, eliminating **choice (B)**. Destruction of the follicular cells that produce T_3 and T_4 would

remove negative feedback, allowing TSH levels to rise, eliminating **choices (A)** and **(D)**. High levels of T_4 would cause too much negative feedback and lower TSH levels, making **choice (C)** the correct answer.

7. C

Steroid hormones are derived from cholesterol. Many of their names end with *–one*, *–ol*, or *–oid*, and they include the hormones of the adrenal cortex and gonads. Aldosterone is a mineralocorticoid from the adrenal cortex, while estrogen and progesterone are sex hormones from the ovaries, eliminating **choices (A)**, **(B)**, and **(D)**. Oxytocin is a peptide hormone and is thus not derived from cholesterol. Peptide and amino acid-derivative hormones often end with *–in* or *–ine*.

8. B

Pancreatic somatostatin secretion is increased by high blood glucose or amino acid levels, leading to both decreased insulin and glucagon secretion, eliminating **choices (A)** and **(D)**. Somatostatin is thus always an inhibitory hormone, confirming **choice (B)**. The stimuli for somatostatin release include high blood glucose or amino acids, as mentioned above, as well as certain gastrointestinal hormones, as is discussed in Chapter 9 of *MCAT Biology Review*—but not cortisol, eliminating **choice (C)**.

9. C

β-cells are responsible for insulin production. The function of insulin is to lower blood glucose levels by promoting the influx of glucose into cells and by stimulating anabolic processes, such as glycogenesis or fat and protein synthesis. Thus, destruction of the β-cells would result in a cessation of insulin production, which would lead to hyperglycemia, or high blood glucose concentrations.

10. D

The stimulus for renin production is low blood pressure, which causes the juxtaglomerular cells of the kidney to produce renin, an enzyme that converts the plasma protein angiotensinogen to angiotensin I. Angiotensin I is then converted to angiotensin II by an enzyme in the lungs; angiotensin II ultimately stimulates the adrenal cortex to secrete aldosterone. Aldosterone helps to restore blood volume by increasing sodium reabsorption in the kidney, leading to an increase in water reabsorption. This removes the initial stimulus for renin production. Thus, **choices (A)**, **(B)**, and **(C)** correctly describe the renin–angiotensin–aldosterone system, while **choice (D)** describes the stimulus for erythropoietin secretion.

11. B

The question stem indicates that the newly discovered hormone functions as a first messenger, stimulating the conversion of ATP to cAMP; cAMP functions as a second messenger, triggering a signaling cascade in the cell. Hormones that act via second messengers and are relatively large in size (short peptides or complex polypeptides) are peptide hormones. This hormone could be a tropic hormone, but it is also entirely possible for it to be a direct hormone; thus, **choice (D)** can be eliminated.

12. B

Regardless of the cause, the low levels of calcium in the blood require treatment. While other therapies are more frequently used to treat hypocalcemia (low blood calcium levels), such as calcium gluconate or calcium chloride, administration of parathyroid hormone would also raise blood calcium concentration. Calcitonin would be a poor choice in this case, as this hormone lowers blood calcium concentrations, eliminating **choice (A)**. Aldosterone and thymosin play no role in calcium homeostasis, eliminating **choices (C)** and **(D)**.

13. C

Both oxytocin and vasopressin (another name for antidiuretic hormone) end with the suffix *–in*; this should hint that they are peptide or amino acid-derivative hormones. These two hormones are both synthesized by the hypothalamus, but released by the posterior pituitary. Remember that the posterior pituitary does not actually synthesize any hormones itself; rather, it contains the axons of cells originating in the hypothalamus and is the site of release for these hormones.

14. C

Dopamine is used in a number of neurological systems; most relevant to the endocrine system is the fact that dopamine secretion prevents prolactin release. Thus, an individual taking medications that block dopamine receptors would lose this inhibition on prolactin release and have elevated prolactin levels.

15. D

The question stem states that an infant who is genotypically female is born with ambiguous genitalia, meaning that the genitalia do not appear to be specifically female or specifically male. In a genotypic female, this indicates that she was exposed to androgens during the fetal period. In addition, she is also losing sodium, causing hyponatremia. This indicates that she has two defects. First, she has excess androgens. Second, she is lacking in aldosterone, a hormone required for proper reuptake of sodium in the kidneys. Both of these hormones are synthesized in the adrenal cortex, making **choice (D)** the correct answer. Note that neither of these hormones is regulated by the hypothalamic–pituitary–adrenal axis, eliminating **choices (A)** and **(B)**.

MCAT Expertise

You may be surprised at the low Star Rating of this chapter, given that this chapter touches on several classic MCAT topics, such as pressure, gases, and equilibrium. And you may well see questions on your MCAT that ask about, for instance, the work done on air in the lungs. However, a question like that would depend much more on your general knowledge of work, energy, and gases (regardless of context) than your knowledge of the respiratory system specifically.

Introduction

Coughing. Fever. Shortness of breath. Hypoxia. All are symptoms of a number of pulmonary diseases, from a flare of *chronic obstructive pulmonary disease* (COPD) to *Streptococcus pneumoniae* (pneumococcal) pneumonia to a type of hypersensitivity pneumonitis also known as *extrinsic allergic alveolitis* (EAA). This last example is a bit more esoteric, and can be brought on by hypersensitivity to anything from dried grass to rat urine to mold that grows in hot tubs—what is sometimes called *hot tub lung*. Not all cases of hot tub lung are severe, but certainly none are enjoyable. They're often misdiagnosed as asthma or bronchitis, and may be treated with steroids, which quell the immune system and reduce the inflammation associated with this illness. Because hot tub lung can potentially go away by itself, antibiotic therapy is not always recommended. As a physician, you may end up simply having to tell your patients that the best way to avoid hot tub lung is to make sure that the tub is cleaned properly and routinely before use.

The lesson here isn't to avoid hot tubs. It's that the lungs are essential, sensitive organs with delicate membranes that must be protected. Many types of stressors (pathogens, particles, or chemicals) can irritate them and cause respiratory distress. In this chapter, we'll look at the structure of the lungs and the microanatomy of respiration. We'll also talk about the mechanics of breathing as well as the overall function of the lungs.

6.1 Anatomy and Mechanism of Breathing

The lungs are located in the **thoracic cavity**, the structure of which is specially designed to perform breathing.

ANATOMY

Key Concept

The nose and mouth serve several important purposes in breathing by removing dirt and particulate matter from the air and warming and humidifying it before it reaches the lungs.

The anatomy of the respiratory system is summarized in Figure 6.1. Gas exchange occurs in the lungs. Air enters the respiratory tract through the external **nares** of the nose and then passes through the nasal cavity, where it is filtered by mucous membranes and nasal hairs (**vibrissae**).

Next, air passes into the pharynx and the larynx. The **pharynx** resides behind the nasal cavity and at the back of the mouth; it is a common pathway for both air destined for the lungs and food destined for the esophagus. In contrast, the **larynx** lies below the pharynx and is only a pathway for air. To keep food out of the respiratory tract, the opening of the larynx (**glottis**) is covered by the **epiglottis** during swallowing. The larynx contains two **vocal cords** that are maneuvered using skeletal muscle and cartilage. From the larynx, air passes into the cartilaginous **trachea** and then into one of the two mainstem **bronchi**. The bronchi and trachea contain ciliated epithelial cells to catch material that has made it past the mucous membranes in the nose and mouth.

Real World

The left lung has a small indentation, making it slightly smaller than the right lung. It also contains only two lobes, while the right lung contains three. Why might this be? It is due to the position of the heart in the thoracic cavity.

In the **lungs**, the bronchi continue to divide into smaller structures known as **bronchioles**, which divide further until they end in the tiny balloon-like structures in which gas exchange occurs (**alveoli**). Each alveolus is coated with **surfactant**, a detergent that lowers surface tension and prevents the alveolus from collapsing on itself. A network of capillaries surrounds each alveolus to carry oxygen and carbon

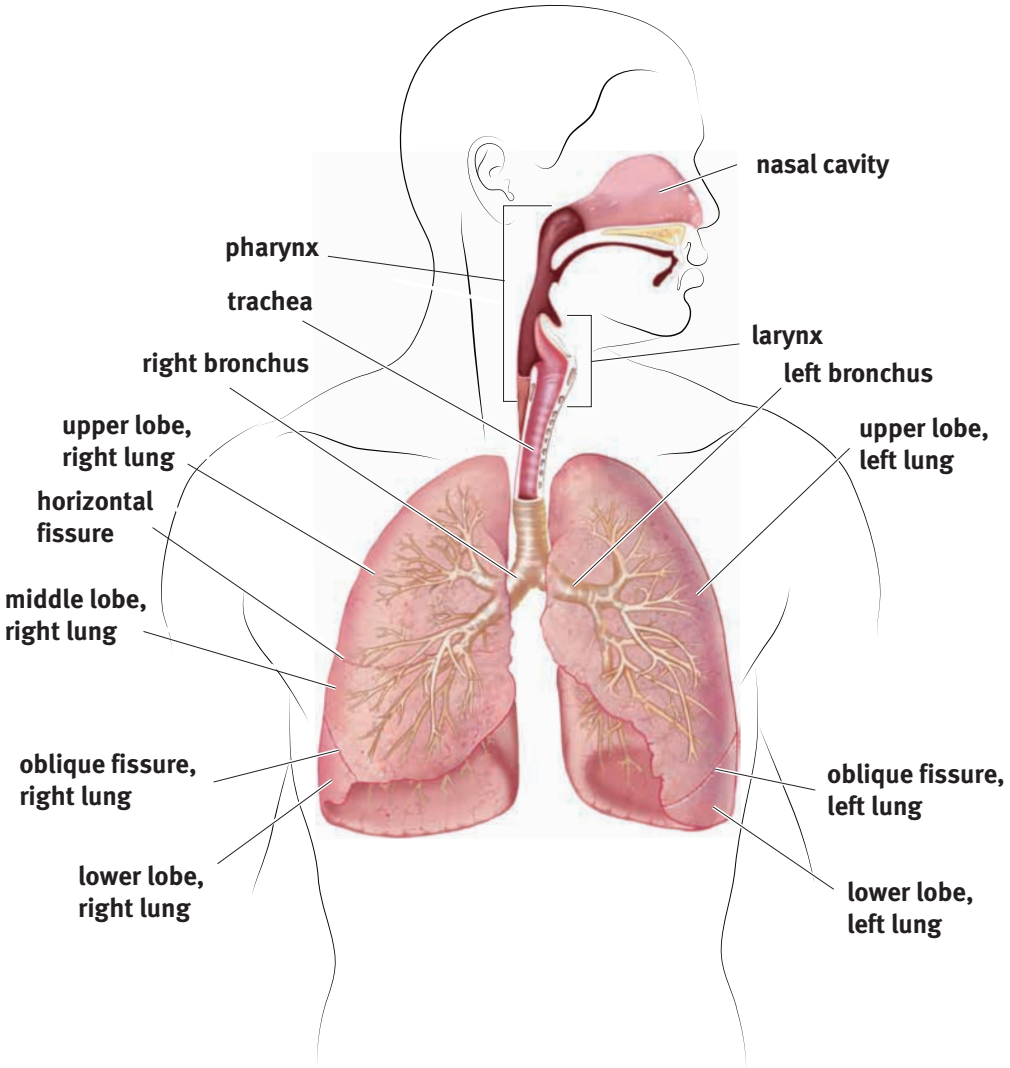

Figure 6.1. Anatomy of the Respiratory System

dioxide. The branching and minute size of the alveoli allow for an exceptionally large surface area for gas exchange—approximately 100 m^2.

The lungs themselves are contained in the thoracic cavity, which also contains the heart. The chest wall forms the outside of the thoracic cavity. Membranes known as **pleurae** surround each lung, as shown in Figure 6.2. The pleura forms a closed sac against which the lung expands. The surface adjacent to the lung is the **visceral pleura**, and the outer part is the **parietal pleura**.

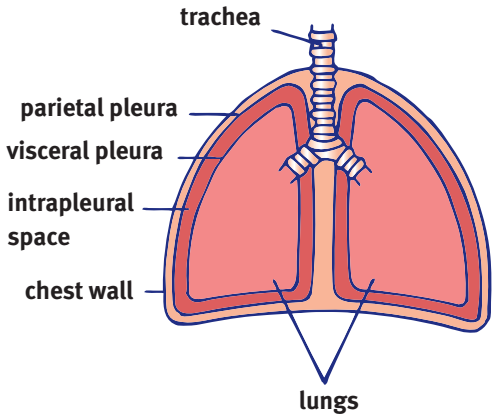

Figure 6.2. Lung Membranes

The lungs do not fill passively and require skeletal muscle to generate the negative pressure for expansion. The most important of these muscles is the **diaphragm**, a thin, muscular structure that divides the thoracic (chest) cavity from the abdominal cavity. The diaphragm is under somatic control, even though breathing itself is under autonomic control. In addition, muscles of the chest wall, back, and neck may also participate in breathing, especially when breathing is labored due to a pathologic condition.

BREATHING

Before we discuss breathing itself, it is worth taking a closer look at the relationship between the pleura and the lungs. Imagine that you have a large, partially deflated balloon. Now, imagine taking your fist and pushing it against the balloon so that the balloon comes up and surrounds your hand. This is analogous to a lung and its pleura. Our fist is the lung, and the balloon represents both pleural layers. The side directly touching our fist is the visceral pleura, and the outer layer is the parietal pleura, which is associated with the chest wall in real life. The space within the sac is referred to as the **intrapleural space**, which contains a thin layer of fluid. This pleural fluid helps lubricate the two pleural surfaces. The pressure differentials that can be created across the pleura ultimately drive breathing, as we explore in the next section.

Let's turn to the mechanics of ventilation, which are grounded in physics. As discussed in Chapters 2 and 3 of *MCAT Physics and Math Review*, we can use pressure to do useful work in a system. Here, we use pressure differentials between the intrapleural space and the lungs to drive air into the lungs.

Real World

The intrapleural space is an example of a potential space—a space that is normally empty or collapsed. In some pathologic states, that potential space can be expanded by fluid or air that accumulates between the two pleural layers. For example, in a pleural effusion, fluid accumulates in the intrapleural space. In a pneumothorax, air collects here. Each of these states disturbs the normal mechanics of the breathing apparatus and can cause atelectasis, or lung collapse.

Inhalation

Inhalation is an active process. We use our diaphragm as well as the **external intercostal muscles** (one of the layers of muscles between the ribs) to expand the thoracic cavity, as shown in Figure 6.3. As the diaphragm flattens and the chest wall expands outward, the **intrathoracic volume** (the volume of the chest cavity) increases. Specifically, because the intrapleural space most closely abuts the chest wall, its volume increases first. Can we predict what will happen to intrapleural pressure? From our understanding of Boyle's law, an increase in intrapleural volume leads to a decrease in intrapleural pressure.

Now we have low pressure in the intrapleural space. What about inside the lungs? The gas in the lungs is initially at atmospheric pressure, which is now higher than the pressure in the intrapleural space. The lungs will therefore expand into the intrapleural space, and the pressure in the lungs will drop. Air will then be sucked in from a higher-pressure environment—the outside world. This mechanism is referred to as **negative-pressure breathing** because the driving force is the lower (relatively negative) pressure in the intrapleural space compared with the lungs.

Bridge

Boyle's law states that, at a constant temperature, the pressure and volume of gases are inversely related. This is the principle underlying negative-pressure breathing: as the chest wall expands, the pressure in the lungs drops, and air is drawn into the lungs.

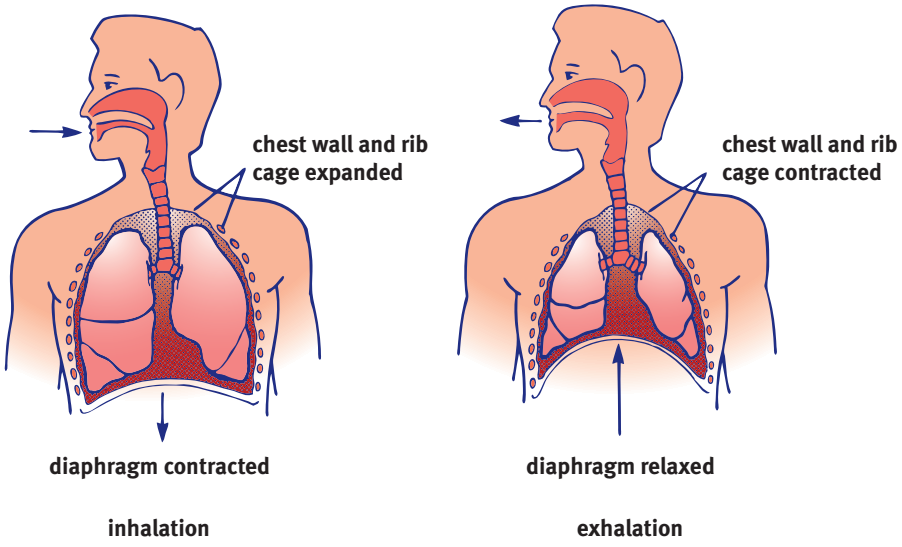

Figure 6.3. Stages of Ventilation
The diaphragm contracts during inhalation and relaxes during exhalation.

Key Concept

Inhalation and exhalation require different amounts of energy expenditure. Muscle contraction is required to create the negative pressure in the thoracic cavity that forces air into the lungs during inspiration. Expiration during calm states is entirely due to elastic recoil of the lungs and the musculature. During more active states, the muscles can be used to force air out and speed up the process of ventilation.

Exhalation

Unlike inhalation, exhalation does not have to be an active process. Simple relaxation of the external intercostal muscles will reverse the processes we discussed in the last paragraph. As the diaphragm and external intercostals relax, the chest cavity decreases in volume. What will happen to pressure in the intrapleural space? It will go up, again explained by Boyle's law. Now pressure in the intrapleural space is higher than in the lungs, which is still at atmospheric pressure. Thus, air will be pushed out, resulting in exhalation. During active tasks, we can speed this process up by using the **internal intercostal muscles** and abdominal muscles, which oppose the external intercostals and pull the rib cage down. This actively decreases the volume of the thoracic cavity. Finally, recall that surfactant prevents the complete collapse of the alveoli during exhalation by reducing surface tension at the alveolar surface.

Real World

Emphysema is a disease characterized by the destruction of the alveolar walls. This results in reduced elastic recoil of the lungs, making the process of exhalation extremely difficult. Most cases of emphysema are caused by cigarette smoking.

Remember the balloon analogy from before. The lungs have a resilient, elastic quality and are attached via the pleurae to the chest wall. The chest wall expands on inhalation, pulling the lungs with it and creating the pressure differential required for inhalation. As the chest wall relaxes, the lungs recoil due to the intrinsic elastic quality of the lungs and surface tension in the alveoli, accentuating the relaxation process. When the lungs recoil, their volume becomes smaller, and the pressure increases. Now the pressure inside the lungs is higher than the outside pressure, and exhalation occurs. Note that the indirect connection of the lungs to the chest wall also prevents them from collapsing completely on recoil, like surfactant.

LUNG CAPACITIES AND VOLUMES

In pulmonology (the medical field associated with the lungs and breathing), we frequently must assess lung capacities and volumes—but we don't have the luxury of removing an individual's lungs to do so. One instrument used to measure these quantities is a **spirometer**. While a spirometer cannot measure the amount of air remaining in the lung after complete exhalation (residual volume), it provides a number of measures that are useful in clinical medicine.

Commonly tested lung volumes include:

- **Total lung capacity** (**TLC**): The maximum volume of air in the lungs when one inhales completely; usually around 6 to 7 liters
- **Residual volume** (**RV**): The minimum volume of air in the lungs when one exhales completely
- **Vital capacity** (**VC**): The difference between the minimum and maximum volume of air in the lungs (TLC – RV)

- **Tidal volume** (**TV**): The volume of air inhaled or exhaled in a normal breath
- **Expiratory reserve volume** (**ERV**): The volume of additional air that can be forcibly exhaled after a normal exhalation
- **Inspiratory reserve volume** (**IRV**): The volume of additional air that can be forcibly inhaled after a normal inhalation

These different lung volumes and capacities can be seen in Figure 6.4.

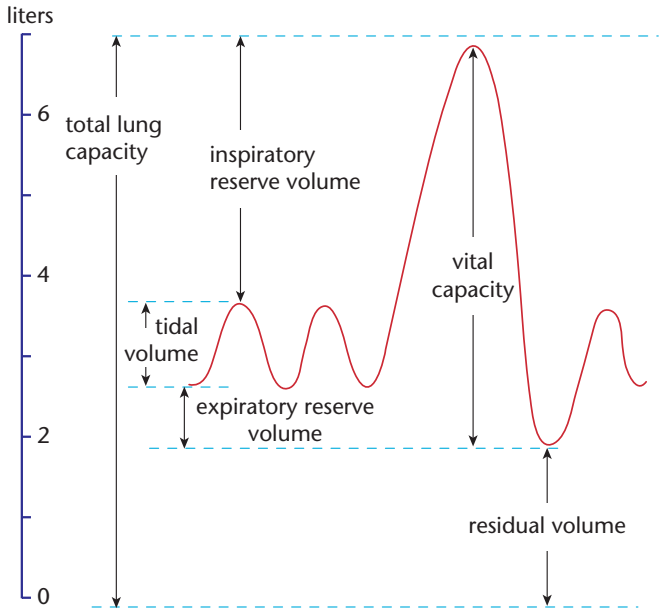

Figure 6.4. Lung Volumes

REGULATION OF BREATHING

Breathing requires input from our nervous control center. Ventilation is primarily regulated by a collection of neurons in the medulla oblongata called the **ventilation center** that fire rhythmically to cause regular contraction of respiratory muscles. These neurons contain **chemoreceptors** that are primarily sensitive to carbon dioxide concentration. As the partial pressure of carbon dioxide in the blood rises (**hypercarbia** or **hypercapnia**), the **respiratory rate** will increase so that more carbon dioxide is exhaled, and carbon dioxide levels in the blood will fall. These cells also respond to changes in oxygen concentration, although this tends to have significance only during periods of significant **hypoxemia** (low oxygen concentration in the blood).

We can, to a limited extent, control our breathing through the cerebrum. We can choose to breathe more rapidly or slowly; however, extended periods of hypoventilation would lead to increased carbon dioxide levels and an override by the medulla oblongata (which would jump-start breathing). The opposite process (hyperventilation) would blow off too much carbon dioxide and ultimately inhibit ventilation.

MCAT Concept Check 6.1:
Before you move on, assess your understanding of the material with these questions.

1. List the structures in the respiratory pathway, from where air enters the nares to the alveoli.

   _____

2. Which muscle(s) are involved in inhalation? Exhalation?
   - Inhalation:

     _____

   - Exhalation:

     _____

3. What is the purpose of surfactant?

   _____

4. What is the mathematical relationship between vital capacity (VC), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and tidal volume (TV)?

   _____

5. If blood levels of CO_2 become too low, how does the brain alter the respiratory rate to maintain homeostasis?

   _____

6.2 Functions of the Respiratory System

No organ system functions alone. The lungs function in gas exchange, but this is only part of the respiratory story. The lungs are lined with a tremendous number of capillaries that can also be used in thermoregulation. The lungs also represent a pathway into the body and serve an immune function to prevent invaders from gaining access to the bloodstream. Finally, as we touched on already, the lungs also allow for control of blood pH by controlling carbon dioxide concentrations. Therefore, the lungs are integrated with many other body systems, including the cardiovascular, immune, renal, and nervous systems.

GAS EXCHANGE

Gas exchange is, of course, the primary function of the lungs. Each alveolus is surrounded by a network of capillaries. The capillaries bring deoxygenated blood from the **pulmonary arteries**, which originate from the right ventricle of the heart. The walls of the alveoli are only one cell thick, which facilitates diffusion of carbon dioxide from the blood into the lungs and oxygen into the blood. The oxygenated blood returns to the left atrium of the heart via the **pulmonary veins**.

The driving force for gas exchange is the pressure differential of the gases. When it initially arrives at the alveoli, blood has a relatively low partial pressure of oxygen and a relatively high partial pressure of carbon dioxide, facilitating transfer of each down its respective concentration gradient, as shown in Figure 6.5. Because the gradient between the blood and air in the lungs is already present as the blood enters the lungs, no energy is required for gas transfer.

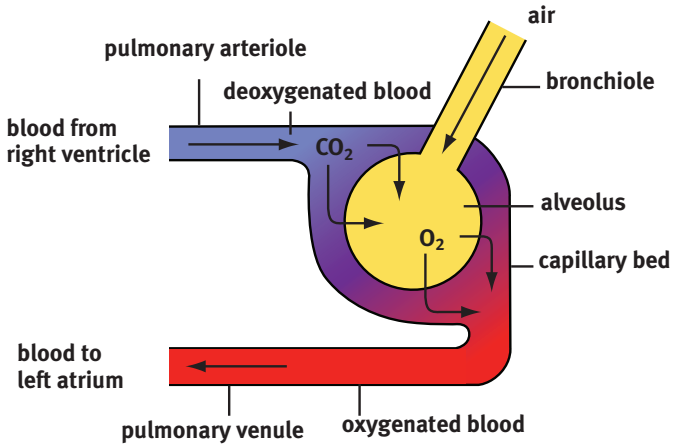

Figure 6.5. Gas Exchange in the Alveolus

How would our respiratory systems adjust if we moved to higher altitudes where less oxygen is available? First, we would breathe more rapidly to try to avoid hypoxia; second, the binding dynamics of hemoglobin to oxygen would be altered to facilitate the unloading of oxygen at the tissues. As we will discuss in Chapter 7 of *MCAT Biology Review*, the natural response of hemoglobin to the decreased carbon dioxide concentration in the environment would actually be to *decrease* the unloading of oxygen to tissues, so other mechanisms can counteract and override this phenomenon to allow adequate delivery of oxygen. We could make more red cells to carry the oxygen. In the long term, we could develop more blood vessels (vascularization), which would facilitate the distribution of oxygen to tissues.

Real World

Diffusion of gases occurs across a very thin membrane between the alveolus and the capillary. However, certain diseases may cause fibrosis, or scarring, of this membrane, resulting in less effective diffusion. Other diseases may cause a limitation of ventilation (gas flow) or perfusion (blood flow) to the lung. All of these mechanisms can cause hypoxia—low blood oxygen levels—although they accomplish that same end result through different means.

Key Concept

O_2 in the alveoli flows down its partial pressure gradient from the alveoli into the pulmonary capillaries, where it can bind to hemoglobin for transport. Meanwhile, CO_2 flows down its partial pressure gradient from the capillaries into the alveoli for expiration.

THERMOREGULATION

In order to maximize gas exchange, there is a tremendous surface area over which the alveoli and capillaries interact. Because the entire respiratory tract is highly vascular, it can also be used for **thermoregulation**, or the regulation of body temperature. Heat—the transfer of thermal energy—is regulated through the body surfaces by **vasodilation** and **vasoconstriction**. As capillaries expand, more blood can pass through these vessels, and a larger amount of thermal energy can be dissipated. As capillaries contract, less blood can pass through them, conserving thermal energy. The capillaries within the nasal and tracheal capillary beds are most frequently used for these purposes within the respiratory system. While these capillary beds provide a mechanism for thermoregulation, humans predominantly regulate temperature using capillaries and sweat glands in the skin, or rapid muscle contraction (shivering). The respiratory system can also transfer heat to the environment through evaporation of water in mucous secretions. Other animals, such as dogs, take advantage of this cooling mechanism by **panting**.

IMMUNE FUNCTION

As mentioned above, the lungs provide a large interface for the body to interact with the outside world. While this is important for gas exchange and thermoregulation, it also comes with potential risks—pathogens such as bacteria, viruses, and fungi can cause infections in the lung, or can attempt to gain access to the body through the rich vascularity of the alveolar membranes. By necessity, the lungs must be able to fight off potential invaders. The first line of defense occurs within the nasal cavity, with small hairs (vibrissae) that help to trap particulate matter and potentially infectious particles. The nasal cavity also contains an enzyme called ***lysozyme***. Also found in tears and saliva, lysozyme is able to attack the peptidoglycan walls of gram-positive bacteria. The internal airways are lined with mucus, which traps particulate matter and larger invaders. Underlying cilia then propel the mucus up the respiratory tract to the oral cavity, where it can be expelled or swallowed; this mechanism is called the **mucociliary escalator**.

The lungs, especially the alveoli, also contain numerous immune cells, including macrophages. **Macrophages** can engulf and digest pathogens and signal to the rest of the immune system that there is an invader. Mucosal surfaces also contain IgA antibodies that help to protect against pathogens that contact the mucous membranes. Finally, **mast cells** also populate the lungs. These cells have preformed antibodies on their surfaces. When the right substance attaches to the antibody, the mast cell releases inflammatory chemicals into the surrounding area to promote an immune response. Unfortunately, these antibodies are often reactive to substances such as pollen and molds, so mast cells also provide the inflammatory chemicals that mediate allergic reactions.

Real World

Pneumonia is an infection of the lung most often caused by bacteria or viruses. *Atypical pneumonia*, commonly called walking pneumonia (because the infection does not require hospitalization and does not leave the patient bedridden), is often caused by very small bacterium called *Mycoplasma pneumoniae*. This bacterium causes a prolonged cough because it damages epithelial cells lining the lung and paralyzes the cilia lining the respiratory tract. The lack of cilia makes it much more difficult to clear mucus from the lungs. The cough lasts until the respiratory epithelial cells have recovered and the cilia are once again functional.

CONTROL OF pH

The respiratory system plays a role in pH balance through the **bicarbonate buffer system** in the blood:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

Questions regarding the bicarbonate buffer system are MCAT favorites, and you are very likely to see it in some form on Test Day. This equation represents an opportunity for the MCAT to test understanding of basic chemistry concepts, such as Le Châtelier's principle, as well as how disturbances in pH may affect respiration.

The body attempts to maintain a pH between 7.35 and 7.45. When the pH is lower, and hydrogen ion concentration is higher (**acidemia**), acid-sensing chemoreceptors just outside the blood–brain barrier send signals to the brain to increase the respiratory rate. Further, an increasing hydrogen ion concentration will cause a shift in the bicarbonate buffer system, generating additional carbon dioxide. As described earlier, the respiratory centers in the brain are sensitive to this increasing partial pressure of carbon dioxide and will also promote an increase in respiratory rate.

As the respiratory rate increases, more carbon dioxide is blown off. This will also push the buffer equation to the left, but notice the difference: the shift to the left in the previous paragraph was caused by an increase in hydrogen ion concentration, which elevated the concentration of carbon dioxide. Here, the removal of carbon dioxide causes a shift to the left that allows the hydrogen ion concentration to drop back to normal.

If the blood is too basic (**alkalemia**), then the body will seek to increase acidity. How can the lungs contribute to this? If the respiratory rate is slowed, then more carbon dioxide will be retained, shifting the buffer equation to right and producing more hydrogen ions and bicarbonate ions. This results in a lower pH.

Overall, the lungs play a role in the immediate adjustment of carbon dioxide levels and, by extension, hydrogen ion levels. However, the lungs do not work alone to maintain proper pH. The kidneys also play a role by modulating secretion and reabsorption of acid and base within the nephron. This is a much slower response, however, and represents long-term compensation. For more information on kidney function and homeostasis, see Chapter 10 of *MCAT Biology Review*.

MCAT Expertise

The division within the sciences is largely artificial; the MCAT often contains questions that integrate multiple science disciplines. A question located in the *Biological and Biochemical Foundations of Living Systems* section may require knowledge of general chemistry. In fact, 10% of this section is chemistry: 5% general chemistry and 5% organic chemistry.

Real World

Metabolic acidosis—a production of excess acid by any mechanism besides hypoventilation—is a common occurrence in medicine. Anaerobic respiration can generate lactic acid; individuals with type 1 diabetes mellitus can produce ketoacids when they are hypoinsulinemic; certain poisons, like methanol and formaldehyde, can produce organic acids. In each of these cases, one of the primary methods of compensation is increasing respiration rate.

Bridge

If H^+ is an acid and HCO_3^- is a base, then why doesn't increasing both of them maintain a constant pH? The reason is because H^+ is a strong acid, while HCO_3^- is a weak base. Just like a titration, discussed in Chapter 10 of *MCAT General Chemistry Review*, this combination will shift the pH of the solution toward the acidic range.

Key Concept

This equation is essential to Test Day success:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

It is likely to be tested in both the *Biological and Biochemical Foundations of Living Systems* and the *Chemical and Physical Foundations of Biological Systems* sections.

MCAT Concept Check 6.2:
Before you move on, assess your understanding of the material with these questions.

1. What are some of the mechanisms used in the respiratory system to prevent infection?

   _____

   _____

   _____

2. What is the chemical equation for the bicarbonate buffer system?

   _____

3. Respiratory failure refers to inadequate ventilation to provide oxygen to the tissues. How would the pH change in respiratory failure?

   _____

Conclusion

As we learn about the human body, it may be easy to reduce the complex and varied functions of the lungs to simply focus on breathing and providing a supply of oxygen. The lungs do indeed perform gas exchange, which relies on differences in partial pressures of gases between the alveoli and the blood. Oxygen is taken up by the blood, while carbon dioxide is released for exhalation. Inhalation and exhalation also require pressure differentials created by anatomical structures such as the chest wall, diaphragm, pleurae, and lungs.

However, the lungs are so much more than just *bags of air*; gas exchange is not the only function of the respiratory system. The respiratory system also serves essential roles in thermoregulation, immunity, and pH regulation. As we go through the individual systems within the human body, take special note of how each system is integrated with the other systems. One of the more clear connections is the binding of oxygen to hemoglobin in the lungs and the circulatory system—a concept we will expand upon in the next chapter, along with considering the effects of altitude, pH, and chemicals on this binding.

CONCEPT SUMMARY

Anatomy and Mechanism of Breathing

- Air is drawn in through the **nares**, and through the nasal cavity and **pharynx**, where it is warmed and humidified. It is filtered by nasal hairs (**vibrissae**) and mucous membranes. It then enters the **larynx**, followed by the **trachea**. The trachea divides into two mainstem **bronchi**, which divide into **bronchioles**, which divide into continually smaller passages until reaching the alveoli.
- **Alveoli** are small sacs that interface with the pulmonary capillaries, allowing gases to diffuse across a one-cell-thick membrane.
- **Surfactant** in the alveoli reduces surface tension at the liquid–gas interface, preventing collapse.
- The pleurae cover the lungs and line the chest wall.
  - The **visceral pleura** lies adjacent to the lung itself.
  - The **parietal pleura** lines the chest wall.
  - The **intrapleural space** lies between these two layers and contains a thin layer of fluid, which lubricates the two pleural surfaces.
- The **diaphragm** is a thin skeletal muscle that helps to create the pressure differential required for breathing.
- Inhalation is an active process.
  - The diaphragm and **external intercostal muscles** expand the thoracic cavity, increasing the volume of the intrapleural space. This decreases the intrapleural pressure.
  - This pressure differential ultimately expands the lungs, dropping their pressure and drawing in air from the environment. This mechanism is termed **negative-pressure breathing**.
- Exhalation may be passive or active.
  - In passive exhalation, relaxation of the muscles of inspiration and elastic recoil of the lungs allow the chest cavity to decrease in volume, reversing the pressure differentials seen in inhalation.
  - In active exhalation, the internal intercostal muscles and abdominal muscles can be used to forcibly decrease the volume of the thoracic cavity, pushing out air.
- A **spirometer** can be used to measure lung capacities and volumes.
  - **Total lung capacity** (**TLC**) is the maximum volume of air in the lungs when one inhales completely.

- **Residual volume** (**RV**) is the minimum volume of air in the lungs when one exhales completely.
- **Vital capacity** (**VC**) is the difference between the minimum and maximum volume of air in the lungs.
- **Tidal volume** (**TV**) is the volume of air inhaled or exhaled in a normal breath.
- **Expiratory reserve volume** (**ERV**) is the volume of additional air that can be forcibly exhaled after a normal exhalation.
- **Inspiratory reserve volume** (**IRV**) is the volume of additional air that can be forcibly inhaled after a normal inhalation.

- Ventilation is regulated by the **ventilation center**, a collection of neurons in the medulla oblongata.
  - **Chemoreceptors** respond to carbon dioxide concentrations, increasing the respiratory rate when there are high concentrations of carbon dioxide in the blood (**hypercarbia** or **hypercapnia**).
  - The ventilation center can also respond to low oxygen concentrations in the blood (**hypoxemia**) by increasing ventilation rate.
  - Ventilation can also be controlled consciously through the cerebrum, although the medulla oblongata will override the cerebrum during extended periods of hypo- or hyperventilation.

Functions of the Respiratory System

- The lungs perform gas exchange with the blood through simple diffusion across concentration gradients.
  - Deoxygenated blood with a high carbon dioxide concentration is brought to the lungs via the **pulmonary arteries**.
  - Oxygenated blood with a low carbon dioxide concentration leaves the lungs via the **pulmonary veins**.
- The large surface area of interaction between the alveoli and capillaries allows the respiratory system to assist in thermoregulation through **vasodilation** and **vasoconstriction** of capillary beds.
- The respiratory system must be protected from potential pathogens.
  - Multiple mechanisms, including vibrissae, mucous membranes, and the **mucociliary escalator**, help filter the incoming air and trap particulate matter.

- **Lysozyme** in the nasal cavity and saliva attacks peptidoglycan cell walls of gram-positive bacteria.
- **Macrophages** can engulf and digest pathogens and signal to the rest of the immune system that there is an invader.
- Mucosal surfaces are covered with IgA antibodies.
- **Mast cells** have antibodies on their surface that, when triggered, can promote the release of inflammatory chemicals. Mast cells are often involved in allergic reactions as well.

- The respiratory system is involved in pH control through the bicarbonate buffer system.
  - When blood pH decreases, respiration rate increases to compensate by blowing off carbon dioxide. This causes a left shift in the buffer equation, reducing hydrogen ion concentration.
  - When blood pH increases, respiration rate decreases to compensate by trapping carbon dioxide. This causes a right shift in the buffer equation, increasing hydrogen ion concentration.

ANSWERS TO CONCEPT CHECKS

6.1

1. Nares → nasal cavity → pharynx → larynx → trachea → bronchi → bronchioles → alveoli
2. Inhalation uses the diaphragm and external intercostal muscles; in labored breathing, muscles of the neck and back may also be involved. Passive exhalation uses the recoil of these same muscles; active exhalation also uses the internal intercostal muscles and abdominal muscles.
3. Surfactant reduces surface tension at the air–liquid interface in the alveoli. This prevents their collapse.
4. Vital capacity is the sum of the inspiratory reserve volume, expiratory reserve volume, and tidal volume: VC = IRV + ERV + TV
5. When CO_2 levels become too low, the brain can decrease the respiratory rate in order to raise CO_2 levels.

6.2

1. Immune mechanisms in the respiratory system include vibrissae in the nares, lysozyme in the mucous membranes, the mucociliary escalator, macrophages in the lungs, mucosal IgA antibodies, and mast cells.
2. $CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$
3. In respiratory failure, ventilation slows, and less carbon dioxide is blown off. As this occurs, the buffer equation shifts to the right, and more hydrogen ions are generated. This results in a lower pH of the blood.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. All of the following facilitate gas exchange in the lungs EXCEPT:

A. thin alveolar walls.
B. multiple subdivisions of the respiratory tree.
C. differences in the partial pressures of O_2 and CO_2.
D. active transporters in alveolar cells.

2. Which of the following associations correctly pairs a stage of respiration with the muscle actions occurring during that stage?

A. Inhalation—diaphragm relaxes
B. Inhalation—internal intercostal muscles contract
C. Exhalation—diaphragm contracts
D. Exhalation—external intercostal muscles relax

3. Total lung capacity is equal to the vital capacity plus the:

A. tidal volume.
B. expiratory reserve volume.
C. residual volume.
D. inspiratory reserve volume.

4. The intrapleural pressure is necessarily lower than the atmospheric pressure during:

A. inhalation, because the expansion of the chest cavity causes compression of the intrapleural space, decreasing its pressure.
B. inhalation, because the expansion of the chest cavity causes expansion of the intrapleural space, decreasing its pressure.
C. exhalation, because the compression of the chest cavity causes compression of the intrapleural space, decreasing its pressure.
D. exhalation, because the compression of the chest cavity causes expansion of the intrapleural space, decreasing its pressure.

5. A patient presents to the emergency room with a stab wound to the left side of the chest. On a chest x-ray, blood is noted to be collecting in the chest cavity, causing collapse of both lobes of the left lung. The blood is most likely located between:

A. the parietal pleura and the chest wall.
B. the parietal pleura and the visceral pleura.
C. the visceral pleura and the lung.
D. the alveolar walls and the lung surface.

6. Each of the following statements regarding the anatomy of the respiratory system is true EXCEPT:

A. the epiglottis covers the glottis during swallowing to ensure that food does not enter the trachea.
B. the trachea and bronchi are lined by ciliated epithelial cells.
C. the pharynx contains two vocal cords, which are controlled by skeletal muscle and cartilage.
D. the nares are lined with vibrissae, which help filter out particulate matter from inhaled air.

7. Which of the following is a correct sequence of passageways through which air travels during inhalation?

A. Pharynx → trachea → bronchioles → bronchi → alveoli
B. Pharynx → trachea → larynx → bronchi → alveoli
C. Larynx → pharynx → trachea → bronchi → alveoli
D. Pharynx → larynx → trachea → bronchi → alveoli

8. Idiopathic pulmonary fibrosis (IPF) is a disease in which scar tissue forms in the alveolar walls, making the lung tissue significantly more stiff. Which of the following findings would likely be detected through spirometry in a patient with IPF?

I. Decreased total lung capacity
II. Decreased inspiratory reserve volume
III. Increased residual volume

A. I only
B. II only
C. I and II only
D. I, II, and III

9. Studies have indicated that premature babies are often deficient in lysozyme. What is a possible consequence of this deficiency?

A. Respiratory distress and alveolar collapse shortly after birth
B. Increased susceptibility to certain infections
C. Inability to humidify air as it passes through the nasal cavity
D. Slowing of the respiratory rate in response to acidemia

10. Some forms of pneumonia cause an excess of fluids such as mucus or pus to build up within an entire lobe of the lung. How will this affect the diffusion of gases within the affected area?

A. Carbon dioxide can diffuse out, but oxygen will not be able to enter the blood.
B. Oxygen can diffuse into the blood, but carbon dioxide cannot diffuse out.
C. No change in diffusion will occur.
D. No diffusion will occur in the affected area.

11. Some people with anxiety disorders respond to stress by hyperventilating. It is recommended that these people breathe into a paper bag and then rebreathe this air. Why is this treatment appropriate?

A. Hyperventilation causes an increase in blood carbon dioxide, and breathing the air in the bag helps to readjust blood levels of carbon dioxide.
B. Hyperventilation causes a decrease in blood carbon dioxide, and breathing the air in the bag helps to readjust blood levels of carbon dioxide.
C. Hyperventilation causes an increase in blood oxygen, and breathing the air in the bag helps to readjust blood levels of oxygen.
D. Hyperventilation causes a decrease in blood oxygen, and breathing the air in the bag helps to readjust blood levels of oxygen.

12. A patient presents to the emergency room with an asthma attack. The patient has been hyperventilating for the past hour and has a blood pH of 7.52. The patient is given treatment and does not appear to respond, but a subsequent blood pH reading is 7.41. Why might this normal blood pH NOT be a reassuring sign?

A. The patient's kidneys may have compensated for the alkalemia.
B. The normal blood pH reading is likely inaccurate.
C. The patient may be descending into respiratory failure.
D. The patient's blood should ideally become acidemic for some time to compensate for the alkalemia.

13. Premature infants with respiratory distress are often placed on ventilators. Often, the ventilators are set to provide positive end-expiratory pressure. Why might this setting be useful for a premature infant?

A. Premature infants lack surfactant.
B. Premature infants lack lysozyme.
C. Premature infants cannot thermoregulate.
D. Premature infants are unable to control pH.

14. In emphysema, the alveolar walls are destroyed, decreasing the recoil of the lung tissue. Which of the following changes may be seen in a patient with emphysema?

A. Increased residual volume
B. Decreased total lung capacity
C. Increased blood concentration of oxygen
D. Decreased blood concentration of carbon dioxide

15. Allergic reactions occur due to an overactive immune response to a substance. Which cells within the respiratory tract play the largest role in the generation of allergic reactions?

A. Alveolar epithelial cells
B. Macrophages
C. Mast cells
D. Ciliated epithelial cells

Explanations to Discrete Practice Questions

1. D

Gas exchange in the lungs relies on passive diffusion of oxygen and carbon dioxide. This is accomplished easily because there is always a difference in the partial pressures of these two gases and because the subdivision of the respiratory tree creates a large surface area of interaction between the alveoli and the circulatory system. In addition, the thin alveolar walls allow for fast diffusion and gas exchange. Therefore, **choices (A)**, **(B)**, and **(C)** can be eliminated. **Choice (D)** is the correct answer because active transport is not used in the gas exchange process in the lungs.

2. D

The muscles involved in ventilation are the diaphragm, which separates the thoracic cavity from the abdominal cavity, and the intercostal muscles between the ribs. During inhalation, the diaphragm contracts and flattens, while the external intercostal muscles contract, pulling the rib cage up and out. These actions cause an overall increase in the volume of the thoracic cavity. During exhalation, both the diaphragm and the external intercostals relax, causing a decrease in the volume of the thoracic cavity because of recoil of these tissues. In forced exhalation, the internal intercostals and abdominal muscles may contract to force out air. Thus, the only correct association from the given answers is **choice (D)**.

3. C

Total lung capacity is equal to the vital capacity (the maximum volume of air that can be forcibly inhaled and exhaled from the lungs) plus the residual volume (the air that always remains in the lungs, preventing the alveoli from collapsing).

4. B

During inhalation, the chest cavity expands, causing expansion of the intrapleural space. According to Boyle's law, an increase in volume at a constant temperature is accompanied by a decrease in pressure. When the intrapleural pressure (and, by extension, the alveolar pressure) is less than atmospheric pressure, air enters the lungs. During exhalation, these pressure gradients reverse; thus, during exhalation, intrapleural pressure is higher than atmospheric pressure, not lower.

5. B

The intrapleural space, bounded by the parietal and visceral pleurae, is a potential space. As such, it is normally collapsed and contains a small amount of fluid. However, introduction of fluid or air into the intrapleural space can fill the space, causing collapse of the lung. The other options listed are too firmly apposed to permit blood to collect in these spaces.

6. C

The pharynx, which lies behind the nasal cavity and oral cavity, is a common pathway for food entering the digestive system and air entering the respiratory system. It is the larynx that contains the vocal cords, not the pharynx.

7. D

Air enters the respiratory tract through the external nares (nostrils) and travels through the nasal cavities. It then passes through the pharynx and into the larynx. Ingested food also passes through the pharynx on its way to the esophagus; to ensure that food does not accidentally enter the

larynx, the epiglottis covers the larynx during swallowing. After the larynx, air goes to the trachea, which eventually divides into two bronchi, one for each lung. The bronchi branch into smaller bronchioles, which terminate in clusters of alveoli. From the given sequences, only **choice (D)** correctly describes the sequence of the passages through which air travels.

8. B

In a patient with IPF, the increased stiffness of the lungs would likely decrease the volume of air the individual could inhale, which would decrease both the total lung capacity and inspiratory reserve volume. However, spirometry cannot measure the total lung capacity accurately because it cannot determine the residual volume—the volume of air left in the lungs when an individual has maximally exhaled. Because the residual volume makes up a portion of the total lung capacity (total lung capacity = vital capacity + residual volume), a spirometer cannot be used to determine the total lung capacity. Therefore, while Statement I is a true statement about individuals with IPF, it cannot appear in the answer choice. Finally, increased stiffness of the lungs would be expected to decrease the residual volume, not increase it; further, residual volume, as described above, cannot be measured with a spirometer.

9. B

Lysozyme is an enzyme present in the nasal cavity, saliva, and tears that degrades peptidoglycan, preventing infection by gram-positive organisms. Thus, premature infants who lack lysozyme are more likely to suffer from infections with these organisms.

10. D

If an area of the lung becomes filled with mucus and inflammatory cells, the area will not be able to participate in gas exchange. Because no air will enter or leave the area, the concentration gradient will no longer exist, and neither oxygen nor carbon dioxide will be able to diffuse across the alveolar wall.

11. B

When people hyperventilate, their respiratory rate increases. When the respiratory rate increases, more carbon dioxide is blown off. This causes a shift to the left in the bicarbonate buffer equation, and the blood becomes more alkaline. Breathing into the bag allows some of this carbon dioxide to be returned to the bloodstream in order to maintain the proper pH.

12. C

When a patient with an asthma attack does not respond to treatment and has been hyperventilating for over an hour, he or she may become fatigued and may not be able to maintain hyperventilation. In this case, the patient begins to decrease his or her breathing rate and is not receiving adequate oxygen. By extension, carbon dioxide is trapped in the blood, and the pH begins to drop. Despite the fact that this pH is normal at the moment, this patient is crashing and may start demonstrating acidemia in the near future. While the kidneys should compensate for alkalemia, this is a slow process and would not normalize the blood pH within an hour; further, adequate compensation by the kidneys would actually be a reassuring sign, eliminating **choice (A)**. There is no evidence to believe the measurement was inaccurate, eliminating **choice (B)**. Finally, after treatment, the patient should return to a normal blood pH with adequate ventilation and would not be expected to overcompensate by becoming acidemic, eliminating **choice (D)**.

13. A

This question requires a few different levels of thinking. The question stem states that premature infants often require ventilation using positive end-expiratory pressures. While you are not expected to know ventilator settings for the MCAT, you should be able to decode what this phrase means: at the end of expiration, the ventilator will provide a higher pressure than normal, which forces extra air into the alveoli. This pressure must be used to prevent alveolar collapse, which should remind you that surfactant serves the same

purpose by reducing surface tension. Thus, it makes sense that if premature babies lack surfactant, providing extra air pressure at the end of expiration would be beneficial.

14. A

The intrinsic elastic properties of the lung are important during exhalation as the passive recoil of lung tissue helps decrease lung volume. With decreased recoil, the patient will have difficulty exhaling completely, increasing the residual volume. The total lung capacity would be expected to increase in this case because there would be less recoil opposing inhalation, eliminating **choice (B)**. With decreased alveolar surface area, one would expect decreased gas exchange, which would decrease blood concentrations of oxygen while increasing blood concentrations of carbon dioxide, eliminating **choices (C)** and **(D)**.

15. C

Allergic reactions occur when a substance binds to an antibody and promotes an overactive immune response with inflammatory chemicals. The antibody is already attached to a mast cell. Thus, when the substance binds to the antibody, the mast cell can release the inflammatory mediators that cause allergic reactions.

Concept Summary 258

Introduction

As late as the 19th century, physicians adhered to the principle of health known as *humoralism*. This theory was developed by Greek and Roman physicians and philosophers and adopted by Islamic physicians; it remained dominant in medical thought and practice until it was ultimately displaced by modern medical research in the 1800s. The theory of humoralism holds that the human body is composed of four fluids or substances called humors—black bile, yellow bile, phlegm, and blood. In the state of health, these four humors are in balance, but excess or deficiency of any one of them would cause illness, disease, and even maladaptive personality characteristics. Over the course of a lifetime, the levels of each of the four humors would rise and fall in accordance with diet and activity, resulting in maladies reflective of the imbalance. Treatments were intended to restore this balance.

Perhaps one of the most well-known treatments associated with humoralism is the practice of bloodletting. Because many diseases were associated with an excess of blood, physicians would rely on the withdrawal of significant amounts of blood from their patients to restore balance to the four humors. Methods for bloodletting were many, and some were dramatic, including drawing blood from major veins in the arm or neck and puncturing arteries. Devices known as scarificators were developed to cut through to the superficial vessels. Most famously, leeches were used, especially in the early 19th century, to draw out the excess blood. In fact, in the

early decades of the 1800s, hundreds of millions of leeches were used by European physicians; in the 1830s, France alone imported about 40 million leeches per year for medical treatments.

Now, while the humoral theory has been completely discredited by modern medical research, some practices associated with humoralism are still being used, albeit based on very different medical understanding and for different purposes. For example, new research has shown that medicinal leeches can be used effectively in microsurgery, where they help prevent blood coagulation, and in reconstructive surgery, where they help stimulate circulation to the reattached tissue.

The cardiovascular system is one of the most commonly tested on the MCAT. It serves a variety of functions, including the movement of respiratory gases, nutrients, and wastes. We will review the structures and functional anatomy of the cardiovascular system and then discuss blood and its functional components. We'll also trace the pathways created by the electrically excitable cells that initiate and spread contractions through the heart. A quick recap of genetics and inheritance will help us to understand the functional consequences of ABO and Rh antigens. In addition, the binding capability of oxygen and carbon dioxide to hemoglobin will be discussed in detail.

7.1 Anatomy of the Cardiovascular System

The **cardiovascular system** consists of a muscular four-chambered **heart**, **blood vessels**, and **blood**, as shown in Figure 7.1. The heart acts as a pump, circulating blood through the vasculature. The vasculature consists of arteries, capillaries, and veins. After blood travels through veins, it is returned to the right side of the heart where it is pumped to the lungs to be reoxygenated. Then, the oxygenated blood returns to the left side of the heart where it is recirculated to the rest of the body.

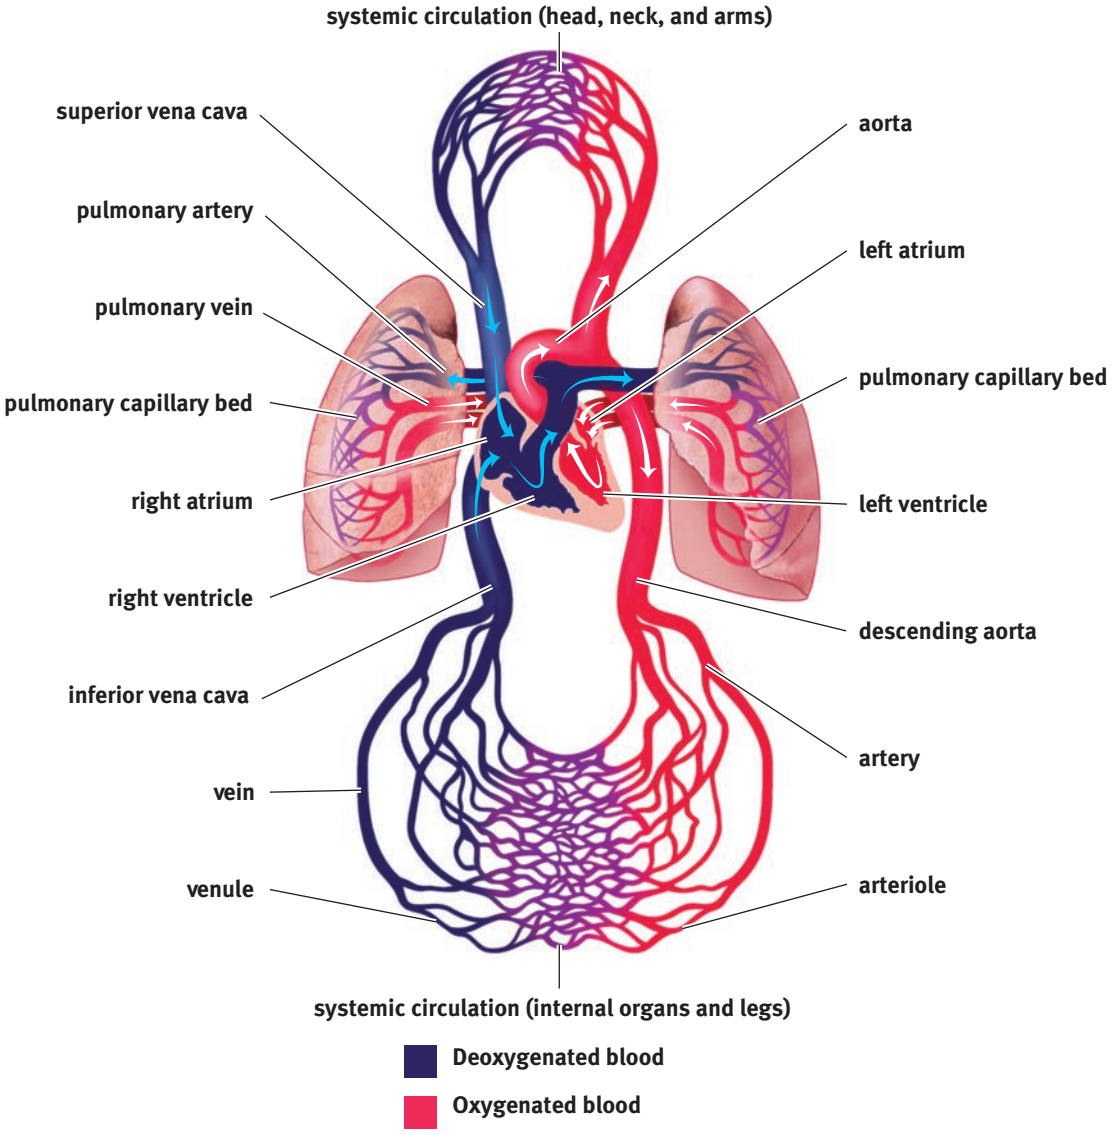

Figure 7.1. Anatomy of the Cardiovascular System

THE HEART

The **heart** is a four-chambered structure composed predominantly of cardiac muscle. We often speak of the heart as a pump, supporting a single circulatory system. However, the heart is actually composed of two pumps supporting two different circulations in series with one another. The right side of the heart accepts deoxygenated blood returning from the body and moves it to the lungs by way of the pulmonary arteries; this constitutes the first pump (**pulmonary circulation**). The second pump is the left side of the heart, which receives oxygenated blood from the lungs by way of the pulmonary veins and forces it out to the body through the aorta (**systemic circulation**).

Each side of the heart consists of an atrium and a ventricle. The **atria** are thin-walled structures where blood is received from either the **venae cavae** (deoxygenated blood entering the right heart) or the **pulmonary veins** (oxygenated blood entering the left heart). The atria contract to push blood into the **ventricles**. After the ventricles fill, they contract to send blood to the lungs and the systemic circulation. Note that the ventricles are far more muscular than the atria, allowing for more powerful contractions necessary to push blood through the rest of the cardiovascular system.

Mnemonic

Atrioventricular valves: **LAB RAT**
Left **A**trium = **B**icuspid
Right **A**trium = **T**ricuspid

The atria are separated from the ventricles by the **atrioventricular valves**. Likewise, the ventricles are separated from the vasculature by the **semilunar valves**. These valves allow the pump to create the pressure within the ventricles necessary to propel the blood forward within the circulation, while also preventing backflow of blood. The valve between the right atrium and the right ventricle is known as the **tricuspid valve** (three leaflets), while the valve between the left atrium and the left ventricle is known as the **mitral** or **bicuspid valve** (two leaflets). The valve that separates the right ventricle from the pulmonary circulation is known as the **pulmonary valve**, while the valve that separates the left ventricle from the aorta is known as the **aortic valve**. Both semilunar valves have three leaflets.

One of the central themes in biology is something that we've touched on already in previous chapters: structure and function are related. The right and left sides of the heart are two different pumps, with the right heart supporting the circulation to the lungs, while the left heart pumps blood into the systemic circulation. Blood leaving the left heart must travel a considerable distance, so blood pressure must be maintained as far away as the feet. Thus, the left heart is actually more muscular than the right heart. In fact, if the right heart were as muscular as the left and pumped blood as forcefully, this would cause damage to the lungs.

Electric Conduction of the Heart

The coordinated, rhythmic contraction of cardiac muscle originates in an electrical impulse generated by and traveling through a pathway formed by four electrically excitable structures, as shown in Figure 7.2. This commonly tested pathway consists of, in order, the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle of His (AV bundle) and its branches, and the Purkinje fibers. Impulse initiation occurs at the **SA node**, which generates 60–100 signals per minute without requiring any neurological input. This small collection of cells is located in the wall of the right atrium. As the depolarization wave spreads from the SA

node, it causes the two atria to contract simultaneously. While most ventricular filling is passive (that is, blood moves from the atria to the ventricles based solely on ventricular relaxation), **atrial systole** (**contraction**) results in an increase in atrial pressure that forces a little more blood into the ventricles. This additional volume of blood is called the **atrial kick** and accounts for about 5–30 percent of cardiac output. Next, the signal reaches the **AV node**, which sits at the junction of the atria and ventricles. The signal is delayed here to allow for the ventricles to fill completely before they contract. The signal then travels down the **bundle of His** and its branches, embedded in the **interventricular septum** (wall), and to the **Purkinje fibers**, which distribute the electrical signal through the ventricular muscle. The muscle cells are connected by **intercalated discs**, which contain many gap junctions directly connecting the cytoplasm of adjacent cells, thereby allowing for coordinated ventricular contraction.

The SA node has an intrinsic rhythm of 60–100 signals per minute, so the normal human heart rate is 60–100 beats per minute. Highly conditioned athletes may have heart rates significantly lower than 60, in the range of 40–50 beats per

Key Concept

Cardiac muscle has myogenic activity, meaning that it can contract without any neurological input. The SA node generates about 60–100 beats per minute, even if all innervation to the heart is cut. The neurological input to the heart is important in speeding up and slowing the rate of contraction, but not generating it in the first place.

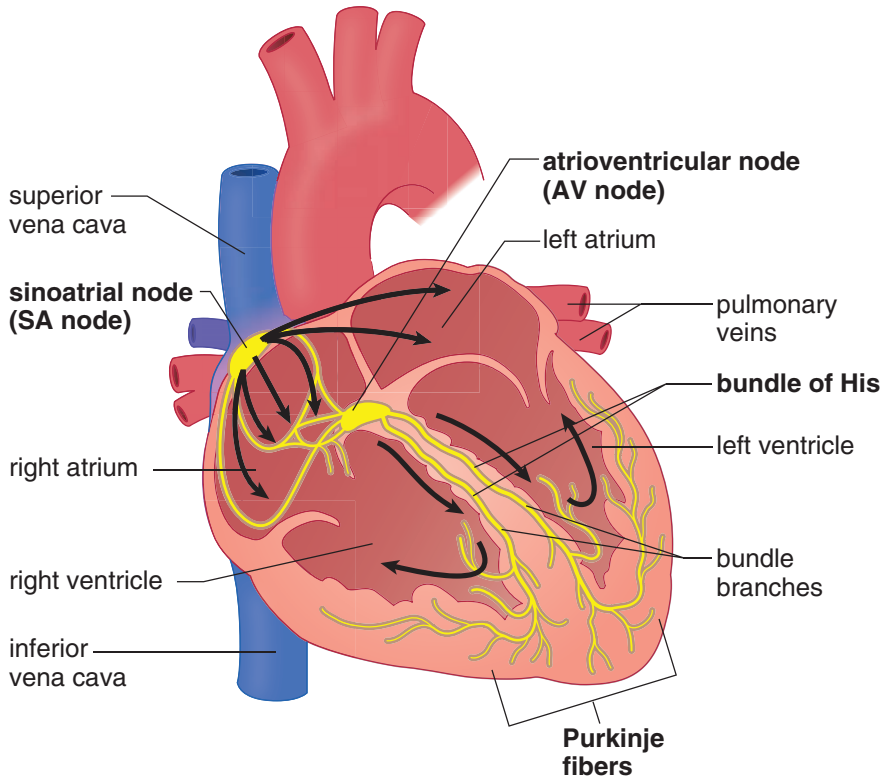

Figure 7.2. Electrical Conduction System of the Heart
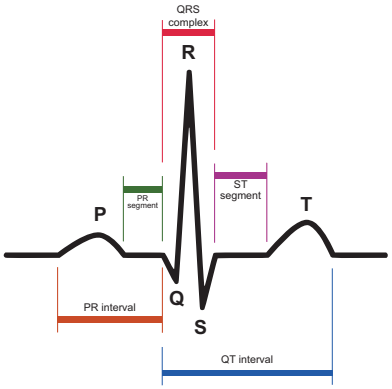
Electrical impulses travel from the SA node to the AV node, through the bundle of His, and finally to the Purkinje fibers.

Real World

The heart's electrical impulses can be detected on the body's surface by placing electrodes on the skin on opposite sides of the heart. A recording of these currents is called an electrocardiogram (ECG or EKG; the *K*, by the way, reflects the German spelling). Electrocardiograms are incredibly powerful tools for assessing the status of a patient's heart. A normal EKG is shown below.



Depolarization precedes cardiac muscle contraction, so the electrical spikes of the EKG occur just before a cardiac contractile event. The P-wave occurs immediately before the atria contract, and the QRS complex occurs just before the ventricles contract. The T-wave represents ventricular repolarization.

Real World

A heart attack, or myocardial infarction, is caused by a lack of bloodflow through the coronary arteries, which results in decreased oxygen delivery to the cardiac muscle itself. The demand on the heart requires too much ATP for anaerobic respiration, so the muscle tissue begins to die. A person suffering a heart attack is often given a β-blocker, which blocks the sympathetic stimulation of the heart, resulting in lower heart rate and lower contractility. With a β-blocker, the heart does not work as hard, so its oxygen demand is diminished, which helps to prevent further damage to cardiac tissue.

minute. Stress, exercise, excitement, surprise, or danger can cause the heart rate to rise significantly above 100.

The circulatory system is under autonomic control. The autonomic division, which consists of the sympathetic ("fight-or-flight") and parasympathetic ("rest-and-digest") branches, controls the heart and affects the vasculature. Sympathetic signals speed up the heart rate and increase the contractility of cardiac muscle, while parasympathetic signals, provided by the **vagus nerve**, slow it down.

Contraction

The heart is a muscle that must contract in order to move blood. Each heartbeat is composed of two phases, known as systole and diastole. During **systole**, ventricular contraction and closure of the AV valves occurs and blood is pumped out of the ventricles. During **diastole**, the heart is relaxed, the semilunar valves are closed, and blood from the atria fills the ventricles. Contraction of the ventricles generates a higher pressure during systole, whereas their relaxation during diastole causes the pressure to decrease. The elasticity of the walls of the large arteries, which stretch to receive the volume of blood from the heart, allows the vessels to maintain sufficient pressure while the ventricular muscles are relaxed. In fact, if it weren't for the elasticity of the large arteries, diastolic blood pressure would plummet to zero. The normal events of one heartbeat, including pressures in the left atrium, left ventricle, and aorta; left ventricular volume; normal and pathologic heart sounds; and an EKG are shown in Figure 7.3.

A measure to be aware of is **cardiac output**, or the total blood volume pumped by a ventricle in a minute. Does it matter which ventricle one chooses? As mentioned previously, the two pumps are connected in series, so the volumes of blood passing through each side must be the same, much like the electrical current between two resistors in series must be the same. Cardiac output (CO) is the product of **heart rate** (HR, beats per minute) and **stroke volume** (SV, volume of blood pumped per beat):

$$CO = HR \times SV$$

Equation 7.1

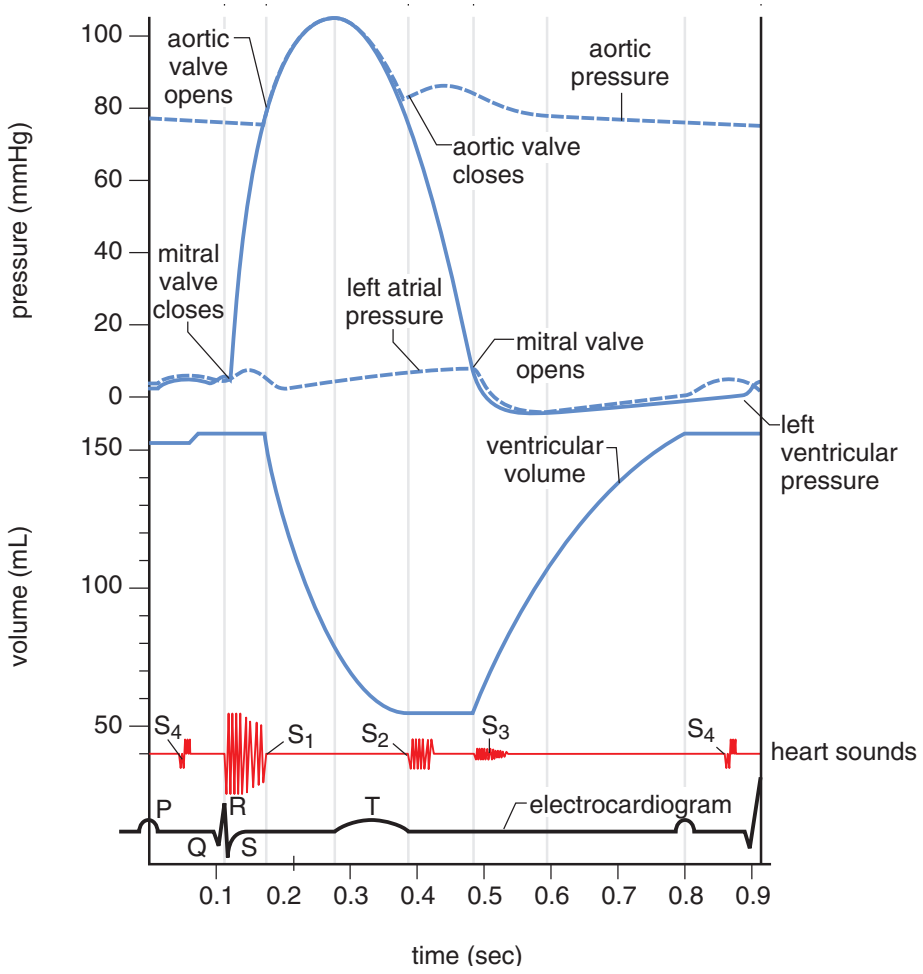


Figure 7.3. The Cardiac Cycle

The MCAT will not expect a thorough understanding of every detail of this diagram; it is more important to see how the changes in valves (open or closed), pressures, and volumes are related.

For humans, cardiac output is about 5 liters per minute. During periods of exercise or rest, the autonomic nervous system will increase (sympathetic) or decrease (parasympathetic) cardiac output, respectively.

THE VASCULATURE

In order to deliver blood to the entire body, the circulatory system utilizes vessels of different sizes. The three major types of vessels are arteries, veins, and capillaries. Blood travels away from the heart in **arteries**, the largest of which in the systemic circulation is the aorta. Major arteries, such as the coronary, common carotid, subclavian, and renal arteries, divide the bloodflow from the aorta toward different peripheral

Real World

The rhythmic impulses we hear when we listen to someone's heart with a stethoscope (*lub dub*) are referred to as the heart sounds. The first sound, S_1, is produced when the two AV valves close at the start of systole to prevent backflow into the atria. The second sound, S_2, is produced when the two semilunar valves close at the end of systole to prevent backflow into the ventricles. Extra heart sounds (S_3 and S_4) can result from stiffness of the heart muscle or high blood pressure. Heart murmurs, which may be so loud as to be audible without a stethoscope, may arise when the valves malfunction and become either narrow and stiff or wide and floppy, resulting in abnormal flow patterns across the valve.

Real World

There is a limit to how fast the heart can beat and still pump blood effectively. Because the heart fills with blood when it is relaxing (diastole), the faster it beats, the less time there is for blood to enter the heart during relaxation. Thus, a faster heartbeat means diminishing returns in terms of the amount of blood supplied to the body. A dangerous condition called ventricular tachycardia (often abbreviated *v-tach*) features a very rapid rate of ventricular contraction. The heart in v-tach cannot properly fill with blood and, paradoxically, stops pumping blood despite its fast rate. Systemic pressures drop precipitously. Death will result unless the heart is forced out of this abnormal rhythm.

Mnemonic

Arteries carry blood **a**way from the heart.

tissues. Arteries branch into **arterioles**, which ultimately lead to **capillaries** that perfuse the tissues. On the venous side of a capillary network, the capillaries join together into **venules**, which join to form **veins**. Venous blood empties into the superior and inferior venae cavae for entry into the right side of the heart. All blood vessels are lined with **endothelial cells**. This special type of cell helps to maintain the vessel by releasing chemicals that aid in vasodilation and vasoconstriction. In addition, endothelial cells can allow white blood cells to pass through the vessel wall and into the tissues during an inflammatory response. Finally, endothelial cells release certain chemicals when damaged that are necessary in the formation of blood clots to repair the vessel and stop bleeding.

Cross-sections of the different blood vessels are shown in Figure 7.4. Don't worry about the names of the layers; simply be able to recognize that the same types of cells comprise the different vessels and that arteries have much more smooth muscle than veins.

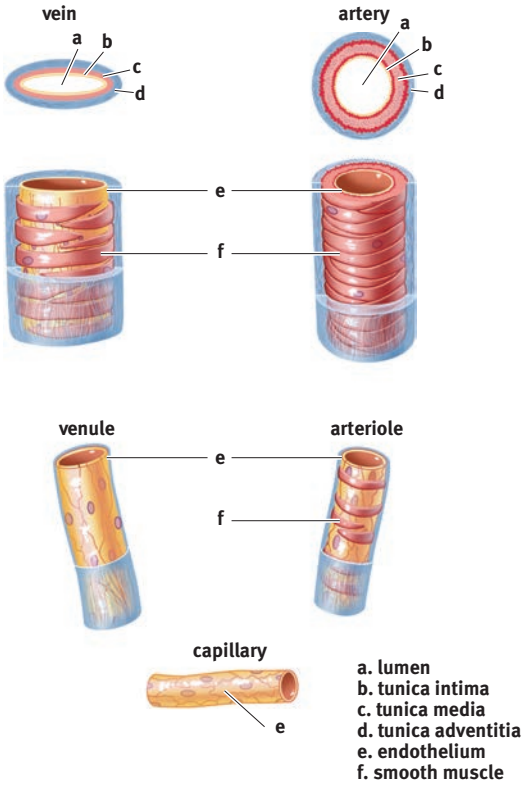

Figure 7.4. Structure of Blood Vessels

Arteries

Arteries move blood away from the heart to the lungs and other parts of the body. Most arteries contain oxygenated blood; in fact, only the pulmonary arteries and umbilical arteries contain deoxygenated blood. Smaller, muscular arteries are known as arterioles.

Arteries are highly muscular and elastic, creating tremendous resistance to the flow of blood. This is one of the reasons why the left heart must generate much higher pressures: to overcome the resistance caused by systemic arteries. After arteries are filled with blood, the elastic recoil from their walls maintains a high pressure and forces blood forward.

Capillaries

Capillaries are vessels with a single endothelial cell layer and are so small that red blood cells must pass through the capillaries in a single-file line. The thin wall of the capillary allows easy diffusion of gases (O_2 and CO_2), nutrients (most notably, glucose), and wastes (ammonia and urea, among others). Capillaries are therefore the interface for communication of the circulatory system with the tissues. Remember, too, that blood also carries hormones, so capillaries allow endocrine signals to arrive at their target tissues.

Capillaries can be quite delicate. When capillaries are damaged, blood can leave the capillaries and enter the interstitial space. If this occurs in a closed space, it results in a bruise.

Veins

Veins are thin-walled, inelastic vessels that transport blood to the heart. Except for the pulmonary and umbilical veins, all veins carry deoxygenated blood. **Venules** are smaller venous structures that connect capillaries to the larger veins of the body.

The smaller amount of smooth muscle in the walls of veins gives them less recoil than arteries. Furthermore, veins are able to stretch to accommodate larger quantities of blood. Indeed, three-fourths of our total blood volume may be in venous circulation at any one time. Note that, even though the volume of arterial blood is normally much less than the volume of venous blood, the total volume passing through either side of the heart per time (cardiac output) is the same.

Given that the heart is located in the chest, bloodflow in most veins is upward from the lower body back to the heart, against gravity. In the inferior vena cava, this translates into a large amount of blood in a vertical column. The pressure at the bottom of this venous column in the large veins of the legs can be quite high. In fact, it can exceed systolic pressure (120 mmHg), going as high as 200 mmHg or more. Thus, veins must have structures to push the blood forward and prevent backflow. Larger veins contain valves; as blood flows forward in the veins, the valves open. When blood tries to move backward, the valves will slam shut. Failure of the venous valves can result in the formation of varicose veins, which are distended where blood has pooled. Pregnant women are especially susceptible to

Real World

Blood clots may form in the deep veins of the legs as a result of injury, inactivity (blood stasis), or a hypercoagulable state (a tendency for the blood to clot excessively). The clots may dislodge and travel through the right atrium and right ventricle, out the pulmonary artery, and into the lungs. Such clots, called pulmonary emboli (or, more specifically, thromboemboli), block segments of the pulmonary arteries and produce rapid, labored breathing and chest pain. Death may occur if the thromboemboli are large.

Real World

Many patients may be immobile following a surgical procedure or during a long hospital stay. This causes a threat of DVT and pulmonary emboli, which are very undesirable complications in someone who is already sick. Thus, in hospitals, special wraps are placed on the legs that contract rhythmically in order to prevent pooling of blood and the formation of blood clots. In addition, many patients receive medications like *heparin* or *warfarin* to prevent the formation of clots.

the formation of varicose veins due to an increase in the total blood volume during pregnancy and compression of the inferior vena cava by the fetus.

In addition to high pressure in the lower extremities, the small amount of smooth muscle also creates a challenge for propelling blood forward. Thus, the veins must rely on an external force to generate the pressure to push blood toward the heart. Most veins are surrounded by skeletal muscles, which squeeze the veins as the muscles contract, forcing the blood up against gravity in much the same way that squeezing the bottom of a tube of toothpaste causes the contents to be expelled through the top of the tube. This is why sitting motionless for long periods of time, such as in the cramped middle seat on a long transoceanic flight or after surgery, can increase the risk of blood clot formation in the veins of the legs and pelvis. Blood pools in the lower extremities, and sluggish blood coagulates more easily. A clot in the deep veins of the leg is called a deep vein thrombosis (DVT). This clot may become dislodged and travel through the right heart to the lungs, where it can cause a life-threatening condition called a pulmonary embolus.

CIRCULATION

Circulation is, by definition, circular. Let's return to the anatomy of the heart and vasculature, shown in Figure 7.1 earlier to determine the flow of blood through the body. A close-up of bloodflow through the heart is also shown in Figure 7.5. Here, we begin with the return of blood to the right atrium. Blood returns to the heart from the body via the venae cavae, which are divided into the **superior vena cava** (**SVC**) and the **inferior vena cava** (**IVC**). The superior vena cava returns blood from the portions of the body above the heart, while the inferior vena cava returns blood from portions of the body below the heart. Deoxygenated blood enters the right atrium, travels through the tricuspid valve, and enters the right ventricle. On contraction, the blood from the right ventricle passes through the pulmonary valve and enters the pulmonary arteries, where it travels to the lungs in continuously smaller vessels. Once the blood reaches the capillaries that line the alveoli, it participates in gas exchange, with carbon dioxide leaving the blood and oxygen entering the blood. The blood then travels into pulmonary venules and into the pulmonary veins, which carry the blood to the left side of the heart. Oxygenated blood enters the left atrium, travels through the mitral valve, and enters the left ventricle. On contraction, the blood from the left ventricle passes through the aortic valve and enters the aorta. From the aorta, blood enters arteries, then arterioles, and then capillaries. After gas and nutrient exchange occurs at the capillaries, the blood enters the venules, which lead to the larger veins. The veins then empty into either the SVC or IVC for return to the right side of the heart.

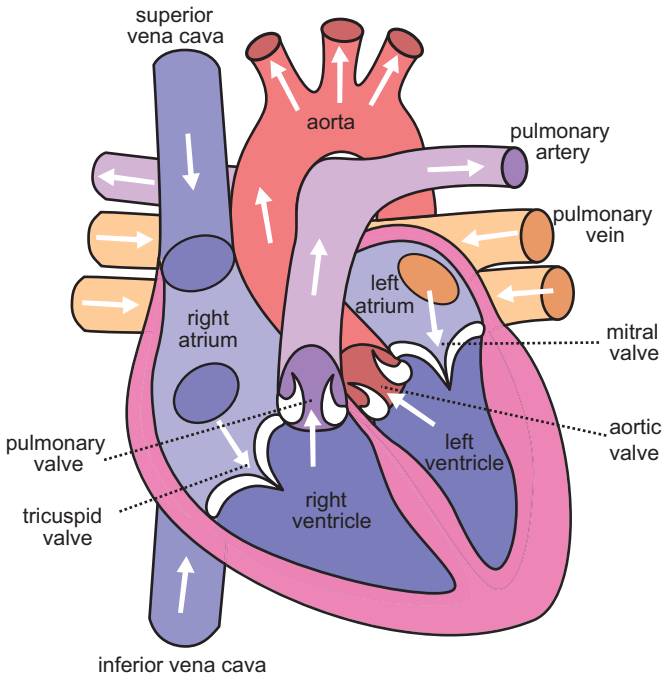

Figure 7.5. Bloodflow through the Heart

Written in shorthand, the pathway appears like this:

$$\text{right atrium} \xrightarrow[\text{valve}]{\text{tricuspid}} \text{right ventricle} \xrightarrow[\text{valve}]{\text{pulmonary}} \text{pulmonary artery} \rightarrow \text{lungs} \rightarrow \text{pulmonary veins} \rightarrow \text{left atrium} \xrightarrow[\text{valve}]{\text{mitral}} \text{left ventricle} \xrightarrow[\text{valve}]{\text{aortic}} \text{aorta} \rightarrow \text{arteries} \rightarrow \text{arterioles} \rightarrow \text{capillaries} \rightarrow \text{venules} \rightarrow \text{veins} \rightarrow \text{venae cavae} \rightarrow \text{right atrium}$$

In most cases, blood will pass through only one capillary bed before returning to the heart. However, there are three **portal systems** in the body, in which blood will pass through two capillary beds in series before returning to the heart. In the **hepatic portal system**, blood leaving capillary beds in the walls of the gut passes through the hepatic portal vein before reaching the capillary beds in the liver. In the **hypophyseal portal system**, blood leaving capillary beds in the hypothalamus travels to a capillary bed in the anterior pituitary to allow for paracrine secretion of releasing hormones. In the **renal portal system**, blood leaving the glomerulus travels through an efferent arteriole before surrounding the nephron in a capillary network called the vasa recta.

Real World

While *bicuspid valve* is an acceptable alternative name for *mitral valve*, it is rarely used in medicine. Most practitioners will refer to valves by one-letter abbreviations (*M* for mitral). The name *mitral* refers to a *miter*, which is the name for the hat the pope and bishops wear in the Catholic faith. The two large leaflets of the mitral valve somewhat resemble this headdress.

MCAT Concept Check 7.1:

Before you move on, assess your understanding of the material with these questions.

1. Starting from entering the heart from the venae cavae, what are the four chambers through which blood passes in the heart? Which valve prevents backflow into each chamber?

Heart Chamber	Valve that Prevents Backflow

2. Starting with the site of impulse initiation, what are the structures in the conduction system of the heart?

_____

_____

3. Compare and contrast arteries, capillaries, and veins:

Vessel	Carries Blood Which Direction?	Relative Wall Thickness	Smooth Muscle Present?	Contains Valves?
Artery				
Capillary				
Vein				

4. Why does the right side of the heart contain less cardiac muscle than the left side?

_____

_____

5. If all autonomic input to the heart were cut, what would happen?

_____

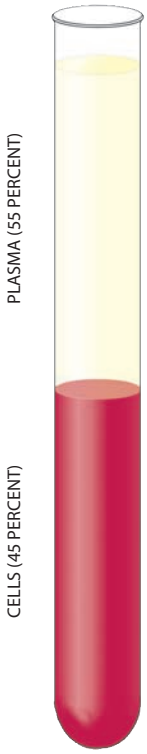
_____

7.2 Blood ★★

Now that we have examined the pump and the pipes through which blood travels, let's take a look at this fluid itself.

COMPOSITION

In the pathologist's lab, we frequently study the composition of the blood using a centrifuge. By spinning the blood at a rapid rate, we can separate this complex fluid into its components, based on density. By volume, blood is about 55% liquid and 45% cells, as shown in Figure 7.6. **Plasma** is the liquid portion of blood, an aqueous mixture of nutrients, salts, respiratory gases, hormones, and blood proteins. The cellular portion of blood consists of three major categories: **erythrocytes**, **leukocytes**, and **platelets**. All blood cells are formed from hematopoietic stem cells, which originate in the bone marrow.



CONSTITUENT	MAJOR FUNCTION
WATER	SOLVENT FOR CARRYING OTHER SUBSTANCES
SALTS SODIUM, POTASSIUM, CALCIUM, MAGNESIUM, CHLORIDE, BICARBONATE	OSMOTIC BALANCE, pH BUFFERING, REGULATION OF MEMBRANE POTENTIAL
PLASMA PROTEINS ALBUMIN FIBRINOGEN IMMUNOGLOBULINS	OSMOTIC BALANCE, pH BUFFERING CLOTTING DEFENSE (ANTIBODIES)
CELL TYPE	**CELL FUNCTION**
ERYTHROCYTES (RED BLOOD CELLS) 3.5 TO 6 MILLION PER CUBIC MILLIMETER OF BLOOD	TRANSPORT OXYGEN AND HELP TO TRANSPORT CARBON DIOXIDE
LEUKOCYTES (WHITE BLOOD CELLS) 4500 TO 11,000 PER CUBIC MILLIMETER OF BLOOD BASOPHIL NEUTROPHIL EOSINOPHIL MONOCYTE LYMPHOCYTE	PRODUCTION OF ANTIBODIES AND DEFENSE AGAINST INFECTION
PLATELETS 150,000 TO 400,000 PER CUBIC MILLIMETER OF BLOOD	BLOOD CLOTTING
SUBSTANCES TRANSPORTED BY BLOOD	
NUTRIENTS (FOR EXAMPLE, GLUCOSE, FATTY ACIDS, VITAMINS), WASTE PRODUCTS OF METABOLISM, RESPIRATORY GASES (OXYGEN AND CARBON DIOXIDE), HORMONES	

Figure 7.6. The Composition of Blood

Erythrocytes—Red Blood Cells

In the body, oxygen and nutrients are delivered to the peripheral tissues, and carbon dioxide and other wastes (such as hydrogen ions and ammonia) are picked up from the peripheral tissues and delivered to the organs that process this waste: the lungs, liver, and kidneys. The **erythrocyte** or **red blood cell** is a specialized cell designed for oxygen transport. Oxygen does not simply dissolve in the cytoplasm of the red blood cell—remember, molecular oxygen is nonpolar and therefore has low solubility in aqueous environments. Rather, each erythrocyte contains about 250 million molecules of **hemoglobin**, each of which can bind four molecules of oxygen. Therefore, each red blood cell can carry approximately 1 billion molecules of oxygen.

Red blood cells are unique in a number of ways, and their modifications reflect the special role they play in the human body. Red blood cells are biconcave, or indented on both sides, which serves a dual purpose. First, this shape assists them in traveling through tiny capillaries. Second, it increases the cell's surface area, which allows for greater gas exchange. Red blood cells are also unique in that, when they mature, the nuclei, mitochondria, and other membrane-bound organelles are lost. The loss of organelles makes space for the molecules of hemoglobin. In addition, the loss of mitochondria in particular means that the red blood cell is not able to metabolize the oxygen it is carrying before it is delivered to peripheral tissues. In other words, red blood cells do not carry out oxidative phosphorylation to generate ATP; rather, they rely entirely on glycolysis for ATP, with lactic acid (arising from fermentation) as the main by-product. Because red blood cells lack nuclei, they are unable to divide. Erythrocytes can live for 120 days in the bloodstream before cells in the liver and spleen phagocytize senescent (old) red blood cells to recycle them for their parts.

In medicine, a complete blood count measures the quantity of each cell type in the blood. For red blood cells, two commonly given measures are the hemoglobin and hematocrit. Hemoglobin, of course, measures the quantity of hemoglobin in the blood, giving a result in grams per deciliter. **Hematocrit** is a measurement of how much of the blood sample consists of red blood cells, given as a percentage. A normal hemoglobin is considered to be between 13.5 and 17.5 for males and between 12.0 and 16.0 for females. A normal hematocrit is considered to be between 41 and 53% for males and between 36 and 46% for females. For example, a patient may have a hemoglobin of 13.8 $\frac{\text{g}}{\text{dL}}$ with a hematocrit of 41.2%.

Leukocytes—White Blood Cells

Leukocytes or **white blood cells** usually comprise less than 1 percent of total blood volume. This translates into about 4500–11,000 leukocytes per microliter of blood, which is a small number relative to the erythrocyte concentration. This number can massively increase under certain conditions when we need more white blood cells, most notably during infection. White blood cells are a crucial part of the immune system, acting as our defenders against pathogens, foreign cells, cancer, and other materials not recognized as *self*. Let's briefly discuss five basic types of leukocytes, which are all categorized into two classes: granulocytes and agranulocytes.

The granular leukocytes or **granulocytes** (**neutrophils**, **eosinophils**, and **basophils**) are so named because they contain cytoplasmic granules that are visible by microscopy. These granules contain a variety of compounds that are toxic to invading microbes, and their contents can be released through exocytosis. Granular leukocytes are involved in inflammatory reactions, allergies, pus formation, and destruction of bacteria and parasites. The specific functions of the three granulocytes are discussed in Chapter 8 of *MCAT Biology Review*.

The agranulocytes, which do not contain granules that are released by exocytosis, consist of **lymphocytes** and **monocytes**. Lymphocytes are important in the **specific immune response**, the body's targeted fight against particular pathogens, such as viruses and bacteria. Some lymphocytes act as primary responders against an infection, while others function to maintain a long-term memory bank of pathogen recognition. These cells, in a very real sense, help our body learn from experience and are prepared to mount a fast response upon repeated exposure to familiar pathogens. Many vaccines work by training these cells. Through exposure to a weakened pathogen, or an antigenic protein of the pathogen (a protein that can be recognized by the immune system), memory cells can be created. For example, most children in the United States receive the varicella (chickenpox) vaccine, which includes a live but weakened strain of the varicella–zoster virus that causes chickenpox. When the vaccine is administered, the virus is recognized as foreign and an immune response is activated. During this process, certain immune cells form a memory of the virus; in other

words, our body learns to remember the virus and prepares itself to ward off the virus if it appears again later in life.

The majority of lymphocyte development in mammals occurs in one of two locations. Those lymphocytes that mature in the bone marrow are referred to as B-cells, and those that mature in the thymus are called T-cells. B-cells are responsible for antibody generation, whereas T-cells kill virally infected cells and activate other immune cells. The details of these two components of the specific immune response are discussed in Chapter 8 of *MCAT Biology Review*.

The other agranulocytes are monocytes, which phagocytize foreign matter such as bacteria. Most organs of the body contain a collection of these phagocytic cells; once they leave the bloodstream and enter an organ, monocytes are renamed **macrophages**. Each organ's macrophage population may have a specific name, as well. In the central nervous system, for example, they are called **microglia**; in the skin, they are called **Langerhans cells**; in bone, they are called **osteoclasts**.

Thrombocytes—Platelets

Thrombocytes or **platelets** are cell fragments or shards released from cells in bone marrow known as **megakaryocytes**. Their function is to assist in blood clotting and they are present in high concentrations (150,000–400,000 per microliter of blood). The enzymatic reactions involved in the formation of a clot (the clotting cascade) will be discussed shortly.

As mentioned above, all of the cellular elements of blood originate in the bone marrow. The production of blood cells and platelets is called **hematopoiesis**, and is triggered by a number of hormones, growth factors, and cytokines. The most notable of these are **erythropoietin**, which is secreted by the kidney and stimulates mainly red blood cell development, and **thrombopoietin**, which is secreted by the liver and kidney and stimulates mainly platelet development. The hematopoietic pathways are shown in Figure 7.7.

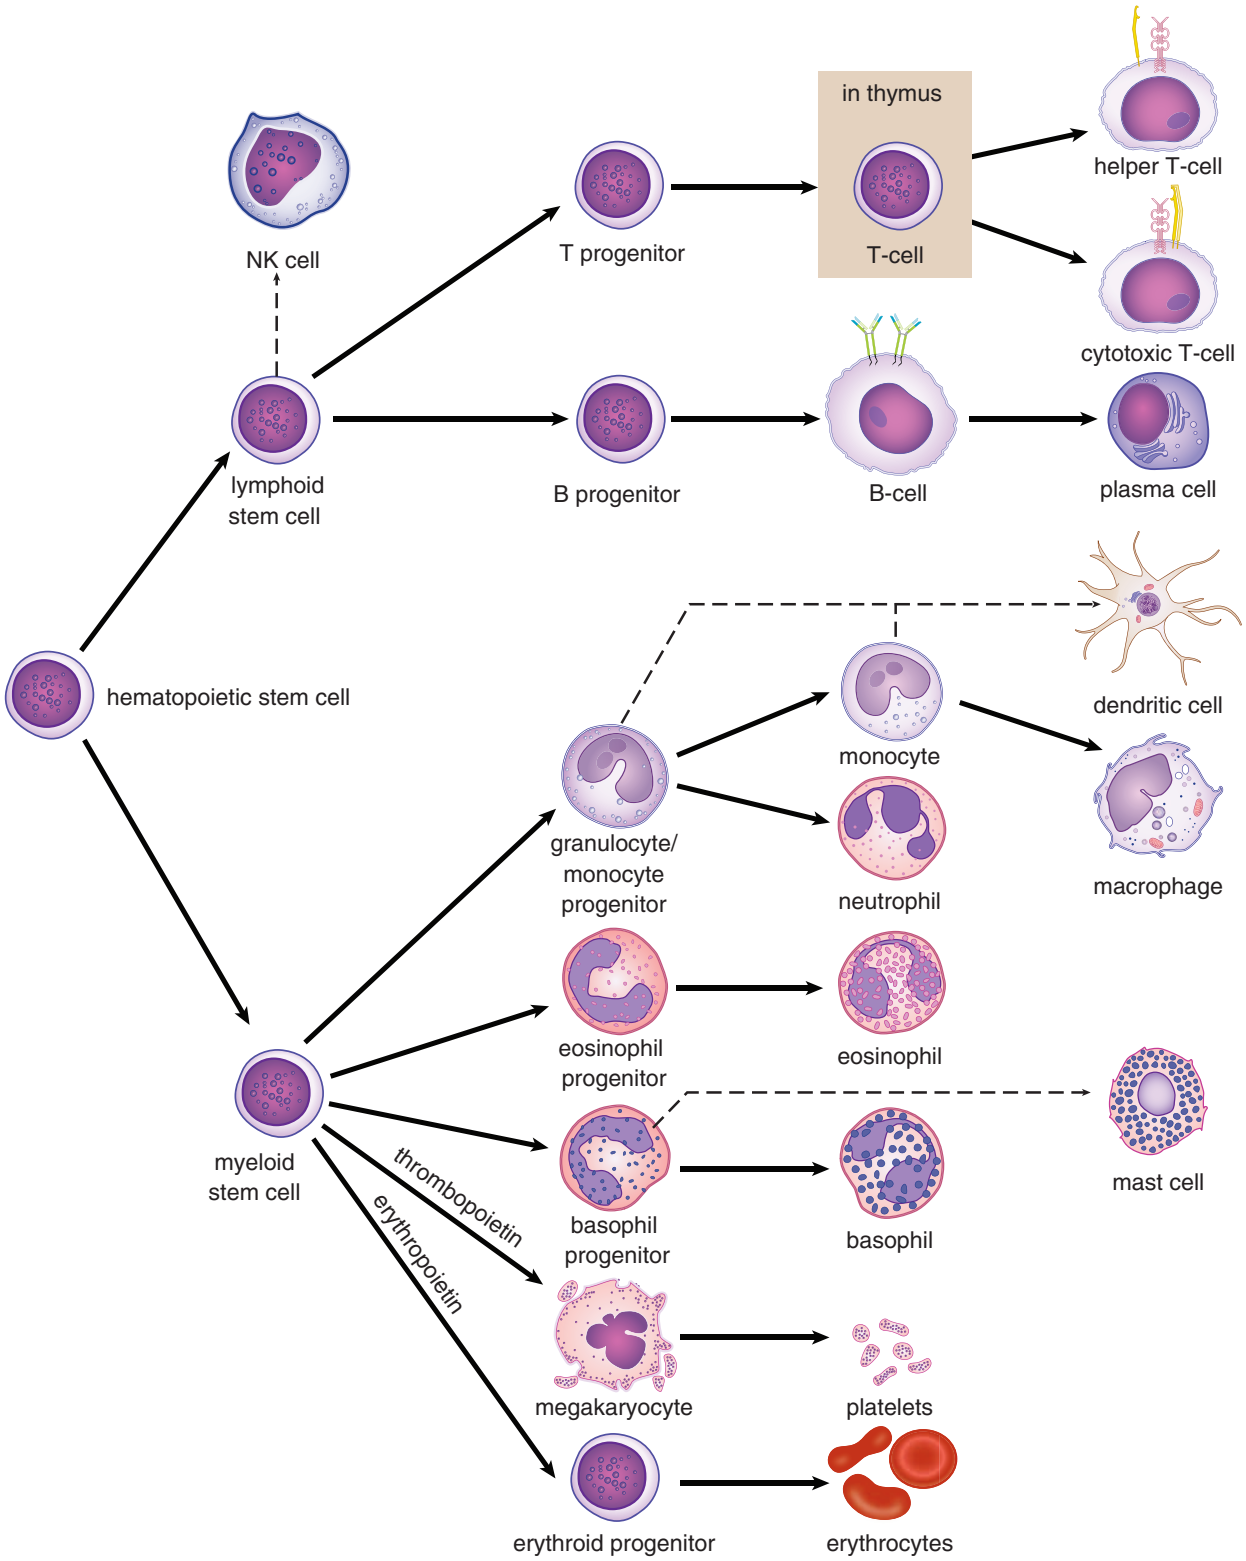


Figure 7.7. Hematopoiesis

BLOOD ANTIGENS

Red blood cells express surface proteins called **antigens**. In general, an antigen is any specific target (usually a protein) to which the immune system can react. The two major antigen families relevant for blood groups are the **ABO antigens** and the **Rh factor**.

ABO Antigens

The ABO system is comprised of three alleles for blood type. In this particular class of erythrocyte cell-surface proteins, the A and B alleles are codominant, which means that a person may express one, both, or none of the ABO antigens. If the A allele (I^A or simply A) is present on one chromosome and the B allele (I^B or B) is present on the other chromosome, both will be expressed, and the person's blood type will be AB. The O allele (i or O) is recessive to both the A and B alleles. People with type O blood do not express either variant of this protein and have a homozygous recessive genotype. The naming system of blood types is based on the presence or absence of these protein variants. The four blood types are: A, B, AB, and O. Because the A and B alleles are dominant, the genotypes for A may be I^AI^A or I^Ai, while the genotypes for B may be I^BI^B or I^Bi.

The ABO classification has important implications for medical practice; it is critical to match blood types for transfusions. It is no exaggeration to say that blood-type matching is a life and death matter, given the severe hemolysis that can result if the donor blood antigen is recognized as foreign by the recipient's immune system. For example, a person with type A blood will recognize the type A protein as *self* but the type B protein as *foreign* and will make antibodies to types B and AB. Because type O blood cells express neither antigen variant, they will not initiate any immune response, regardless of the recipient's actual blood type; people with type O blood are therefore considered **universal donors** because their blood will not cause ABO-related hemolysis in any recipient. However, a recipient who is type O will produce both anti-A *and* anti-B antibodies and can only receive blood from other type O individuals. On the other hand, people with type AB blood are considered **universal recipients** because they can receive from all blood types: no blood antigen is foreign to AB individuals, so no adverse reactions will occur upon transfusion. A more thorough description of each blood type is given in Table 7.1. Note that whole blood is almost never given in a transfusion; rather, packed red blood cells (with no plasma) are generally given. Thus, we care only about the donor's red blood cell antigens (and not his or her plasma antibodies) when determining whether hemolysis will occur.

MCAT Expertise

There are two different ways of writing the ABO alleles: I^A, I^B, and i; or A, B, and O. Be comfortable using either system because the MCAT could show one or the other. Because the former system is more common in medical practice, we'll be using it throughout this book.

Another important point needs to be made here about antibodies. Antibodies are created in response to an antigen, and they specifically target that antigen. You would not expect to have antibodies to the Ebola virus if you had never been exposed to it. This is true for the Rh factor as well—an Rh-negative individual would not have anti-Rh antibodies prior to exposure to Rh-positive blood. Why, then, does an individual lacking the A allele automatically have an anti-A antibody? The reason may lie in the gut: research has demonstrated that *E. coli* that inhabit the colon may have proteins that match the A and B alleles. This would serve as a source of exposure and would allow one to develop anti-A (or anti-B) antibodies prior to exposure to another person's blood. This is why ABO compatibility is so important during blood transfusions—giving the wrong ABO blood type would lead to rapid hemolysis.

Blood Type	Genotype(s)	Antigens Produced	Antibodies Produced	Can Donate to …	Can Receive from …
A	I^AI^A, I^Ai	A	anti-B	A, AB	A, O
B	I^BI^B, I^Bi	B	anti-A	B, AB	B, O
AB	I^AI^B	A and B	none	AB only	A, B, AB, O (universal recipient)
O	ii	none	anti-A and anti-B	A, B, AB, O (universal donor)	O only

Table 7.1. ABO Blood Types

Rh Factor

The **Rh factor** (so named because it was first described in rhesus monkeys) is also a surface protein expressed on red blood cells. Although at one time it was thought to be a single antigen, it has since been found to exist as several variants. When left unmodified, Rh-positive (Rh^+) or Rh-negative (Rh^-) refers to the presence or absence of a specific allele called D. The presence or absence of D can also be indicated with a plus or minus subscript on the ABO blood type (such as O^+, or AB^-). Rh-positivity follows autosomal dominant inheritance; one positive allele is enough for the protein to be expressed.

The Rh factor status is particularly important in maternal–fetal medicine. During childbirth, no matter how good the obstetrician is, women are exposed to a small amount of fetal blood. If a woman is Rh^- and her fetus is Rh^+, she will become sensitized to the Rh factor, and her immune system will begin making antibodies against it. This is not a problem for the first child; by the time the mother starts

MCAT Expertise

You are almost guaranteed to see at least one question on blood groups on Test Day. It is critical that you learn how the system works (I^A and I^B are codominant, i is recessive).

Key Concept

Antigens are the stimuli for B-cells to make antibodies. After exposure of a B-cell to its specific antigen, the cell becomes an antibody-producing factory.

Real World

The most common blood type in the United States is O^+. The least common is AB^-.

Real World

In blood bank pathology, the Rh factor is often referred to as D. Note that while the A, B, and D proteins are the most important for blood typing, dozens of other antigens can (and should) be matched as well, including C, E, Kell, Lewis, Duffy, and others. The more antigens that are correctly matched, the lower the probability of hemolysis.

Real World

When an Rh^- woman is pregnant with an Rh^+ fetus, the risk of erythroblastosis fetalis in subsequent Rh-mismatched pregnancies can usually be avoided by giving the Rh^- mother Rh-immunoglobulin (RhoGAM) during pregnancy and immediately after delivery. Administration of immunoglobulin (which is a type of passive immunization) will absorb the fetus's Rh^+ cells, preventing the production of anti-Rh antibodies by the mother.

producing antibodies, the child has already been born. However, any subsequent pregnancy in which the fetus is Rh^+ will present a problem because maternal anti-Rh antibodies can cross the placenta and attack the fetal blood cells, resulting in hemolysis of the fetal cells. This condition is known as **erythroblastosis fetalis** and can be fatal to the fetus. Today, we can use medicine to prevent this condition. There is less concern with ABO mismatching between mother and fetus because these maternal antibodies are of a class called IgM, which does not readily cross the placenta (unlike anti-Rh IgG antibodies, which can).

MCAT Concept Check 7.2:

Before you move on, assess your understanding of the material with these questions.

1. What are the components of plasma?

_____

_____

2. An individual with B^+ blood is in an automobile accident and requires a blood transfusion. What blood types could he receive? The same individual is so thankful that, after recovery, he decides to donate blood. To which blood types could he donate?
   - Could receive from:

     _____
   - Could donate to:

     _____

3. What does a hematocrit measure? What are the units for hematocrit?

_____

4. Which types of leukocytes are involved in the specific immune response?

_____

5. Where do platelets come from?

_____

6. Which cell type(s) in blood contain nuclei? Which do not?
   - Contain nuclei:

     _____
   - Do not contain nuclei:

     _____

7.3 Physiology of the Cardiovascular System

The cardiovascular system transports many compounds, including gases, nutrients, and waste products, to and from the body's tissues through the red blood cells and plasma. Furthermore, it serves an important role in immunity through specialized cells, such as leukocytes, which help the body fight localized or systemic pathogens. Capillaries within the body can dilate and constrict to maintain proper body temperature. In addition, the circulatory system mediates the formation of blood clots to repair damaged vessels. These functions reflect the important jobs of the cardiovascular system, which include maintenance of blood pressure, gas and solute exchange, coagulation, and thermoregulation.

BLOOD PRESSURE

Before we can even discuss gas and solute exchange, it is important to recognize that, for the circulatory system to serve its predominant functions, blood pressure must be kept sufficiently high to propel blood forward. Blood pressure, therefore, provides healthcare professionals with information regarding the effectiveness of the circulatory system. In addition, high blood pressure, or *hypertension*, is a pathological state that may result in damage to the blood vessels and organs. Blood pressure is a measure of the force per unit area exerted on the wall of the blood vessels and is measured with a **sphygmomanometer**. Sphygmomanometers measure the gauge pressure in the systemic circulation, which is the pressure above and beyond atmospheric pressure (760 mmHg at sea level), as discussed in Chapter 4 of *MCAT Physics and Math Review*. Blood pressure is expressed as a ratio of the systolic (ventricular contraction) to diastolic (ventricular relaxation) pressures. Pressure gradually drops from the arterial to venous circulation, with the largest drop occurring across the arterioles, as shown in Figure 7.8. Normal blood pressure is considered to be between 90/60 and 120/80.

Key Concept

The largest drop in blood pressure occurs across the arterioles. This is necessary because the capillaries are thin-walled and unable to withstand the pressure of the arterial side of the vasculature.

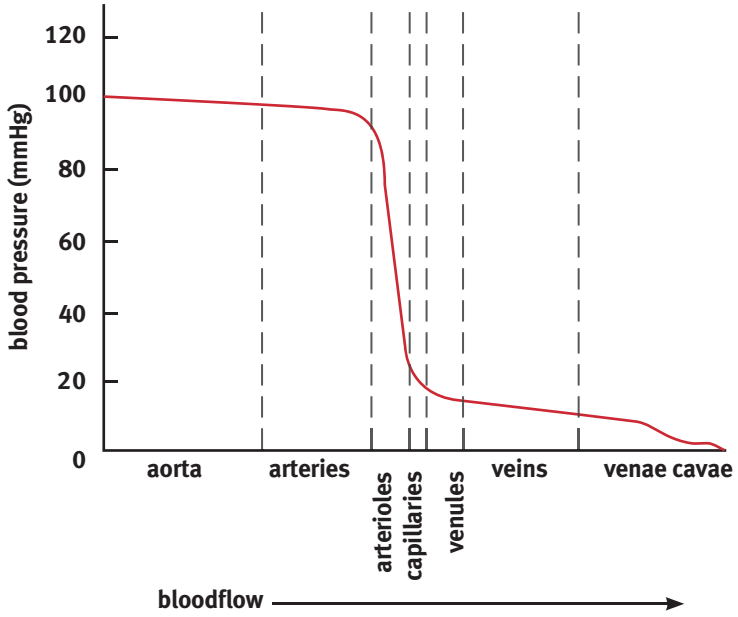

Figure 7.8. Mean Arterial Pressure at Different Locations in the Cardiovascular System

An analogy can be drawn between circulation and an electric circuit. Much like an electromotive force (voltage) drives a current through a given electrical resistance, the pressure gradient across the circulatory system drives cardiac output through a given vascular resistance. This analogy is an important one to remember because the equations of electric circuits can be applied to the cardiovascular system. For example, Ohm's law (V = IR) can be translated into the following equation in circulation:

$$\Delta P = \text{CO} \times \text{TPR}$$

Equation 7.2

where ΔP is the pressure differential across the circulation, CO is the cardiac output, and TPR is the total peripheral (vascular) resistance.

It is also important to note that arterioles and capillaries act much like resistors in a circuit. When electricity travels through a wire, the wire itself provides an intrinsic level of resistance that limits the flow of electricity through it. Resistance is based on three factors: resistivity, length, and cross-sectional area. Resistivity has no obvious correlate in physiology, but the other two factors certainly do. The longer a blood vessel is, the more resistance it offers. The larger the cross-sectional area of a blood

vessel, the less resistance it offers. In addition, arteries are highly muscular and are able to expand and contract as needed to change vascular resistance and maintain blood pressure. Arterioles can also contract to limit the amount of blood entering a given capillary bed (much like increasing resistance will decrease current flow to a given branch in a circuit). Finally, with the exception of the three portal systems, all systemic capillary beds are in parallel with each other. Therefore, opening capillary beds will decrease vascular resistance (like adding another resistor in parallel) and, assuming the body can compensate, increase cardiac output.

Blood pressure is regulated using baroreceptors in the walls of the vasculature. Baroreceptors are specialized neurons that detect changes in the mechanical forces on the walls of the vessel. When the blood pressure is too low, they can stimulate the sympathetic nervous system, which causes vasoconstriction, thereby increasing the blood pressure. In addition, chemoreceptors can sense when the osmolarity of the blood is too high, which could indicate dehydration. This promotes the release of antidiuretic hormone (ADH or vasopressin), a peptide hormone made in the hypothalamus but stored in the posterior pituitary, which increases the reabsorption of water, thereby increasing blood volume and pressure (while also diluting the blood). Low perfusion to the juxtaglomerular cells of the kidney stimulates aldosterone release through the renin–angiotensin–aldosterone system; aldosterone increases the reabsorption of sodium (and, by extension, water), thereby increasing the blood volume and pressure.

So, what if blood pressure is too high? Neurologically, sympathetic impulses could decrease, permitting relaxation of the vasculature with a concurrent drop in blood pressure. Within the heart, specialized atrial cells are able to secrete a hormone called **atrial natriuretic peptide** (**ANP**). This hormone aids in the loss of salt within the nephron, acting as a natural diuretic with loss of fluid. Interestingly, ANP is a fairly weak diuretic. Some fluid is lost, but it is often not enough to counter the effects of a high-salt diet on blood pressure. Indeed, the human body has many different ways to raise blood pressure, but very few ways to lower it.

GAS AND SOLUTE EXCHANGE

Blood pressure ensures sufficient forward flow of blood through the system. However, what happens when the blood reaches the capillaries? Here, oxygen and nutrients diffuse out of the blood into tissues, while waste products like carbon dioxide, hydrogen ions, urea, and ammonia diffuse into the blood. In addition, hormones are secreted into the capillaries, travel with the circulation, and diffuse into their target tissue. Ions and fluid must also be returned to the blood to ensure that no area

Real World

Vital signs include temperature, heart rate, respiratory rate, and blood pressure. They provide a quick snapshot of a person's condition at a given moment. High blood pressure may indicate clinical hypertension, anxiety, catecholamine-producing tumors, or stimulant use, while low blood pressure may indicate hemorrhage, a heart attack, sepsis (severe bloodstream infection), or neurological damage. These are very broad differential diagnoses; however, vital signs combined with a quick clinical history provide a way for clinicians to identify the patients that require immediate intervention.

becomes too swollen with fluid. Regardless of the substance being exchanged, there is one fundamental concept to be considered in this process: concentration gradients. In each case, one side of the capillary wall has a higher concentration of a given substance than the other. This allows for movement of gases and solutes by diffusion.

Oxygen

Oxygen is carried primarily by **hemoglobin** in the blood. Hemoglobin is a protein composed of four cooperative subunits, each of which has a prosthetic heme group that binds to an oxygen molecule. The binding of oxygen occurs at the heme group's central iron atom, which can undergo changes in its oxidation state. The binding or releasing of oxygen to or from the iron atom in the heme group is an oxidation–reduction reaction. It is also important to note that some oxygen does diffuse into the blood and dissolve into the plasma, but this amount is negligible compared to the quantity of oxygen bound to hemoglobin. The level of oxygen in the blood is often measured as the partial pressure of O_2 within the blood, or P_aO_2. A normal P_aO_2 is approximately 70–100 mmHg. However, this measurement is inconvenient because it involves taking a sample of blood from an artery. **Oxygen saturation**—that is, the percentage of hemoglobin molecules carrying oxygen—is easily measured using a finger probe. Most healthy people have an oxygen saturation above 97%.

In the lungs, oxygen diffuses into the alveolar capillaries. As the first oxygen binds to a heme group, it induces a conformational shift in the shape of hemoglobin from taut to relaxed. This shift increases hemoglobin's affinity for oxygen, making it easier for subsequent molecules of oxygen to bind to the remaining three unoccupied heme groups. As other heme groups acquire an oxygen molecule, the affinity continues to increase, thus creating a positive feedback-like (spiraling forward) mechanism. Once all of the hemoglobin subunits are bound to oxygen, the removal of one molecule of oxygen will induce a conformational shift, decreasing the overall affinity for oxygen, and making it easier for the other molecules of oxygen to leave the heme groups. This is again a spiraling forward process; as oxygen molecules leave hemoglobin, it becomes progressively easier for more oxygen to be removed. This phenomenon is a form of allosteric regulation referred to as **cooperative binding** and results in the classic sigmoidal (*S*-shaped) oxyhemoglobin dissociation curve shown in Figure 7.9.

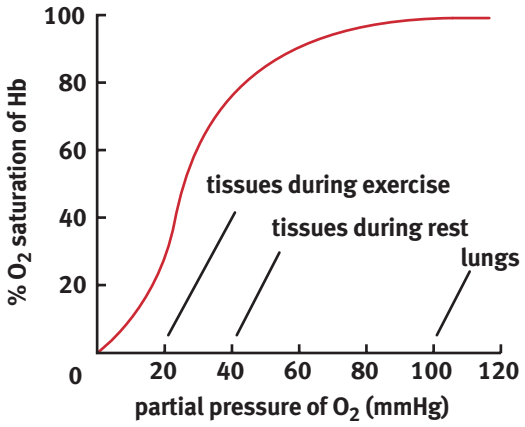

Figure 7.9. Oxyhemoglobin Dissociation Curve

Before looking at shifts in this curve, let's make sure we understand what everything means. According to the curve, the blood is 100% saturated in the lungs, at a partial pressure of 100 mmHg O_2. The tissues are at a lower partial pressure of oxygen, around 40 mmHg during rest; at this lower partial pressure, the hemoglobin is approximately 80% saturated. Therefore, about 100 – 80 = 20% of the oxygen has been released from the hemoglobin. Where did this oxygen go? Into the tissues, of course.

During exercise, the partial pressure of oxygen in the tissues is even lower—around 20 mmHg. At this lower partial pressure, the hemoglobin is approximately 30% saturated. Therefore, about 100 – 30 = 70% of the oxygen has been released to the tissues. In reality, unloading of oxygen is also facilitated by shifts in the hemoglobin curve that occur during exercise, as described later.

Carbon Dioxide

Delivering oxygen to tissues is only part of the job of transporting respiratory gases; removing carbon dioxide gas (CO_2), the primary waste product of cellular respiration, is also important. Carbon dioxide gas, like oxygen gas, is nonpolar and therefore has low solubility in the aqueous plasma; only a small percentage of the total CO_2 being transported in the blood to the lungs will be dissolved in the plasma. Carbon dioxide can be carried by hemoglobin, but hemoglobin has a much lower affinity for carbon dioxide than for oxygen. The vast majority of CO_2 exists in the blood as the bicarbonate ion (HCO_3^-). When CO_2 enters a red blood

cell, it encounters the enzyme *carbonic anhydrase*, which catalyzes the combination reaction between carbon dioxide and water to form carbonic acid (H_2CO_3). Carbonic acid, a weak acid, will dissociate into a proton and the bicarbonate anion. The hydrogen ion (proton) and bicarbonate ion both have high solubilities in water, making them a more effective method of transporting metabolic waste products to the lungs for excretion. Upon reaching the alveolar capillaries in the lungs, the same reactions that led to the formation of the proton and bicarbonate anion can be reversed, allowing us to breathe out carbon dioxide:

$$CO_2\,(g) + H_2O\,(l) \underset{\text{carbonic anhydrase}}{\rightleftharpoons} H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

This chemical reaction is important, not only because it provides an effective means of ridding the body's tissues of carbon dioxide gas, but also because the concentration of free protons in the blood affects pH; the pH, in turn, can have allosteric effects on the oxyhemoglobin dissociation curve. Increased carbon dioxide production will cause a right shift in the bicarbonate buffer equation, resulting in decreased pH (increased $[H^+]$). These protons can bind to hemoglobin, reducing hemoglobin's affinity for oxygen. This decreased affinity can be seen in the oxyhemoglobin curve as a shift to the right; this is known as the **Bohr effect**. Note that the triggers for this right shift (increased P_aCO_2, increased $[H^+]$, decreased pH) are often associated with oxygen demand; higher rates of cellular metabolism result in increased carbon dioxide production and accumulation of lactic acid, both of which decrease pH. This decreased affinity allows more oxygen to be unloaded at the tissues, as shown in Figure 7.10. Looking at the red and green lines, we see that hemoglobin is nearly 100% saturated in the lungs (at a partial pressure of 100 mmHg O_2) for both lines. However, the green line is significantly lower than the red one when we reach a partial pressure of 20 mmHg O_2, around that of exercising muscle. Therefore, the right shift results in a greater unloading of oxygen into the tissues.

Mnemonic

Causes of a **right** shift of the oxyhemoglobin curve: **Exercise** is the **right** thing to do.

The following occur during **exercise**:

- Increased P_aCO_2
- Increased $[H^+]$ (decreased pH)
- Increased temperature

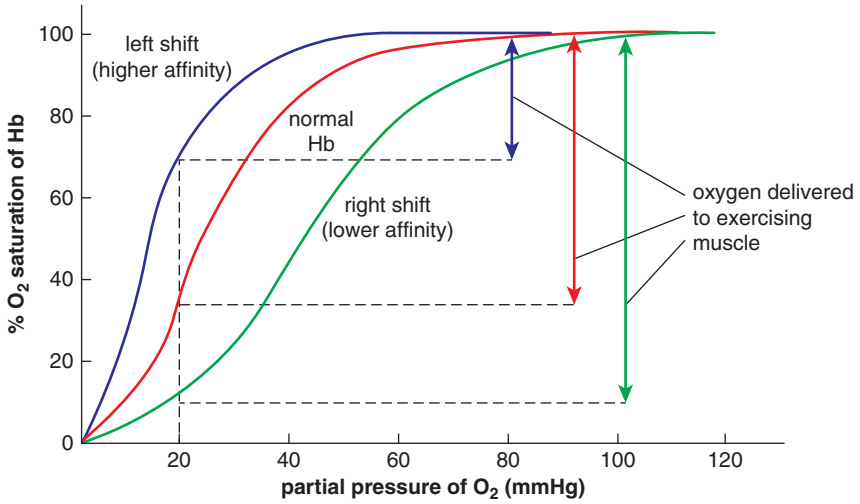

Figure 7.10. Shifts in the Oxyhemoglobin Dissociation Curve

Other causes of a right shift in the oxyhemoglobin curve include increased temperature and increased 2,3-bisphosphoglycerate (2,3-BPG), a side product of glycolysis in red blood cells.

A left shift, like the blue line in Figure 7.10, may occur due to decreased P_aCO_2, decreased $[H^+]$, increased pH, decreased temperature, and decreased 2,3-BPG. In addition, **fetal hemoglobin** (**HbF**) has a higher affinity for oxygen than **adult hemoglobin** (**HbA**). This should make sense because fetal red blood cells must literally pull oxygen off of maternal hemoglobin and onto fetal hemoglobin.

The bicarbonate buffer system is also important because it links the respiratory and renal systems. Disturbances in either of these systems can lead to changes in the pH of the blood. For example, if an individual hyperventilates, excess CO_2 will be blown off, shifting the bicarbonate buffer system to the left and decreasing the concentration of protons. This leads to an increase in pH, or what is known as respiratory alkalosis. The kidney can compensate for this change by increasing excretion of bicarbonate, which brings the pH back to normal. In contrast, in *renal tubular acidosis type I*, the kidney is unable to excrete acid effectively. This leads to a buildup of protons in the blood (metabolic acidosis), which causes the buffer system to shift to the left. The excess CO_2 formed in the process can be exhaled, and the person may increase respiratory rate to compensate, bringing the pH back to normal.

Key Concept

Fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin, and therefore has a left-shifted curve compared to adult hemoglobin.

Nutrients, Waste, and Hormones

In addition to respiratory gases, blood also carries nutrients, waste products, and hormones to the appropriate location for use or disposal. As discussed earlier, concentration gradients guide much of the movement of these substances to and from the tissues.

Carbohydrates and amino acids are absorbed into the capillaries of the small intestine and enter the systemic circulation via the hepatic portal system. Fats are absorbed into lacteals in the small intestine, bypassing the hepatic portal circulation to enter systemic circulation via the thoracic duct. When released from intestinal cells, fats are packaged in lipoproteins, which are water-soluble. The absorption of nutrients is covered more extensively in Chapter 9 of *MCAT Biology Review*.

Wastes, such as carbon dioxide, ammonia, and urea, enter the bloodstream by traveling down their respective concentration gradients from the tissues to the capillaries. The blood eventually travels to the kidney, where these waste products are filtered or secreted for elimination from the body.

Hormones enter the circulation in or near the organ where the hormone is produced. This usually occurs by exocytosis, allowing for secretion of hormones into the bloodstream. Certain hormones are carried by proteins in the blood and are released under specific conditions. Once hormones reach their target tissues, they can activate cell-surface receptors (peptide hormones) or diffuse into the cell to activate intracellular or intranuclear receptors (steroid hormones).

Fluid Balance

In the bloodstream, two pressure gradients are essential for maintaining a proper balance of fluid volume and solute concentrations between the blood and the interstitium (the cells surrounding the blood vessels). These are the opposing but related hydrostatic and osmotic (oncotic) pressures.

Hydrostatic pressure is the force per unit area that the blood exerts against the vessel walls. This is generated by the contraction of the heart and the elasticity of the arteries, and can be measured upstream in the large arteries as blood pressure. Hydrostatic pressure pushes fluid out of the bloodstream and into the interstitium through the capillary walls, which are somewhat leaky by design. **Osmotic pressure**, on the other hand, is the "sucking" pressure generated by solutes as they attempt to draw water into the bloodstream. Because most of this osmotic pressure is attributable to plasma proteins, it is usually called **oncotic pressure**.

At the arteriole end of a capillary bed, hydrostatic pressure (pushing fluid out) is much larger than oncotic pressure (drawing fluid in), and there is a net efflux of water from the circulation, as shown in Figure 7.11. As fluid moves out of the vessels, the hydrostatic pressure drops significantly, but the osmotic pressure stays about the same. Therefore, at the venule end of the capillary bed, hydrostatic pressure (pushing fluid out) has dropped below oncotic pressure (drawing fluid in), and there is a net influx of water back into the circulation.

Key Concept

Hydrostatic pressure *pushes* fluid *out* of vessels and is dependent on blood pressure driven by the heart and the elastic arteries. Osmotic pressure *pulls* fluid back *into* the vessels and is dependent on the number of particles dissolved in the plasma; most are proteins, so we often refer to this as oncotic pressure.

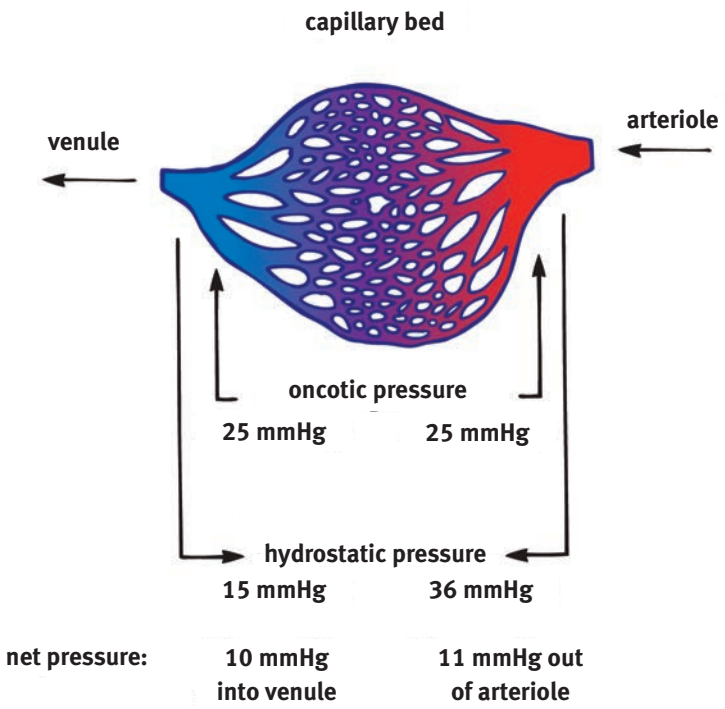

Figure 7.11. Starling Forces at a Capillary Bed

The balance of these opposing pressures, also called **Starling forces**, is essential for maintaining the proper fluid volumes and solute concentrations inside and outside the vasculature. Imbalance of these pressures can result in too much or too little fluid in the tissues. For example, accumulation of excess fluid in the interstitium results in a condition called **edema**. We should note that some interstitial fluid is also taken up by the lymphatic system. Most lymphatic fluid (**lymph**) is returned to the central circulatory system by way of a channel called the **thoracic duct**. Blockage of lymph nodes by infection or surgery can also result in edema. Although you do not need to learn or memorize the Starling equation, which quantifies the net filtration rate between two fluid compartments, you should understand that the movement of solutes and fluid at the capillary level is governed by pressure differentials, just like the movement of carbon dioxide and oxygen in the lungs.

COAGULATION

We have now covered most of the functions of red blood cells and plasma. We've briefly touched on white blood cells, which we'll explore more extensively in Chapter 8 of *MCAT Biology Review*. This leaves us with platelets, which protect the vascular system in the event of damage by forming a clot. **Clots** are composed of both coagulation factors (proteins) and platelets, and they prevent (or at least minimize) blood loss. When the endothelium of a blood vessel is damaged, it exposes the underlying connective tissue, which contains collagen and a protein called **tissue factor**. When platelets come into contact with exposed collagen, they sense this as evidence of injury. In response, they release their contents and begin to aggregate, or clump together. Simultaneously, **coagulation factors**, most of which are secreted by the liver, sense tissue factor and initiate a complex activation cascade. While the details of the coagulation cascade are beyond the scope of the MCAT, it is important to know that the endpoint of the cascade is the activation of **prothrombin** to form **thrombin** by **thromboplastin**. Thrombin can then convert **fibrinogen** into **fibrin**. Fibrin ultimately forms small fibers that aggregate and cross-link into a woven structure, like a net, that captures red blood cells and other platelets, forming a stable clot over the area of damage, as shown in Figure 7.12. A clot that forms on a surface vessel that has been cut is called a scab.

Ultimately, the clot will have to be broken down. This task is accomplished predominantly by **plasmin**, which is generated from **plasminogen**.

Real World

Certain genetic diseases, such as hemophilia, cause malfunctions in the cascade of clotting reactions and increase the risk of life-threatening blood loss from even relatively minor injuries. Hemophilia A is the most common and, as a sex-linked trait, is far more common in males than females.

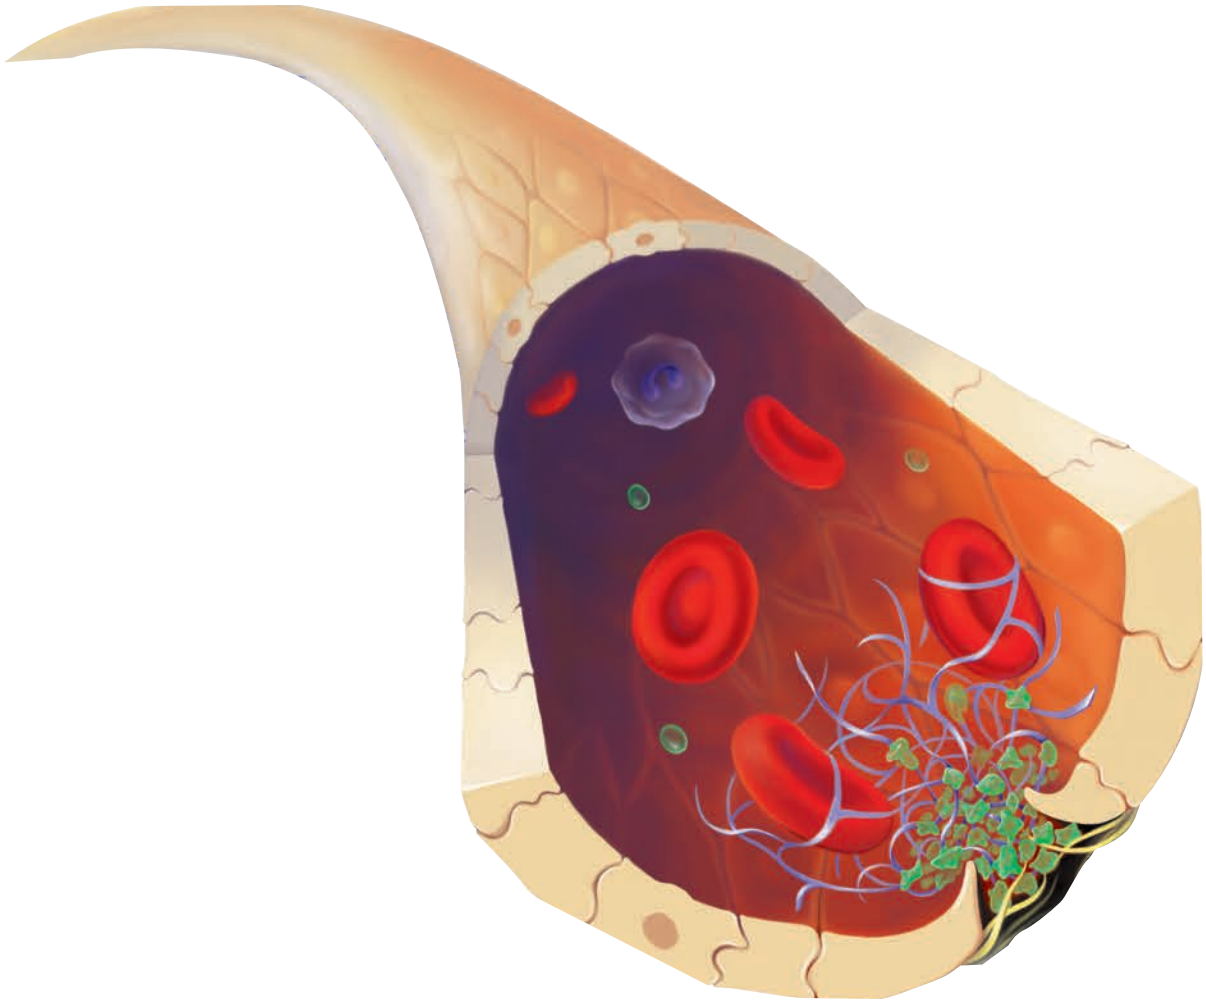

Figure 7.12. Thrombus (Clot) Formation

Thrombus formation, or blood clotting, occurs when blood vessels are injured. The process begins when platelets attach to the matrix that becomes exposed when the endothelial cells lining blood vessels are disrupted. This attachment then activates quiescent $\alpha_{IIb}\beta_3$ integrin molecules, causing them to adhere to circulating proteins—including fibrinogen, which forms bridges to additional platelets. Together the cells and proteins ultimately form a network of cells and fibers dense enough to plug the injury and prevent blood loss until the wound can be repaired.

MCAT Concept Check 7.3:

Before you move on, assess your understanding of the material with these questions.

1. In bacterial sepsis (overwhelming bloodstream infection), a number of capillary beds throughout the body open simultaneously. What effect would this have on the blood pressure? Besides the risk of infection, why might sepsis be dangerous for the heart?

_____

_____

2. What is the chemical equation for the bicarbonate buffer system? What enzyme catalyzes this reaction?

_____

3. Where should you look on the oxyhemoglobin dissociation curve to determine the amount of oxygen that has been delivered to tissues?

_____

4. What can cause a right shift of the oxyhemoglobin dissociation curve? What can cause a left shift?

   - Right shift:

     _____

   - Left shift:

     _____

5. Exposure of which subendothelial compounds start the coagulation cascade? What protein helps stabilize the clot?

   - Starts the cascade:

     _____

   - Stabilizes the clot:

     _____

Conclusion

The cardiovascular system is one of the most commonly tested MCAT topics. You should be familiar with its basic structure: a system with two pumps in series. The right ventricle pumps blood into the pulmonary circulation, while the left ventricle pumps blood into the systemic circulation. We discussed the myogenic activity of cardiac muscle and the pathway that electricity follows in the heart through the SA node, AV node, bundle of His, and Purkinje fibers. The movement of blood through the vascular system is a function of the heart's pumping to generate pressure. Blood pressure is a measure of the blood's force per unit area on the vessel walls and is recorded as a gauge pressure (pressure above and beyond atmospheric pressure). We discussed the differences in structure between arteries, capillaries, and veins, and how these anatomical differences are reflective of their different functions. We then reviewed the composition of blood along with the three major blood cell types. We examined the ABO and Rh antigen systems, which frequently appear on the MCAT due to their widespread clinical relevance. The blood's ability to carry oxygen and carbon dioxide was also described; recall that carbon dioxide is primarily carried as bicarbonate ions in the blood. The conversion of carbon dioxide to and from this ion is accomplished by the enzyme carbonic anhydrase.

In this chapter, we focused on the functions of red blood cells, plasma, and platelets. We briefly examined the immune system, which is primarily driven by the actions of white blood cells and their products. Immunology is considered one of the most challenging courses in medical school, as you'll learn about dozens of cytokines, clusters of differentiation (CD), and specialized cell types. In the next chapter, we'll focus on the basics of immunology, discussing the major components of the innate (nonspecific) and adaptive (specific) immune responses.

CONCEPT SUMMARY

Anatomy of the Cardiovascular System

- The **cardiovascular system** consists of a muscular four-chambered heart, blood vessels, and blood.
- The **heart** is composed of **cardiac muscle** and supports two different circulations: the **pulmonary circulation** and the **systemic circulation**.
  - Each side of the heart consists of an **atrium** and a **ventricle**.
  - The atria are separated from the ventricles by the **atrioventricular valves** (**tricuspid** on the right, **mitral** [**bicuspid**] on the left).
  - The ventricles are separated from the vasculature by the **semilunar valves** (**pulmonary** on the right, **aortic** on the left).
  - The pathway of blood is: right atrium $\xrightarrow[\text{valve}]{\text{tricuspid}}$ right ventricle $\xrightarrow[\text{valve}]{\text{pulmonary}}$ pulmonary artery → lungs → pulmonary veins → left atrium $\xrightarrow[\text{valve}]{\text{mitral}}$ left ventricle $\xrightarrow[\text{valve}]{\text{aortic}}$ aorta → arteries → arterioles → capillaries → venules → veins → venae cavae → right atrium
  - The left side of the heart contains more muscle than the right side because the systemic circulation has a much higher resistance and pressure.
  - Electrical conduction of the heart starts at the **sinoatrial** (**SA**) **node** and then goes to the **atrioventricular** (**AV**) **node**. From the AV node, electrical conduction goes to the **bundle of His** before traveling through the **Purkinje fibers**.
  - **Systole** refers to the period during ventricular contraction when the AV valves are closed. During **diastole**, the heart is relaxed and the semilunar valves are closed.
  - The **cardiac output** is the product of **heart rate** and **stroke volume**.
  - The sympathetic nervous system increases the heart rate and contractility. The parasympathetic nervous system decreases heart rate.
- The vasculature consists of arteries, veins, and capillaries.
  - **Arteries** are thick, highly muscular structures with an elastic quality. This allows for recoil and helps to propel blood forward within the system. Small muscular arteries are **arterioles**, which control flow into capillary beds.
  - **Capillaries** have walls that are one cell thick, making them so narrow that red blood cells must travel through them in single-file lines. Capillaries are the sites of gas and solute exchange.
  - **Veins** are inelastic, thin-walled structures that transport blood to the heart. They are able to stretch in order to accommodate large volumes of blood

but do not have recoil capability. Veins are compressed by surrounding skeletal muscles and have **valves** to maintain one-way flow. Small veins are called **venules**.

- A portal system is one in which blood passes through two capillary beds in series.
  - In the **hepatic portal system**, blood travels from the gut capillary beds to the liver capillary bed via the hepatic portal vein.
  - In the **hypophyseal portal system**, blood travels from the hypothalamus to the anterior pituitary.
  - In the **renal portal system**, blood travels from the glomerulus to the vasa recta through an efferent arteriole.

Blood

- Blood is composed of cells and plasma, an aqueous mixture of nutrients, salts, respiratory gases, hormones, and blood proteins.
- **Erythrocytes** (**red blood cells**) lack mitochondria, a nucleus, and organelles in order to make room for **hemoglobin**, a protein that carries oxygen. Common measurements include hemoglobin concentration and **hematocrit**, the percent of blood composed of erythrocytes.
- **Leukocytes** (**white blood cells**) are formed in the bone marrow. They are a crucial part of the immune system.
  - Granular leukocytes such as neutrophils, eosinophils, and basophils play a role in nonspecific immunity.
  - Agranulocytes, including lymphocytes and monocytes, also play a role in immunity, with lymphocytes playing a large role in specific immunity.
- **Thrombocytes** (**platelets**) are cell fragments from **megakaryocytes** that are required for coagulation.
- Blood antigens include the surface antigens A, B, and O, as well as Rh factor (D).
  - The I^A (A) and I^B (B) alleles are codominant, while the i (O) allele is recessive. An individual has antibodies for any ABO alleles he or she does not have.
  - Positive Rh factor is dominant. An Rh-negative individual will only create anti-Rh antibodies after exposure to Rh-positive blood.

Physiology of the Cardiovascular System

- **Blood pressure** refers to the force per unit area that is exerted on the walls of blood vessels by blood. It is divided into systolic and diastolic components.
  - It must be high enough to overcome the resistance created by arterioles and capillaries, but low enough to avoid damaging the vasculature and surrounding structures.

- It can be measured with a **sphygmomanometer**.
- The blood pressure is maintained by baroreceptor and chemoreceptor reflexes. Low blood pressure promotes **aldosterone** and **antidiuretic hormone** (**ADH** or **vasopressin**) release. High blood osmolarity also promotes ADH release. High blood pressure promotes **atrial natriuretic peptide** (**ANP**) release.

- Gas and solute exchange occurs at the level of the capillaries and relies on the existence of concentration gradients to facilitate diffusion across the capillary walls. Capillaries are also leaky, which aids in transport of gases and solutes.
  - **Starling forces** consist of **hydrostatic pressure** and **osmotic** (**oncotic**) **pressure**. Hydrostatic pressure is the pressure of the fluid within the blood vessel, while osmotic pressure is the "sucking" pressure drawing water toward solutes. Oncotic pressure is osmotic pressure due to proteins. Hydrostatic pressure forces fluid out at the arteriolar end of a capillary bed; oncotic pressure draws it back in at the venule end.
  - Oxygen is carried by hemoglobin, which exhibits **cooperative binding**. In the lungs, there is a high partial pressure of oxygen, resulting in loading of oxygen onto hemoglobin. In the tissues, there is a low partial pressure of oxygen, resulting in unloading. With cooperative binding, each successive oxygen bound to hemoglobin increases the affinity of the other subunits, while each successive oxygen released decreases the affinity of the other subunits.
  - Carbon dioxide is largely carried in the blood in the form of carbonic acid, or bicarbonate and hydrogen ions. Carbon dioxide is nonpolar and not particularly soluble, while bicarbonate, hydrogen ions, and carbonic acid are polar and highly soluble.
  - A high P_aCO_2, high $[H^+]$, low pH, high temperature, and high concentration of 2,3-BPG can cause a right shift in the **oxyhemoglobin dissociation curve**, reflecting a decreased affinity for oxygen.
  - In addition to the opposites of the causes of a right shift, a left shift can also be seen in fetal hemoglobin compared to adult hemoglobin.
  - Nutrients, wastes, and hormones are carried in the bloodstream to tissues for use or disposal.

- **Coagulation** results from an activation cascade.
  - When the endothelial lining of a blood vessel is damaged, the collagen and **tissue factor** underlying the endothelial cells are exposed. This results in a cascade of events known as the **coagulation cascade**, ultimately resulting in the formation of a clot over the damaged area.
  - Platelets bind to the collagen and are stabilized by **fibrin**, which is activated by **thrombin**.
  - Clots can be broken down by **plasmin**.

ANSWERS TO CONCEPT CHECKS

7.1

1.

Heart Chamber	Valve that Prevents Backflow
Right atrium	Tricuspid valve
Right ventricle	Pulmonary valve
Left atrium	Mitral (bicuspid) valve
Left ventricle	Aortic valve

2. Sinoatrial (SA) node → atrioventricular (AV) node → bundle of His (AV bundle) and its branches → Purkinje fibers

3.

Vessel	Carries Blood Which Direction?	Relative Wall Thickness	Smooth Muscle Present?	Contains Valves?
Artery	Away from heart	Thick	Yes, a lot	No
Capillary	From arterioles to venules	Very thin (one cell layer)	No	No
Vein	Toward heart	Thin	Yes, a little	Yes

4. The right side of the heart pumps blood into a lower-resistance circuit and must do so at lower pressures; therefore, it requires less muscle. The left side of the heart pumps blood into a higher-resistance circuit at higher pressures; therefore, it requires more muscle.
5. If all autonomic innervation to the heart were lost, the heart would continue beating at the intrinsic rate of the pacemaker (SA node). The individual would be unable to change his or her heart rate via the sympathetic or parasympathetic nervous system, but the heart would not stop beating.

7.2

1. Plasma is an aqueous mixture of nutrients, salts, respiratory gases, hormones, and blood proteins (clotting proteins, immunoglobulins, and so on).
2. A B^+ person could receive blood from a B^+, B^-, O^+, or O^- person. A B^+ person could donate blood to a B^+ or AB^+ person.
3. Hematocrit measures the percentage of a blood sample occupied by red blood cells. It is measured in percentage points.
4. Lymphocytes are involved in specific immune defense.
5. Platelets are cellular fragments or shards that are given off by megakaryocytes in the bone marrow.
6. Only leukocytes (including neutrophils, eosinophils, basophils, monocytes/macrophages, and lymphocytes) contain nuclei. Erythrocytes and platelets do not.

7.3

1. Opening up more capillary beds (which are in parallel) will decrease the overall resistance of the circuit. The cardiac output will therefore increase in an attempt to maintain constant blood pressure. This is a risk to the heart because the increased demand on the heart can eventually tire it, leading to a heart attack or a precipitous drop in blood pressure.
2. The bicarbonate buffer system equation is $CO_2\ (g) + H_2O\ (l) \rightleftharpoons H_2CO_3\ (aq) \rightleftharpoons H^+\ (aq) + HCO_3^-\ (aq)$. The combining of carbon dioxide and water is catalyzed by carbonic anhydrase.
3. The amount of oxygen delivery can be seen as a drop in the *y*-value (percent hemoglobin saturation) on an oxyhemoglobin dissociation curve. For example, if the blood is 100% saturated while in the lungs (at 100 mmHg O_2) and only 80% saturated while in tissues (at 40 mmHg O_2), then 20% of the oxygen has been released to tissues.
4. A right shift can be caused by increased CO_2, increased $[H^+]$, decreased pH, increased temperature, or increased 2,3-BPG. A left shift can be caused by decreased CO_2, decreased $[H^+]$, increased pH, decreased temperature, decreased 2,3-BPG, or in fetal hemoglobin (in comparison to adult hemoglobin).
5. The coagulation cascade can be started by exposure of collagen and tissue factor. The clot is stabilized by fibrin.

EQUATIONS TO REMEMBER

(7.1) **Cardiac output:** $CO = HR \times SV$

(7.2) **Ohm's law applied to circulation:** $\Delta P = CO \times TPR$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following is a FALSE statement regarding erythrocytes?

A. Erythrocytes contain hemoglobin.
B. Erythrocytes are anaerobic.
C. The nuclei of erythrocytes are located in the middle of the biconcave disc.
D. Erythrocytes are phagocytized in the spleen and liver after a certain period of time.

2. Which of the following is the correct sequence of a cardiac impulse?

A. SA node → AV node → Purkinje fibers → bundle of His → ventricles
B. AV node → bundle of His → Purkinje fibers → ventricles → atria
C. SA node → atria → AV node → bundle of His → Purkinje fibers → ventricles
D. SA node → AV node → atria → bundle of His → Purkinje fibers → ventricles

3. Hemoglobin's affinity for O_2:

A. increases in exercising muscle tissue.
B. decreases as blood P_aCO_2 decreases.
C. decreases as blood pH decreases.
D. is higher in maternal blood than in fetal blood.

4. Which of the following correctly traces the circulatory pathway?

A. Superior vena cava → right atrium → right ventricle → pulmonary artery → lungs → pulmonary veins → left atrium → left ventricle → aorta
B. Superior vena cava → left atrium → left ventricle → pulmonary artery → lungs → pulmonary veins → right atrium → right ventricle → aorta
C. Aorta → right atrium → right ventricle → pulmonary artery → lungs → pulmonary veins → left atrium → left ventricle → superior vena cava
D. Superior vena cava → right atrium → right ventricle → pulmonary veins → lungs → pulmonary artery → left atrium → left ventricle → aorta

5. At the venous end of a capillary bed, the osmotic pressure:

A. is greater than the hydrostatic pressure.
B. results in a net outflow of fluid.
C. is significantly higher than the osmotic pressure at the arterial end.
D. causes proteins to enter the interstitium.

6. A patient's chart reveals that he has a cardiac output of 7500 mL per minute and a stroke volume of 50 mL. What is his pulse, in beats per minute?

A. 50
B. 100
C. 150
D. 400

7. An unconscious patient is rushed into the emergency room and needs an immediate blood transfusion. Because there is no time to check her medical history or determine her blood type, which type of blood should she receive?

A. AB^+
B. AB^-
C. O^+
D. O^-

8. Which of the following is true regarding arteries and veins?

A. Arteries are thin-walled, muscular, and elastic, whereas veins are thick-walled and inelastic.
B. Arteries always conduct oxygenated blood, whereas veins always carry deoxygenated blood.
C. The blood pressure in the aorta is always higher than the pressure in the superior vena cava.
D. Arteries facilitate blood transport by using skeletal muscle contractions, whereas veins make use of the pumping of the heart to push blood.

9. At any given time, there is more blood in the venous system than the arterial system. Which of the following features of veins allows for this?

A. Relative lack of smooth muscle in the wall
B. Presence of valves
C. Proximity of veins to lymphatic vessels
D. Thin endothelial lining

10. Which of the following is involved in the body's primary blood-buffering mechanism?

A. Fluid intake
B. Absorption of nutrients in the gastrointestinal system
C. Carbon dioxide produced from metabolism
D. Hormones released by the kidney

11. Due to kidney disease, a person is losing albumin into the urine. What effect is this likely to have within the capillaries?

A. Increased oncotic pressure
B. Increased hydrostatic pressure
C. Decreased oncotic pressure
D. Decreased hydrostatic pressure

12. The tricuspid valve prevents backflow of blood from the:

A. left ventricle into the left atrium.
B. aorta into the left ventricle.
C. pulmonary artery into the right ventricle.
D. right ventricle into the right atrium.

13. The world record for the longest-held breath is 22 minutes and 0 seconds. If a sample were taken from this individual during the last minute of breath-holding, which of the following might be observed?

A. Increased hemoglobin affinity for oxygen
B. Decreased P_aCO_2
C. Increased hematocrit
D. Decreased pH

14. A person has a heart attack that primarily affects the wall between the two ventricles. Which portion of the electrical conduction system is most likely affected?

A. AV node
B. SA node
C. Bundle of His
D. Left ventricular muscle

15. Which vascular structure creates the most resistance to blood flow?

A. Aorta
B. Arterioles
C. Capillaries
D. Veins

Explanations to Discrete Practice Questions

1. C

Erythrocytes, or red blood cells, are produced in the red bone marrow and circulate in the blood for about 120 days, after which they are phagocytized in the spleen and the liver, eliminating **choice (D)**. Red blood cells have a disk-like shape and lose their membranous organelles (like mitochondria and nuclei) during maturation. This makes **choice (C)** the correct answer. Erythrocytes are filled with hemoglobin; their lack of mitochondria makes their metabolism solely anaerobic, eliminating **choices (A)** and **(B)**.

2. C

An ordinary cardiac contraction originates in, and is regulated by, the sinoatrial (SA) node. The impulse travels through both atria, stimulating them to contract simultaneously. The impulse then arrives at the atrioventricular (AV) node, which momentarily slows conduction, allowing for completion of atrial contraction and ventricular filling. The impulse is then carried by the bundle of His and its branches through the Purkinje fibers in the walls of both ventricles, generating a strong contraction.

3. C

According to the Bohr effect, decreasing the pH in the blood decreases hemoglobin's affinity for O_2. This makes **choice (C)** the correct answer. The affinity is generally lowered in exercising muscle to facilitate unloading of oxygen to tissues, eliminating **choice (A)**. A decrease in the P_aCO_2 would cause a decrease in $[H^+]$ or increased pH—which increases hemoglobin's affinity for O_2, eliminating **choice (B)**. Finally, **choice (D)** is incorrect because hemoglobin's affinity for O_2 is higher in fetal blood than in adult blood.

4. A

Blood drains from the superior and inferior venae cavae into the right atrium. It passes through the tricuspid valve and into the right ventricle, and then through the pulmonary valve into the pulmonary artery, which leads to the lungs. Oxygenated blood returns to the left atrium via the pulmonary veins. It flows through the mitral valve into the left ventricle. From the left ventricle, it is pumped through the aortic valve into the aorta for distribution throughout the body.

5. A

The exchange of fluid is greatly influenced by the relative balance between the hydrostatic and osmotic pressures of blood and tissues. The osmotic (oncotic) pressure remains relatively constant; however, the hydrostatic pressure at the arterial end is greater than the hydrostatic pressure at the venous end. As a result, fluid moves out of the capillaries at the arterial end and back in at the venous end. Fluid is reabsorbed at the venous end because the osmotic pressure exceeds the hydrostatic pressure. Proteins should not cross the capillary wall under normal circumstances.

6. C

The first step in solving this problem is to define cardiac output: cardiac output = heart rate × stroke volume. We can therefore divide the cardiac output by the stroke volume to determine heart rate:

$$\text{HR} = \frac{\text{CO}}{\text{SV}} = \frac{7500\ \frac{\text{mL}}{\text{min}}}{50\ \frac{\text{mL}}{\text{beat}}} = 150\ \frac{\text{beats}}{\text{min}}$$

Note that this heart rate is actually pathologically fast; a normal heart rate is considered to be between 60 and 100 beats per minute.

7. D

Without knowing a patient's blood type, the only type of transfusion that we can safely give is O^-. People with O^- blood are considered universal donors because their blood cells contain no surface antigens. Therefore, O^- blood can be given to anyone without causing potentially life-threatening consequences from ABO incompatibility.

8. C

The only answer choice that correctly describes arteries and veins is **choice (C)**; the pressure in the aorta usually ranges between 120 and 80 mmHg, depending on whether the heart is in systole or diastole, whereas the pressure in the superior vena cava is near zero. **Choice (A)** is incorrect because arteries are thick-walled and veins are thin-walled. **Choice (B)** is also incorrect; this relationship is reversed in pulmonary and umbilical circulation. **Choice (D)** is reversed as well; arteries make use of the pumping of the heart and the "snapping back" of their elastic walls to transport blood, whereas venous blood is propelled along by skeletal muscle contractions.

9. A

The relative lack of smooth muscle in venous walls allows stretching to store most of the blood in the body. Valves in the veins allow for one-way flow of blood toward the heart, not stretching. Both arteries and veins are close to lymphatic vessels, which has no bearing on their relative difference in volume. Both arteries and veins have a single-cell endothelial lining.

10. C

Carbon dioxide is a byproduct of metabolism in cells that later combines with water to form bicarbonate in a reaction catalyzed by carbonic anhydrase. This system is blood plasma's most important buffer system. Food and fluid absorption are not significant sources of buffering, eliminating **choices (A)** and **(B)**. While the kidney can be involved in acid–base balance, it is through its filtration, secretion, and reabsorption mechanisms, not hormones, eliminating **choice (D)**.

11. C

In circulation, plasma proteins play an important role in generating osmotic (oncotic) pressure. This allows water that is displaced at the arterial end of a capillary bed by hydrostatic pressure to be reabsorbed at the venule end. Loss of these plasma proteins would cause a decrease in the plasma osmotic (oncotic) pressure.

12. D

The atrioventricular valves are located between the atria and the ventricles on both sides of the heart. Their role is to prevent backflow of blood into the atria. The valve on the right side of the heart has three cusps and is called the tricuspid valve. It prevents backflow of blood from the right ventricle into the right atrium.

13. D

Holding one's breath for a prolonged period would result in a drop of oxygenation and an increase in P_aCO_2. The increased carbon dioxide would associate with water to form carbonic acid, which would dissociate into a proton and bicarbonate anion. Further, the low oxygen saturation would eventually lead to anaerobic metabolism in some tissues, causing an increase in lactic acid. These would all lead to a decreased pH.

14. C

The cardiac conduction system starts at the SA node, which is located near the top of the right atrium, and continues down to the AV node, which is located between the two AV valves. The bundle of His is located within the wall between the ventricles, and is likely to be affected if the wall between the ventricles has been damaged by a heart attack. This may affect the left ventricle, but the left ventricular muscle itself is not part of the cardiac conduction system.

15. B

The greatest amount of resistance is provided by the arterioles, which also results in the greatest drop in blood pressure. Arterioles are highly muscular and have the ability to contract and dilate in order to affect blood pressure.

Introduction

Over the past few decades, the public's imagination has been captured by alarming reports of "flesh-eating" bacteria and diseases. In fact, these bacteria do not actually eat flesh, but that doesn't make them any less dangerous. "Flesh-eating" bacteria cause a condition called *necrotizing fasciitis*, a serious disease that requires aggressive medical and surgical treatment, including intravenous antibiotics, surgical debridement (removal) of the necrotic tissue, and sometimes even amputation. Many different types of bacteria, including group A *Streptococcus*, *Clostridium perfringens*, and methicillin-resistant *Staphylococcus aureus* (MRSA), can cause necrotizing fasciitis. The pathological and life-threatening impact of this disease is a massive destruction of skin, muscle, and connective tissue by the release of bacterial toxins called superantigens. These proteins cause the immune system to become nonspecifically overactivated. Necrotizing fasciitis is dangerous not only because of the bacteria and subsequent inflammatory response, but also because the destruction of skin—a nonspecific immune defense—leaves the body susceptible to superinfection (infection with another pathogen).

In this chapter, we will consider this type of nonspecific defense as well as specific immune defenses. The human body relies on the interaction between the innate (nonspecific) and adaptive (specific) immune systems in order to protect itself from disease. However, the immune system is not always perfect in its responses. Sometimes the immune system may become overactivated, as is the case with necrotizing fasciitis, or it may become activated against the same human it is supposed to protect. In this chapter, we will discuss the individual parts of the immune system and how these parts work together to protect from disease. In addition, we will discuss the concept of autoimmunity, or disease that results from immune attack against oneself. We'll briefly touch on vaccines, which take advantage of our understanding of the immune system to protect us from life-threatening infections. The immune system is largely integrated with the lymphatic system, which will be discussed in this chapter as well.

8.1 Structure of the Immune System ★★★

Each day, the human body is exposed to numerous bacteria, viruses, fungi, and even parasites. Yet our bodies are able to protect us from infection most of the time. Even when we do get sick, the immune system is usually able to contain and eliminate the infection.

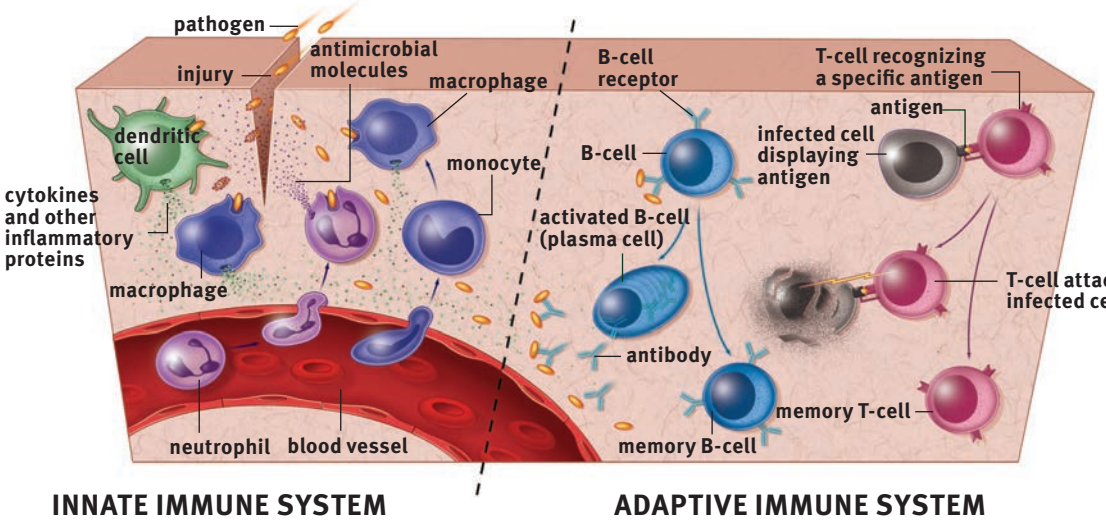
MCAT Expertise

The immune system is a topic where cell biology, biochemistry, anatomy, and biology interact. Thus, it is a topic that allows the MCAT to ask questions that integrate these four topics. As we discuss these complex ideas, focus on the big picture first, creating a mental image to help you to put these concepts together. Then go back and plug in the details. This approach will foster your ability to associate structure with function and to think critically about the topic on Test Day.

INNATE AND ADAPTIVE IMMUNITY

In order to fight infection, the human body has two different divisions of the immune system: innate and adaptive immunity, compared in Figure 8.1. **Innate immunity** is composed of defenses that are always active against infection, but lack the ability to target specific invaders over others; for this reason, it is also called **nonspecific immunity**. **Adaptive** or **specific immunity** refers to the defenses that target a specific pathogen. This system is slower to act, but can maintain immunological memory of an infection to be able to mount a faster attack in subsequent infections.

The mammalian immune system has two overarching divisions. The innate part (*left side*) acts near entry points into the body and is always at the ready. If it fails to contain a pathogen, the adaptive division (*right side*) kicks in, mounting a later but highly targeted attack against the specific invader.



INNATE IMMUNE SYSTEM
This system includes, among other components, antimicrobial molecules and various phagocytes (cells that ingest and destroy pathogens). These cells, such as dendritic cells and macrophages, also activate an inflammatory response, secreting proteins called cytokines that trigger an influx of immune cells from the blood. Among the recruits are more phagocytes—notably monocytes (which can mature into macrophages) and neutrophils.

ADAPTIVE IMMUNE SYSTEM
This system features B-cells and T-cells. Activated B-cells secrete antibody molecules that bind to antigens—specific components unique to a given invader—and destroy the invader directly or mark it for attack by others. T-cells recognize antigens displayed on cells. Some T-cells help to activate B-cells and other T-cells (*not shown*); other T-cells directly attack infected cells. T- and B-cells spawn memory cells that promptly eliminate invaders encountered before.

Figure 8.1. Divisions of the Immune System

ANATOMY

The immune system is not housed in a single organ, as shown in Figure 8.2. The structure and components that serve as nonspecific defenses often serve functions in other organ systems. The **bone marrow** produces all of the **leukocytes** (**white blood cells**) that participate in the immune system through the process of hematopoiesis, discussed in Chapter 7 of *MCAT Biology Review*. The **spleen** is a location of blood storage and activation of **B-cells**, which turn into **plasma cells** to produce antibodies as part of adaptive immunity. Note that when B-cells leave the bone marrow, they are considered mature but naïve (because they have not yet been exposed to an antigen). Because these antibodies dissolve and act in the blood (rather than within cells), this division of adaptive immunity is called **humoral immunity**. **T-cells**, another class of adaptive immune cells, mature in the **thymus**, a small gland just in front of the pericardium, the sac that protects the heart. T-cells are the

Real World

Lay people not involved in medicine often say that their "glands" are swollen when they feel a sensation of fullness around the throat. From a biological standpoint, lymph nodes are not glands—they do not secrete products into the bloodstream (endocrine) or ducts (exocrine). What they are actually experiencing is known medically as *lymphadenopathy*, or the swelling of the lymph nodes that occurs with activation of the immune system.

Key Concept

Organs of the immune system:

- Lymph nodes filter lymph and are a site where immune responses can be mounted.
- Bone marrow is the site of immune cell production.
- The thymus is the site of T-cell maturation.
- The spleen is a storage area for blood, filters blood and lymph, and is a site where immune responses can be mounted.

agents of **cell-mediated immunity** because they coordinate the immune system and directly kill virally infected cells. Finally, **lymph nodes**, a major component of the lymphatic system, provide a place for immune cells to communicate and mount an attack; B-cells can be activated here as well. Other immune tissue is found in close proximity to the digestive system, which is a site of potential invasion by pathogens. These tissues are commonly called **gut-associated lymphoid tissue** (**GALT**) and include the **tonsils** and **adenoids** in the head, **Peyer's patches** in the small intestine, and lymphoid aggregates in the **appendix**.

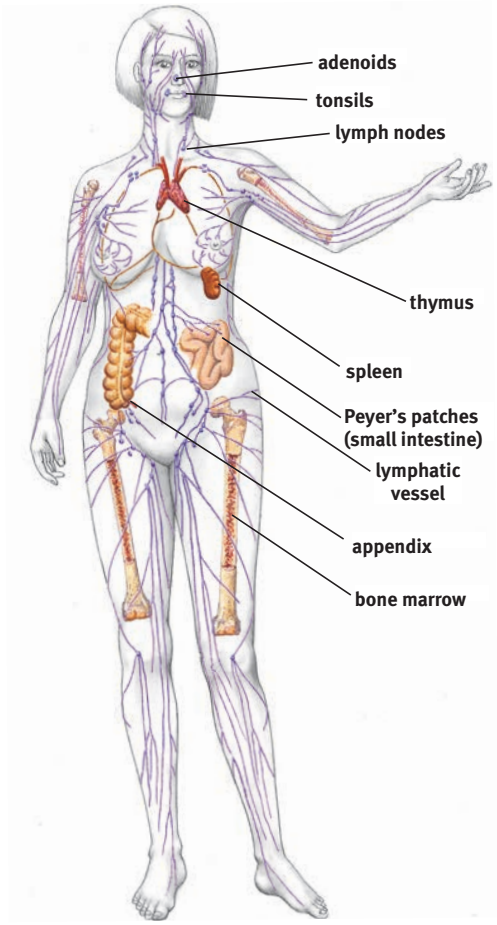


Figure 8.2. Anatomy of the Immune and Lymphatic Systems

Leukocytes are produced in the bone marrow through hematopoiesis, shown in Figure 8.3. (Note: This is the same image shown in Figure 7.7, but is copied here for convenience.) Leukocytes are divided into two groups of cells: **granulocytes** and **agranulocytes**. This name refers to the presence or absence of **granules** in the cytoplasm. These granules contain toxic enzymes and chemicals, which can be released by exocytosis, and are particularly effective against bacterial, fungal, and parasitic pathogens. Both granulocytes and agranulocytes come from a common

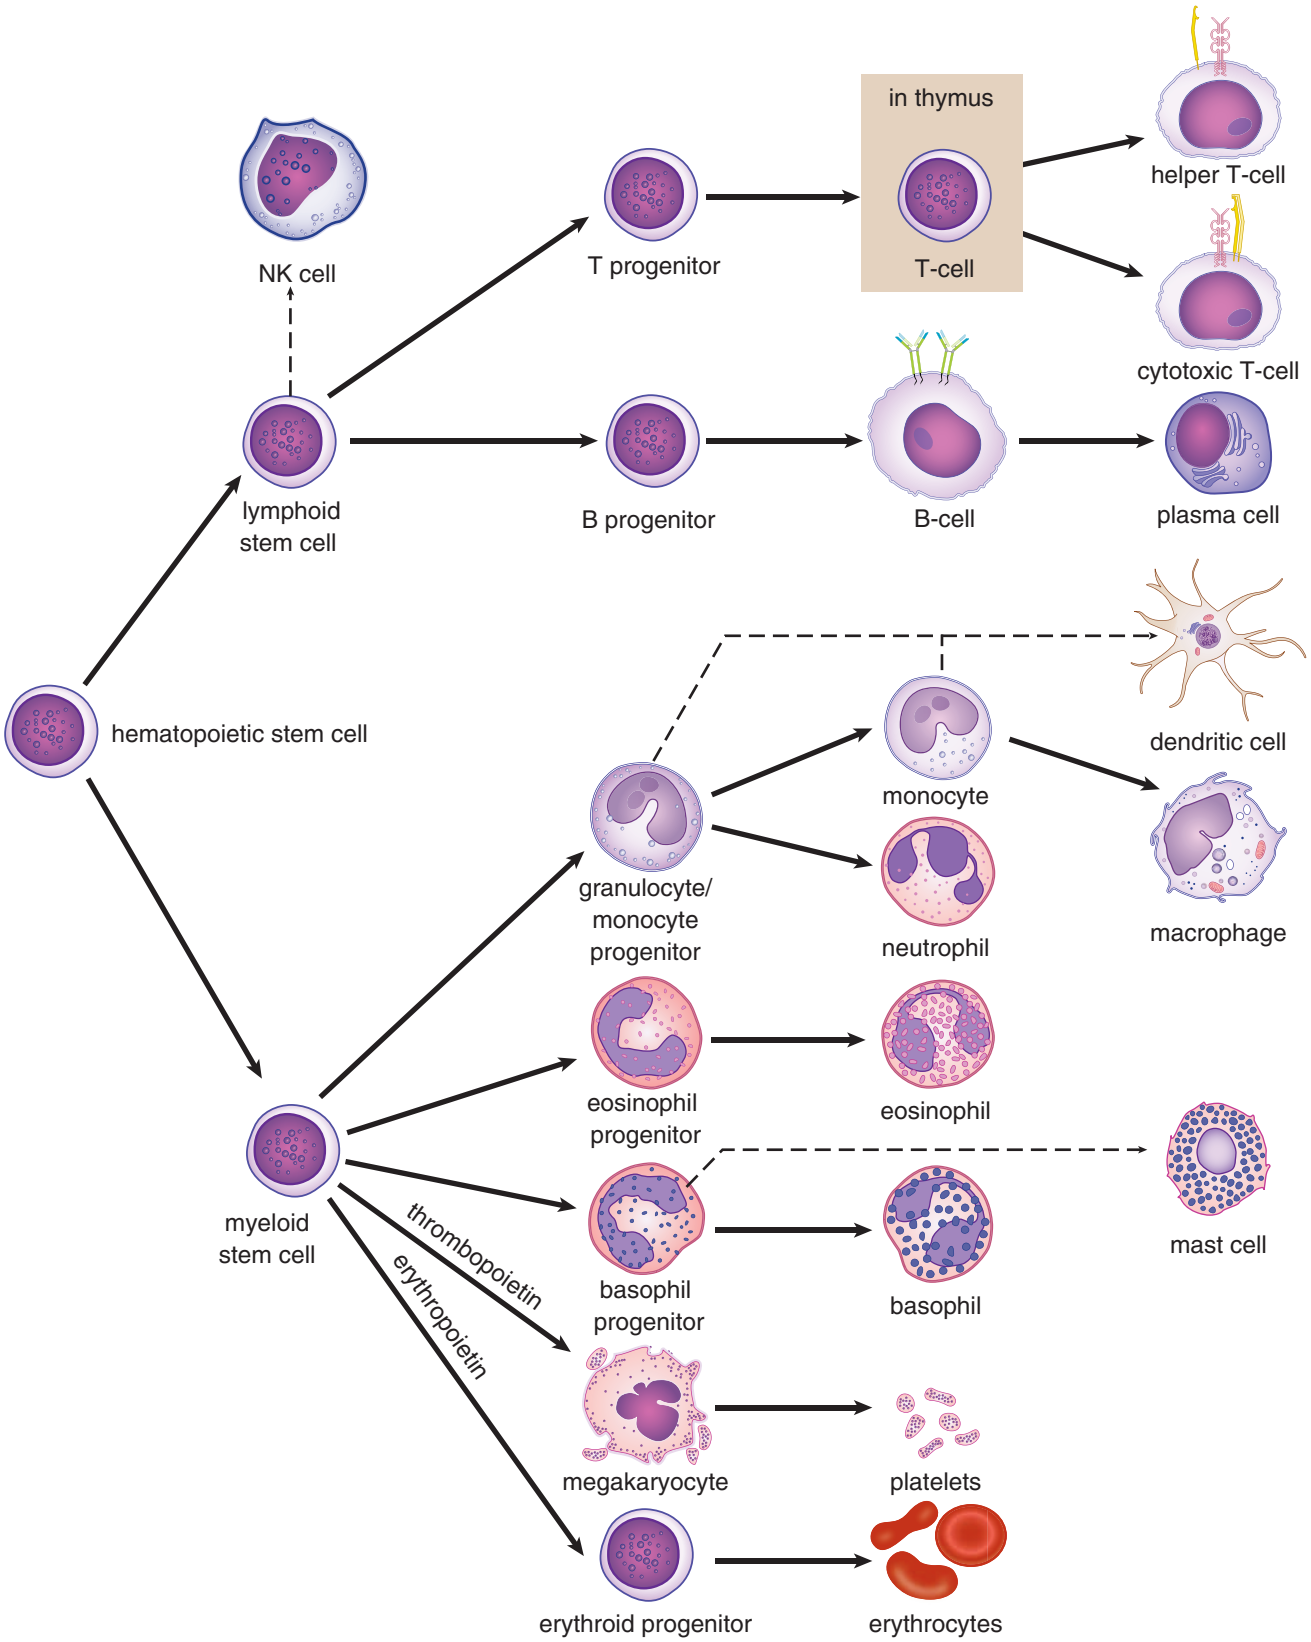

Figure 8.3. Hematopoiesis

Real World

One of the tests often ordered by physicians is known as a complete blood count (CBC). This test counts the number of red blood cells, platelets, and white blood cells. If the CBC is ordered with a differential, it means that each type of white blood cell is counted. Any cell populations that are abnormal may indicate a particular type of infection given the right clinical conditions. For example, if 90 percent of the white blood cells are neutrophils, it is possible that a bacterial infection is present. If 20 percent of the white blood cells are eosinophils, it is possible that an invasive parasitic infection is present.

precursor: **hematopoietic stem cells**. Remember from Chapter 7 of *MCAT Biology Review* that hematopoietic stem cells are also the cell type that gives rise to red blood cells and platelets. Granulocytes include cells such as **neutrophils**, **eosinophils**, and **basophils**. The names of these cells actually refer to the way that the cells appear after staining with certain chemicals. Agranulocytes include the **lymphocytes**, which are responsible for antibody production, immune system modulation, and targeted killing of infected cells. **Monocytes**, which are phagocytic cells in the bloodstream, are also considered agranulocytes. They become **macrophages** in tissues; many tissues have resident populations of macrophages with specific names (such as **microglia** in the central nervous system, **Langerhans cells** in the skin, and **osteoclasts** in bone).

Innate immunity refers to the responses cells can carry out without learning; for this reason, it is also known as the **nonspecific immune response**. Conversely, adaptive immunity is developed as immune cells learn to recognize and respond to particular antigens and is often aptly referred to as the **specific immune response**. We can also divide the specific immune system into **humoral immunity** (driven by B-cells and antibodies) and **cell-mediated immunity** (provided by T-cells).

MCAT Concept Check 8.1:

Before you move on, assess your understanding of the material with these questions.

1. What are the differences between innate and adaptive immunity?
   - Innate immunity:

     _____
   - Adaptive immunity:

     _____

2. Compare and contrast B- and T-cells:

Cell Type	Site of Development	Site of Maturation	Major Functions	Specific or Nonspecific?	Humoral or Cell-Mediated?
B-cell					
T-cell					

3. Which cells are considered granulocytes? Which are considered agranulocytes?
   - Granulocytes:

     _____

   - Agranulocytes:

     _____

8.2 The Innate Immune System ★

The innate immune system consists of cells and structures that offer nonspecific protection.

NONCELLULAR NONSPECIFIC DEFENSES

Our first line of defense is the **skin** (**integument**). In Chapter 10 of *MCAT Biology Review*, we will discuss the more specific homeostatic functions of the skin; for now, we'll focus on how skin protects the body. The skin provides a physical barrier between the outside world and our internal organs, excluding most bacteria, viruses, fungi, and parasites from entering the body. Additionally, antibacterial enzymes called **defensins** can be found on the skin. Sweat also has antimicrobial properties. The skin is an important first line of defense: a cut or abrasion on the skin provides an entry point for pathogens into the body. Deeper wounds allow pathogens to penetrate deeper into the body.

As discussed in Chapter 6 of *MCAT Biology Review*, the respiratory system also has mechanisms to prevent pathogens from entering the body. The respiratory passages are mucous membranes, lined with cilia to trap particulate matter and push it up toward the oropharynx, where it can be swallowed or expelled. While mucus helps to trap particulates like smoke and dirt, it also helps to prevent bacteria and viruses from gaining access to the lung tissue below. Several other mucous membranes, including around the eye and in the oral cavity, produce a nonspecific bacterial enzyme called **lysozyme**, which is secreted in tears and saliva, respectively.

The Gastrointestinal Tract

The gastrointestinal tract also plays a role in nonspecific immunity. First, the stomach secretes acid, resulting in the elimination of most pathogens. In addition, the gut is also colonized by bacteria. Most of these bacteria lack the necessary

Real World

The GI tract of a newborn baby is particularly susceptible to infection because the newborn's immune system is underdeveloped and the GI tract is not yet colonized. Breast milk contains a family of antibodies that are particularly effective on mucosal surfaces and helps to defend newborn babies against gastrointestinal infections.

characteristics to cause infection. Because there is already such a large bacterial population in the gut, many potential invaders are not able to compete and are thus kept at bay. Many antibiotics reduce the population of gut flora, thus providing an opportunity for the growth of pathogens resistant to that antibiotic.

Complement

The **complement** system consists of a number of proteins in the blood that act as a nonspecific defense against bacteria. Complement can be activated through a **classical pathway** (which requires the binding of an antibody to a pathogen) or an **alternative pathway** (which does not require antibodies). The complement proteins punch holes in the cell walls of bacteria, making them osmotically unstable. Despite the association with antibodies, complement is considered a nonspecific defense because it cannot be modified to target a specific organism over others.

Interferons

To protect against viruses, cells that have been infected with viruses produce **interferons**, proteins that prevent viral replication and dispersion. Interferons cause nearby cells to decrease production of both viral and cellular proteins. They also decrease the permeability of these cells, making it harder for a virus to infect them. In addition, interferons upregulate MHC class I and class II molecules, resulting in increased antigen presentation and better detection of the infected cells by the immune system, as described in the next section. Interferons are responsible for many "flu-like" symptoms that occur during viral infection, including malaise, tiredness, muscle soreness, and fever.

CELLS OF THE INNATE IMMUNE SYSTEM

So, what happens when bacteria, viruses, fungi, or parasites breach these defenses? The cells of the innate immune system are always poised and ready to attack.

Macrophages

Macrophages, a type of agranulocyte, reside within the tissues. These cells derive from blood-borne **monocytes** and can become a **resident population** within a tissue (becoming a permanent, rather than transient cell group in the tissue). Many of these resident macrophages are highlighted throughout *MCAT Biology Review*, including microglia in the central nervous system, Langerhans cells in the skin, and osteoclasts in bone. When a bacterial invader enters a tissue, the macrophages become activated. The activated macrophage does three things. First, it phagocytizes the invader through endocytosis. Then, it digests the invader using enzymes. Finally, it presents little pieces of the invader (mostly peptides)

to other cells using a protein called **major histocompatibility complex** (**MHC**). MHC binds to a pathogenic peptide (also called an **antigen**) and carries it to the cell surface, where it can be recognized by cells of the adaptive immune system. In addition, macrophages release **cytokines**—chemical substances that stimulate inflammation and recruit additional immune cells to the area.

MHC molecules come in two main classes: class I and class II. All nucleated cells in the body display **MHC class I** molecules. Any protein produced within a cell can be loaded onto MHC-I and presented on the surface of the cell, as shown in Figure 8.4. This allows the immune system to monitor the health of these cells and to detect if the cells have been infected with a virus or another intracellular pathogen; only those cells that are infected would be expected to present an unfamiliar (nonself) protein on their surface. Therefore, the MHC-I pathway is often called the **endogenous pathway** because it binds antigens from inside the cell. Cells that have been invaded by intracellular pathogens can then be killed by a certain group of T-cells (cytotoxic T-lymphocytes) to prevent infection of other cells.

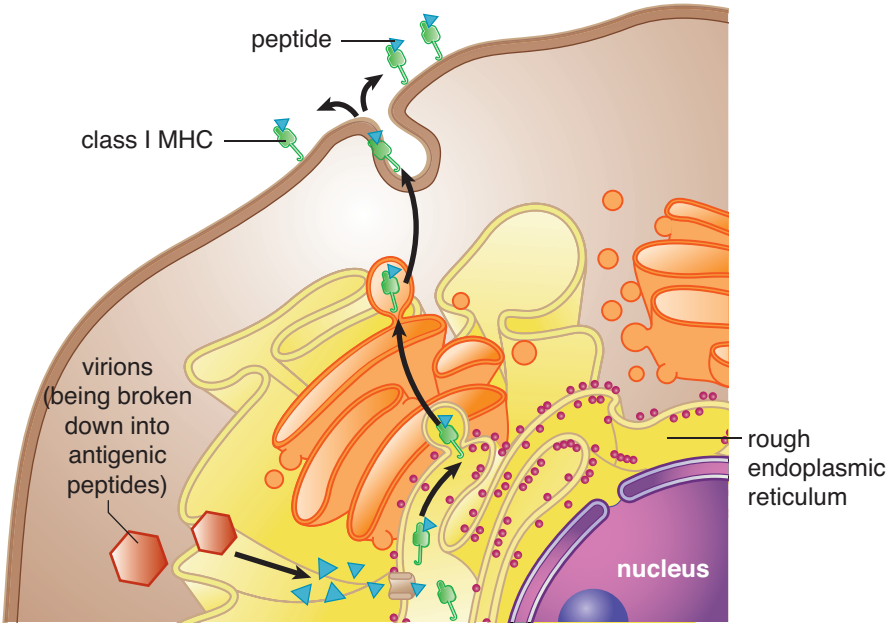

Figure 8.4. Endogenous Pathway for Antigen Presentation (MHC Class I)
MHC-I exists in all nucleated cells.

Real World

MHC molecules are highly variable among humans, but can usually be divided into particular subtypes. People with certain MHC subtypes have different susceptibility to disease, and some subtypes are considerably more susceptible to autoimmune diseases. It is also important to match the MHC types of the donor and recipient as closely as possible during transplants to avoid rejection of the graft.

Key Concept

Major histocompatibility complex molecules are joined with antigens. The MHC–antigen complex then goes to the cell surface to display the antigen. This allows the immune system to monitor the health of cells. MHC-I is in all nucleated cells and presents endogenous antigens. MHC-II is in antigen-presenting cells and presents exogenous antigens.

MHC class II molecules are mainly displayed by professional **antigen-presenting cells** like macrophages, as shown in Figure 8.5. Remember that these phagocytic cells pick up pathogens from the environment, process them, and then present them on MHC-II. An **antigen** is a substance (usually a pathogenic protein) that can be targeted by an antibody. While antibody production is the domain of the adaptive immune system, it is important to understand that cells of the innate immune system also present antigens. Because these antigens originated outside the cell, this pathway is often called the **exogenous pathway**. The presentation of an antigen by an immune cell may result in the activation of both the innate and adaptive immune systems. Professional antigen-presenting cells include macrophages, **dendritic cells** in the skin, some B-cells, and certain activated epithelial cells.

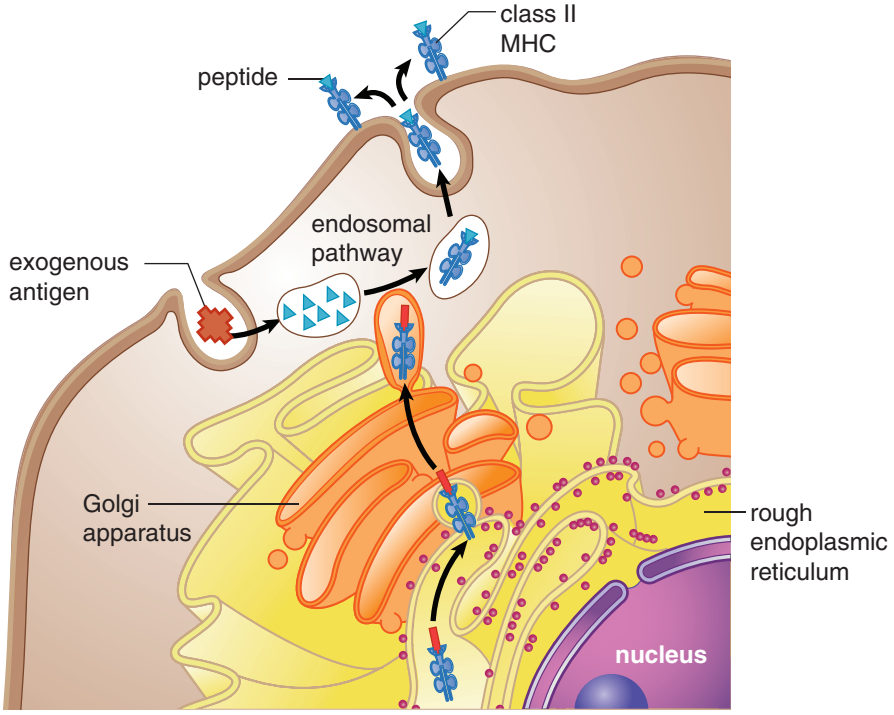

Figure 8.5. Exogenous Pathway for Antigen Presentation (MHC Class II)
MHC-II exists only in professional antigen-presenting cells, like macrophages, dendritic cells, some B-cells, and some activated epithelial cells.

Macrophages and dendritic cells also have special receptors known as **pattern recognition receptors** (**PRR**), the best-described of which are **toll-like receptors** (**TLR**). PRRs are able to recognize the category of the invader (bacterium, virus, fungus, or parasite). This allows for the production of appropriate cytokines to recruit the right type of immune cells; each immune cell has different weapons that can target particular groups of pathogens.

Natural Killer Cells

In the arms race between the human immune system and pathogens, some pathogens have found ways to avoid certain defenses. For example, some viruses cause downregulation of MHC molecules, making it harder for T-cells to recognize the presence of an infection. **Natural killer** (**NK**) **cells**, a type of nonspecific lymphocyte, are able to detect the downregulation of MHC and induce apoptosis in these virally infected cells. Cancer cells may also downregulate MHC production, so NK cells also offer protection from the growth of cancer as well.

Granulocytes

In addition to macrophages, the granulocytes, which include neutrophils, eosinophils, and basophils (and closely related mast cells) are also involved in nonspecific defense. **Neutrophils** are the most populous leukocyte in blood and are very short-lived (a bit more than five days). These cells are phagocytic, like macrophages, and target bacteria. Neutrophils can literally follow bacteria using **chemotaxis**—the sensing of certain products given off by bacteria and migration of neutrophils to follow these products back to the source (the bacterium itself). Neutrophils can also detect bacteria once they have been **opsonized** (marked with an antibody from a B-cell). Other cells, like natural killer cells, macrophages, monocytes, and eosinophils, also contain receptors for antibodies and can attack opsonized bacteria. Dead neutrophil collections are responsible for the formation of **pus** during an infection.

Eosinophils contain bright red-orange granules and are primarily involved in allergic reactions and invasive parasitic infections. Upon activation, eosinophils release large amounts of **histamine**, an inflammatory mediator. This results in vasodilation and increased leakiness of the blood vessels, allowing additional immune cells (especially macrophages and neutrophils) to move out of the bloodstream and into the tissue. **Inflammation** is particularly useful against extracellular pathogens, including bacteria, fungi, and parasites.

Finally, **basophils** contain large purple granules and are involved in allergic responses. They are the least populous leukocyte in the bloodstream under normal conditions. **Mast cells** are closely related to basophils, but have smaller

Key Concept

Histamine causes inflammation by inducing vasodilation and the movement of fluid and cells from the bloodstream into tissues.

granules and exist in the tissues, mucosa, and epithelium. Both basophils and mast cells release large amounts of histamine in response to allergens, leading to inflammatory responses.

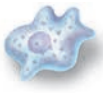
The functions of many cell types of both the innate and adaptive immune systems are highlighted in Figure 8.6.

The immune system consists of innate cells, which form a first line of defense against pathogens, and members of the adaptive system, which target invaders with greater specificity.

INNATE

MACROPHAGE
This immune defender engulfs and consumes pathogens.

MAST CELL
This cell releases histamine and other chemicals that promote inflammation.



GRANULOCYTES
Three cell types with tiny granules in their interiors—neutrophils, eosinophils, and basophils—participate in the inflammatory response.

DENDRITIC CELL
It presents antigens—fragments of protein or other molecules from pathogens or cancer cells—to adaptive immune cells, inducing the cells to attack bearers of the displayed antigens.

NATURAL KILLER CELL
This cell destroys the body's own cells that have become infected with pathogens; it also goes after cancer cells.

ADAPTIVE

B-CELL
Antigens stimulate this cell to divide and produce antibodies that neutralize invaders or tag them for killing.

T-CELL
A killer T-cell destroys an infected cell in which it detects the presence of antigens. Other T-cells—such as helper and regulatory types—coordinate the immune response.

Figure 8.6. Cells of the Immune System

MCAT Concept Check 8.2:

Before you move on, assess your understanding of the material with these questions.

1. For each of the noncellular nonspecific immune defenses listed below, provide a brief description of its immunologic function:
   - Skin: _____
   - Defensins: _____
   - Lysozyme: _____
   - Mucus: _____
   - Stomach acid: _____
   - Normal gastrointestinal flora: _____
   - Complement: _____
2. Which cells are professional antigen-presenting cells? _____
3. What are the differences between MHC-I and MHC-II?
   - MHC-I: _____
   - MHC-II: _____

4. What stimulus activates each of the following types of cells?
   - Natural killer cells:

     _____
   - Neutrophils:

     _____
   - Eosinophils:

     _____
   - Basophils and mast cells:

     _____

8.3 The Adaptive Immune System ★★

The adaptive immune system can identify specific invaders and mount an attack against that pathogen. The response is variable and depends on the identity of the pathogen. The adaptive immune system can be divided into two divisions: humoral immunity and cell-mediated (cytotoxic) immunity. Each involves the identification of the specific pathogen and organization of an appropriate immune response.

CELLS OF THE ADAPTIVE IMMUNE SYSTEM

The adaptive immune system consists mainly of two types of lymphocytes, B-cells and T-cells. B-cells govern the humoral response, while T-cells mount the cell-mediated response. All cells of the immune system are created in the bone marrow, but B- and T-cells mature in different locations. B-cells mature in the bone marrow (although the B in their name originally stood for the bursa of Fabricius, an organ found in birds), and T-cells mature in the thymus. When we are exposed to a pathogen, it may take a few days for the physical symptoms to be relieved. This occurs because the adaptive immune response takes time to form specific defenses against the pathogen.

Key Concept

B-cells mature in the **b**one marrow.
T-cells mature in the **t**hymus.

Humoral Immunity

Humoral immunity, which involves the production of **antibodies**, may take as long as a week to become fully effective after initial infection. These antibodies are specific to the antigens of the invading microbe. Antibodies are produced by B-cells, which are lymphocytes that originate and mature in the bone marrow and are activated in the spleen and lymph nodes.

Antibodies (also called **immunoglobulins** [**Ig**]) can carry out many different jobs in the body. Just as antigens can be displayed on the surface of cells or can float freely in blood, chyle (lymphatic fluid), or air, so too can antibodies be present on the surface of a cell or secreted into body fluids. When an antibody binds to an antigen, the response will depend on the location. For antibodies secreted into body fluids, there are three main possibilities: first, once bound to a specific antigen, antibodies may attract other leukocytes to phagocytize those antigens immediately. This is called opsonization, as described earlier. Second, antibodies may cause pathogens to clump together or **agglutinate**, forming large insoluble complexes that can be phagocytized. Third, antibodies can block the ability of a pathogen to invade tissues, essentially neutralizing it. For cell-surface antibodies, the binding of antigen to a B-cell causes activation of that cell, resulting in its proliferation and formation of plasma and memory cells, as described later in this chapter. In contrast, when antigen binds to antibodies on the surface of a mast cell, it causes **degranulation** (exocytosis of granule contents), allowing the release of histamine and causing an inflammatory allergic reaction.

Antibodies are Y-shaped molecules that are made up of two identical **heavy chains** and two identical **light chains**, as shown in Figure 8.7. Disulfide linkages and noncovalent interactions hold the heavy and light chains together. Each antibody has an **antigen-binding region** at the end of what is called the **variable region** (**domain**), at the tips of the Y. Within this region, there are specific polypeptide sequences that will bind one, and only one, specific antigenic sequence. Part of the reason it takes so long to initiate the antibody response is that each B-cell undergoes **hypermutation** of its antigen-binding region, trying to find the best match for the antigen. Only those B-cells that can bind the antigen with high affinity survive, providing a mechanism for generating specificity called **clonal selection**. The remaining part of the antibody molecule is known as the **constant region** (**domain**). It is this region that cells such as natural killer cells, macrophages, monocytes, and eosinophils have receptors for, and that can initiate the complement cascade. Each B-cell makes only one type of antibody, but we have many B-cells, so our immune system can recognize many antigens. Further, antibodies come in five different isotypes (IgM, IgD, IgG, IgE, and IgA). While the specific purposes of each antibody isotype is outside the scope of the MCAT, you should know that the different types can be used at different times during the adaptive immune response, for different types of pathogens, or in different locations in the body. Cells can change which isotype of antibody they produce when stimulated by specific cytokines in a process called **isotype switching**.

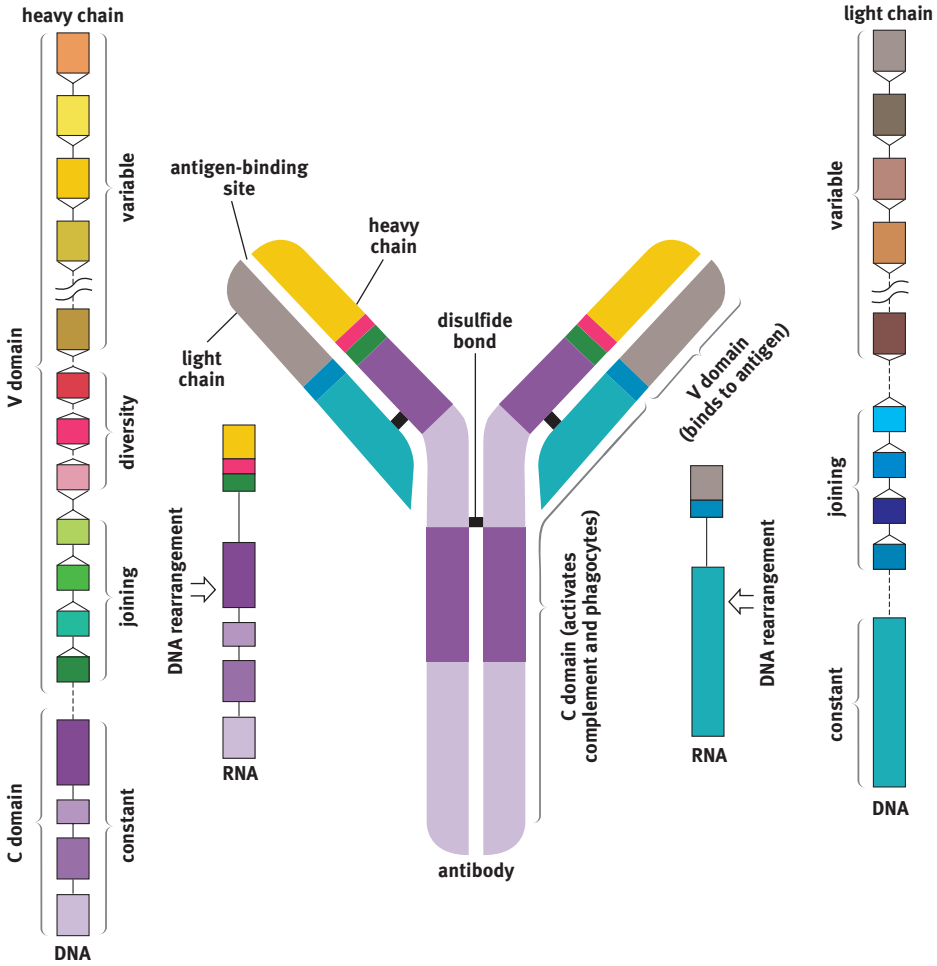


Figure 8.7. Structure of an Antibody Molecule

Not all B-cells that are generated actively or constantly produce antibodies. Antibody production is an energetically expensive process, and there is no reason to expend energy producing antibodies that are not needed. Instead, **naïve** B-cells (those that have not yet been exposed to an antigen) wait in the lymph nodes for their particular antigen to come along. Upon exposure to the correct antigen, a B-cell will proliferate and produce two types of daughter cells. **Plasma cells** produce large amounts of antibodies, whereas **memory B-cells** stay in the lymph node, awaiting reexposure to the same antigen. This initial activation takes approximately seven to ten days and is known as the **primary response**. The plasma cells will eventually die, but the memory cells may last the lifetime of the organism. If the same microbe is ever encountered again, the memory cells jump into action and produce the antibodies specific to that pathogen. This immune response, called the **secondary response**, will be more rapid and robust. The development of these lasting memory cells is the basis of the efficacy of **vaccinations**.

Cytotoxic Immunity

Whereas humoral immunity is based on the activity of B-cells, cell-mediated immunity involves the T-cells. T-cells mature in the thymus, where they undergo both positive and negative selection. **Positive selection** refers to maturing only cells that can respond to the presentation of antigen on MHC (cells that cannot respond to MHC undergo apoptosis because they will not be able to respond in the periphery). **Negative selection** refers to causing apoptosis in cells that are self-reactive (activated by proteins produced by the organism itself). The maturation of T-cells is facilitated by **thymosin**, a peptide hormone secreted by thymic cells. Once the T-cell has left the thymus, it is mature but naïve. Upon exposure to antigen, T-cells will also undergo clonal selection so that only those with the highest affinity for a given antigen proliferate.

There are three major types of T-cells: helper T-cells, suppressor T-cells, and killer (cytotoxic) T-cells. **Helper T-cells** (**T_h**), also called **$CD4^+$ T-cells**, coordinate the immune response by secreting chemicals known as **lymphokines**. These molecules are capable of recruiting other immune cells (such as plasma cells, cytotoxic T-cells, and macrophages) and increasing their activity. The loss of these cells, as occurs in **human immunodeficiency virus** (**HIV**) infection, prevents the immune system from mounting an adequate response to infection; in advanced HIV infection, also called **acquired immunodeficiency syndrome** (**AIDS**), even weak pathogens can cause devastating consequences as opportunistic infections. $CD4^+$ T-cells respond to antigens presented on MHC-II molecules. Because MHC-II presents exogenous antigens, $CD4^+$ T-cells are most effective against bacterial, fungal, and parasitic infections.

Cytotoxic T-cells (**T_c** or **CTL**, for cytotoxic T-lymphocytes), also called **$CD8^+$ T-cells**, are capable of directly killing virally infected cells by injecting toxic chemicals that promote apoptosis into the infected cell. $CD8^+$ T-cells respond to antigens presented on MHC-I molecules. Because MHC-I presents endogenous antigens, $CD8^+$ T-cells are most effective against viral (and intracellular bacterial or fungal) infections.

Suppressor or **regulatory T-cells** (**T_{reg}**) also express CD4, but can be differentiated from helper T-cells because they also express a protein called *Foxp3*. These cells help to tone down the immune response once infection has been adequately contained. These cells also turn off self-reactive lymphocytes to prevent autoimmune diseases: this is termed **self-tolerance**.

Finally, **memory T-cells** can be generated. Similar to memory B-cells, these cells lie in wait until the next exposure to the same antigen. When activated, they result in a more robust and rapid response.

Real World

"CD" in immunology stands for *cluster of differentiation* and includes cell-surface markers that can be detected by the lab technique called flow cytometry; these markers give an indication of the types of leukocytes under investigation, how many are present, and in what state of maturity they are.

Key Concept

$CD4^+$ T-cells are better at fighting extracellular infections, while $CD8^+$ T-cells are better at targeting intracellular infections.

Mnemonic

CD × MHC = 8
$CD4^+$ cells respond to MHC-**II (4 × 2 = 8)**
$CD8^+$ cells respond to MHC-**I (8 × 1 = 8)**

Real World

Many suppressor T-cells were formerly self-reactive T-cells that have been turned off. When a suppressor T-cell inactivates another lymphocyte, it can either target it for destruction or promote its conversion into another suppressor T-cell.

A summary of the different types of lymphocytes in adaptive (specific) immunity is shown in Figure 8.8.

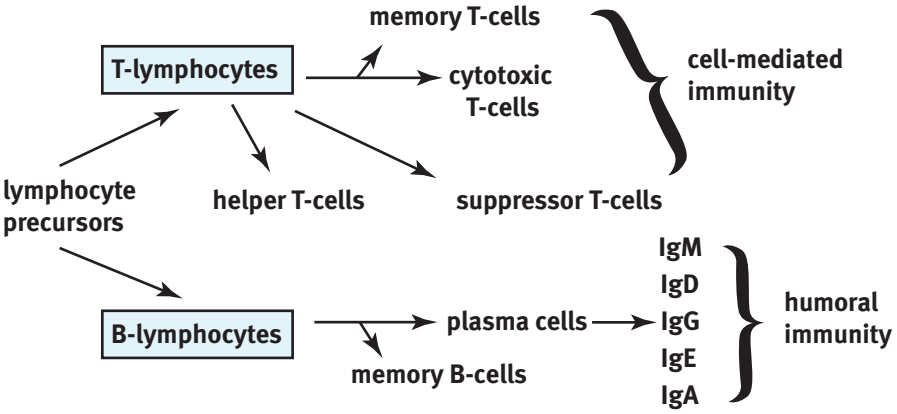

Figure 8.8. Lymphocytes of Specific Immunity
This diagram shows the differentiation of lymphocyte precursors and the cell types involved in specific immunity.

ACTIVATION OF THE ADAPTIVE IMMUNE SYSTEM

When the human body encounters an antigen, the immune system must be able to respond. It is important to note that the innate and adaptive immune systems are not really disparate entities that function separately. The proper functioning of the entire immune system depends on the interactions between these two systems. There are five types of infectious pathogens: bacteria, viruses, fungi, parasites (including protozoa, worms, and insects), and prions (for which there are no immune defenses). While the immune system's response depends on the specific identity of the pathogen, we present two classic examples: a bacterial (extracellular pathogen) infection and a viral (intracellular pathogen) infection. Keep in mind that this categorization is imperfect; for example, some bacteria, like *Mycobacterium tuberculosis* and *Listeria monocytogenes*, actually live intracellularly.

Bacterial (Extracellular Pathogen) Infections

Macrophages are like the sentinels of the human body, always on the lookout for potential invaders. Let's say a person suffers a laceration and bacteria are introduced into the body via this laceration. First, macrophages (and other antigen-presenting cells) engulf the bacteria and subsequently release inflammatory mediators. These cells also digest the bacteria and present antigens from the pathogen on their surfaces in conjunction with MHC-II. The cytokines attract inflammatory cells, including neutrophils and additional macrophages. Mast cells are activated by the inflammation and degranulate, resulting in histamine release and increased leakiness of the capillaries. This augments the ability of the immune cells to leave the bloodstream to travel to the affected tissue. The dendritic

cell then leaves the affected tissue and travels to the nearest lymph node, where it presents the antigen to B-cells. B-cells that produce the correct antibody proliferate through clonal selection to create plasma cells and memory cells. Antibodies then travel through the bloodstream to the affected tissue, where they tag the bacteria for destruction.

At the same time, dendritic cells are also presenting the antigen to T-cells, activating a T-cell response. In particular, $CD4^+$ T-cells are activated. These cells come in two types, called T_h1 and T_h2. T_h1 cells release interferon gamma (IFN-γ), which activates macrophages and increases their ability to kill bacteria. T_h2 cells help activate B-cells and are more common in parasitic infections.

After the pathogen has been eliminated, plasma cells die, but memory B- and T-cells remain. These memory cells allow for a much faster secondary response upon exposure to the pathogen at a later time.

Viral (Intracellular Pathogen) Infections

In a viral infection, the virally infected cell will begin to produce interferons, which reduce the permeability of nearby cells (decreasing the ability of the virus to infect these cells), reduce the rate of transcription and translation in these cells (decreasing the ability of the virus to multiply), and cause systemic symptoms (malaise, muscle aching, fever, and so on). These infected cells also present intracellular proteins on their surface in conjunction with MHC-I; in a virally infected cell, at least some of these intracellular proteins will be viral proteins.

$CD8^+$ T-cells will recognize the MHC-I and antigen complex as foreign and will inject toxins into the cell to promote apoptosis. In this way, the infection can be shut down before it is able to spread to nearby cells. In the event that the virus downregulates the production and presentation of MHC-I molecules, natural killer cells will recognize the absence of MHC-I and will accordingly cause apoptosis of this cell.

Again, once the pathogen has been cleared, memory T-cells will be generated that can allow a much faster response to be mounted upon a second exposure.

RECOGNITION OF SELF AND NONSELF

Self-antigens are the proteins and carbohydrates present on the surface of every cell of the body. Under normal circumstances, these self-antigens signal to immune cells that the cell is not threatening and should not be attacked. However, when the immune system fails to make the distinction between *self* and *foreign*, it may attack cells expressing particular self-antigens, a condition known as **autoimmunity**. Note that autoimmunity is only one potential problem with immune functioning:

another problem arises when the immune system misidentifies a foreign antigen as dangerous when, in fact, it is not. Pet dander, pollen, and peanuts are not inherently threatening to human life, yet some people's immune systems are hypersensitive to these antigens and become overactivated when these antigens are encountered in what is called an allergic reaction. Allergies and autoimmunity are part of a family of immune reactions classified as **hypersensitivity reactions**.

The human body strives to prevent autoimmune reactions very early in T-cell and B-cell maturation processes. T-cells are educated in the thymus. Part of this education involves the elimination of T-cells that respond to self-antigens, called negative selection. Immature B-cells that respond to self-antigens are eliminated before they leave the bone marrow. However, this process is not perfect, and occasionally a cell that responds to self-antigens is allowed to survive. Most autoimmune diseases can be treated with a number of therapies; one common example is administration of **glucocorticoids** (modified versions of cortisol), which have potent immunosuppressive qualities.

Real World

Autoimmune diseases can result in destruction of tissues, causing various deficiencies. Type I diabetes mellitus results from autoimmune destruction of the β-cells of the pancreas. This results in an inability to produce insulin, characterized by high blood sugars and excessive utilization of fats and proteins for energy. Other examples of autoimmune diseases include multiple sclerosis, myasthenia gravis, psoriasis, systemic lupus erythematosus, rheumatoid arthritis, Graves' disease, and Guillain–Barré syndrome.

IMMUNIZATION

Often, diseases can have significant, long-term consequences. Infection with the poliovirus, for example, can leave a person disabled for the remainder of his or her life. Polio used to be a widespread illness; however, today we hardly hear about it outside of the Indian subcontinent because of a highly effective vaccination program, which led to the elimination of polio from the Western hemisphere.

Immunization can be achieved in an active or passive fashion. In **active immunity**, the immune system is stimulated to produce antibodies against a specific pathogen. The means by which we are exposed to this pathogen may either be natural or artificial. Through natural exposure, antibodies are generated by B-cells once an individual becomes infected. Artificial exposure (through vaccines) also results in the production of antibodies; however, the individual never experiences true infection. Instead, he or she receives an injection or intranasal spray containing an antigen that will activate B-cells to produce antibodies to fight the specific infection. The antigen may be a weakened or killed form of the microbe, or it may be a part of the microbe's protein structure.

Immunization may also be achieved passively. **Passive immunity** results from the transfer of antibodies to an individual. The immunity is transient because only the antibodies, and not the plasma cells that produce them, are given to the individual. Natural examples are the transfer of antibodies across the placenta during pregnancy to protect the fetus and the transfer of antibodies from a mother to her nursing infant through breast milk. In some cases of exposure, such as to the rabies virus or tetanus, intravenous immunoglobulin may be given to prevent the pathogen from spreading.

Real World

In 1998, a paper published in *The Lancet* claimed to have found a link between vaccines and autism. This paper has since been withdrawn from *The Lancet* after it was demonstrated to be fraudulent and scientifically inaccurate. In fact, no well-designed scientific study has yet shown this link to exist. However, the sensationalist reporting of this connection in the lay population has led many parents to avoid immunizing their children. Since 1998, outbreaks of measles and mumps in the United States and other industrialized nations have raised concerns about the resurgence of illnesses that were previously almost eradicated. Vaccines do carry risks, including rare cases of encephalitis (brain inflammation) and Guillain–Barré syndrome (an autoimmune disease in which the myelin of peripheral nerves is attacked), but so too do the pathogens these vaccines protect against.

MCAT Concept Check 8.3:

Before you move on, assess your understanding of the material with these questions.

1. For each of the lymphocytes listed below, what are its main functions?
   - Plasma cell:

     _____
   - Memory B-cell:

     _____
   - Helper T-cell:

     _____
   - Cytotoxic T-cell:

     _____
   - Suppressor (regulatory) T-cell:

     _____
   - Memory T-cell:

     _____

2. What are the three main effects circulating antibodies can have on a pathogen?
   - _____
   - _____
   - _____

3. How do antibodies become specific for a given antigen?

   _____

4. What is meant by positive and negative selection?
   - Positive selection:

     _____
   - Negative selection:

     _____

5. Which cells account for the fact that the secondary response to a pathogen is much more rapid and robust than the primary response?

   _____

6. What is the difference between active and passive immunity?
   - Active immunity:

     _____

   - Passive immunity:

     _____

8.4 The Lymphatic System ★★

The immune system and the lymphatic system are intimately related. B-cells proliferate and develop within the lymphatic system, especially the lymph nodes. This system also serves other necessary functions for the body.

STRUCTURE

The lymphatic system, along with the cardiovascular system, is a type of circulatory system. It is made up of one-way vessels that become larger as they move toward the center of the body. These vessels carry lymphatic fluid **(lymph)** and most join to comprise a large **thoracic duct** in the posterior chest, which then delivers the fluid into the left subclavian vein (near the heart).

Lymph nodes are small, bean-shaped structures along the lymphatic vessels. Lymph nodes contain a lymphatic channel, as well as an artery and a vein. The lymph nodes provide a space for the cells of the immune system to be exposed to possible pathogens.

Real World

Certain cancers, especially breast cancer, are prone to spread via lymphatic channels. Mastectomy, a surgery that removes the breast, is one of the treatments for breast cancer. In order to ensure that all of the cancer has been removed, local lymph nodes are often removed at the same time.

FUNCTION

The lymphatic system serves many different purposes for the body by providing a secondary system for circulation.

Equalization of Fluid Distribution

At the capillaries, fluid leaves the bloodstream and goes into the tissues. The quantity of fluid that leaves the tissues at the arterial end of the capillary bed depends on both hydrostatic and oncotic pressures (Starling forces). Remember that the oncotic pressure of the blood draws water back into the vessel at the venule end, once hydrostatic pressure has decreased. Because the net pressure drawing fluid in at the venule end is slightly less than the net pressure pushing fluid out at the arterial end, a small amount of fluid remains in the tissues. Lymphatic vessels drain these tissues and subsequently return the fluid to the bloodstream.

The lymphatics offer some protection against pathology. For example, if the blood has a low concentration of albumin (a key plasma protein), the oncotic pressure of the blood is decreased, and less water is driven back into the bloodstream at the venule end. Thus, this fluid will collect in the tissues. Provided that the lymphatic channels are not blocked, much of this fluid may eventually return to the bloodstream via the lymphatics. Only when the lymphatics are overwhelmed does **edema** occur—swelling due to fluid collecting in tissue.

Transportation of Biomolecules

The lymphatic system also transports fats from the digestive system into the bloodstream. **Lacteals**, small lymphatic vessels, are located at the center of each villus in the small intestine. Fats, packaged into chylomicrons by intestinal mucosal cells, enter the lacteal for transport. Lymphatic fluid carrying many chylomicrons takes on a milky white appearance and is called **chyle**.

Immunity

As stated previously in this chapter, lymph nodes are a place for antigen-presenting cells and lymphocytes to interact. B-cells proliferate and mature in the lymph nodes in collections called **germinal centers**.

MCAT Concept Check 8.4:

Before you move on, assess your understanding of the material with these questions.

1. *Filariasis* is the name for an infection with a certain group of parasites, most notably *Wuchereria bancrofti*. This parasite resides in lymph nodes and causes blockage of flow. If an individual had a *W. bancrofti* infection in the lymph nodes of his or her thigh, what would likely happen?

_____

_____

2. What structure is primarily responsible for returning materials from lymphatic circulation to the cardiovascular system?

_____

Conclusion

The ability to fend off microbial invasion is critical to our survival. The immune system is housed in many locations in the body and involves multiple different organs and cell types. Nonspecific mechanisms, such as intact skin, mucous membranes, defensins, lysozyme, complement, interferons, natural killer cells, neutrophils,

eosinophils, basophils, and monocytes/macrophages, constitute a complex first line of defense; these mechanisms comprise the innate immune system, which is capable of an immediate response but cannot target a specific pathogen or maintain immunologic memory. The adaptive immune system, comprised of B- and T-cells (lymphocytes), allows for our immune system to target individual pathogens and learn from past exposure. Thus, once we are infected with a certain strain of virus, activation of specific immunity confers long-term protection against that particular virus. We take advantage of this secondary response through immunization, and we can see the problems specificity can have when a self-antigen is labeled as foreign, leading to autoimmune disease.

If the immune system is focused on destroying pathogens, including bacteria, then it's an interesting transition we make in the next chapter. We're going from a "sterilization" system to one in which bacterial colonization is the norm. From oral flora to the normal gut bacteria, our ability to digest and absorb nutrients is intimately linked to symbiotic bacteria throughout the digestive tract. In the next chapter, we will explore the anatomy and physiology of the digestive system, which provides us with the raw materials to generate energy, build proteins, and carry out activities of daily living.

CONCEPT SUMMARY

Structure of the Immune System

- The immune system can be divided into innate and adaptive immunity.
  - **Innate immunity** is composed of defenses that are always active, but that cannot target a specific invader and cannot maintain immunologic memory; also called **nonspecific immunity**.
  - **Adaptive immunity** is composed of defenses that take time to activate, but that target a specific invader and can maintain immunologic memory; also called **specific immunity**.
- The immune system is dispersed in the body.
  - Immune cells come from the **bone marrow**.
  - The **spleen** and **lymph nodes** are sites where immune responses can be mounted, and in which B-cells are activated.
  - The **thymus** is the site of T-cell maturation.
  - **Gut-associated lymphoid tissue (GALT)** includes the **tonsils** and **adenoids**.
- **Leukocytes**, or white blood cells, are involved in immune defenses.

The Innate Immune System

- Many of the nonspecific defenses are noncellular.
  - The **skin** acts as a physical barrier and secretes antimicrobial compounds, like **defensins**.
  - **Mucus** on mucous membranes traps pathogens; in the respiratory system, the mucus is propelled upward by cilia and can be swallowed or expelled.
  - Tears and saliva contain **lysozyme**, an antibacterial compound.
  - The stomach produces acid, killing most pathogens. Colonization of the gut helps prevent overgrowth by pathogenic bacteria through competition.
  - The **complement** system can punch holes in the cell walls of bacteria, making them osmotically unstable.
  - **Interferons** are given off by virally infected cells and help prevent viral replication and dispersion to nearby cells.
- Many of the nonspecific defenses are also cellular.
  - **Macrophages** ingest pathogens and present them on **major histocompatibility complex** (**MHC**) molecules. They also secrete **cytokines**.
  - **MHC class I** (**MHC-I**) is present in all nucleated cells and displays **endogenous antigen** (proteins from within the cell) to cytotoxic T-cells ($CD8^+$ cells).
  - **MHC class II** (**MHC-II**) is present in professional antigen-presenting cells (macrophages, dendritic cells, some B-cells, and certain activated epithelial

cells) and displays **exogenous antigen** (proteins from outside the cell) to helper T-cells ($CD4^+$ cells).

- **Dendritic cells** are antigen-presenting cells in the skin.
- **Natural killer cells** attack cells not presenting MHC molecules, including virally infected cells and cancer cells.
- **Granulocytes** include neutrophils, eosinophils, and basophils.
- **Neutrophils** ingest bacteria, particularly opsonized bacteria (those marked with antibodies). They can follow bacteria using **chemotaxis**.
- **Eosinophils** are used in allergic reactions and invasive parasitic infections. They release **histamine**, causing an inflammatory response.
- **Basophils** are used in allergic reactions. **Mast cells** are related cells found in the skin.

The Adaptive Immune System

- **Humoral immunity** is centered on antibody production by plasma cells, which are activated **B-cells**.
  - **Antibodies** target a particular **antigen**. They contain two heavy chains and two light chains. They have a **constant region** and a **variable region**; the tip of the variable region is the **antigen-binding region**.
  - When activated, the antigen-binding region undergoes **hypermutation** to improve the specificity of the antibody produced. Cells may be given signals to switch **isotypes** of antibody (IgM, IgD, IgG, IgE, IgA).
  - Circulating antibodies can **opsonize** pathogens (mark them for destruction), cause **agglutination** (clumping) into insoluble complexes that are ingested by phagocytes, or neutralize pathogens.
  - Cell-surface antibodies can activate immune cells or mediate allergic reactions.
  - **Memory B-cells** lie in wait for a second exposure to a pathogen and can then mount a more rapid and vigorous immune response (**secondary response**).
- **Cell-mediated** (**cytotoxic**) **immunity** is centered on the functions of **T-cells**.
  - T-cells undergo maturation in the thymus through **positive selection** (only selecting for T-cells that can react to antigen presented on MHC) and **negative selection** (causing apoptosis in self-reactive T-cells). The peptide hormone **thymosin** promotes T-cell development.
  - **Helper T-cells (T_h** or **$CD4^+$)** respond to antigen on MHC-II and coordinate the rest of the immune system, secreting **lymphokines** to activate various arms of immune defense. **T_h1 cells** secrete **interferon gamma**, which activates macrophages. **T_h2 cells** activate B-cells, primarily in parasitic infections.
  - **Cytotoxic T-cells** (**T_c**, **CTL**, or **$CD8^+$**) respond to antigen on MHC-I and kill virally infected cells.

- **Suppressor** (**regulatory**) **T-cells** ($\mathbf{T_{reg}}$) tone down the immune response after an infection and promote self-tolerance.
- **Memory T-cells** serve a similar function to memory B-cells.

- In **autoimmune** conditions, a self-antigen is recognized as foreign, and the immune system attacks normal cells.
- In **allergic** reactions, nonthreatening exposures incite an inflammatory response.
- Immunization is a method of inducing **active immunity** (activation of B-cells that produce antibodies to an antigen) prior to exposure to a particular pathogen.
- **Passive immunity** is the transfer of antibodies to an individual.

The Lymphatic System

- The **lymphatic system** is a circulatory system that consists of one-way vessels with intermittent lymph nodes.
- The lymphatic system connects to the cardiovascular system via the **thoracic duct** in the posterior chest.
- The lymphatic system equalizes fluid distribution, transports fats and fat-soluble compounds in **chylomicrons**, and provides sites for mounting immune responses.

ANSWERS TO CONCEPT CHECKS

8.1

1. Innate immunity consists of defenses that are always active against pathogens, but that are not capable of targeting specific invaders. It takes longer to mount a response with adaptive immunity, but the response targets a specific pathogen and maintains immunologic memory of the infection to mount a faster response during subsequent infections.
2.

Cell Type	Site of Development	Site of Maturation	Major Functions	Specific or Nonspecific?	Humoral or Cell-Mediated?
B-cell	Bone marrow	Bone marrow (but are activated in spleen or lymph nodes)	Produce antibodies	Specific	Humoral
T-cell	Bone marrow	Thymus	Coordinate immune system and directly kill infected cells	Specific	Cell-mediated

3. Granulocytes include neutrophils, eosinophils, and basophils. Agranulocytes include B- and T-cells (lymphocytes) and monocytes (macrophages).

8.2

1. Skin provides a physical barrier and secretes antimicrobial enzymes. Defensins are examples of antibacterial enzymes on the skin. Lysozyme is antimicrobial and is present in tears and saliva. Mucus is present on mucous membranes and traps incoming pathogens; in the respiratory system, cilia propel the mucus upward so it can be swallowed or expelled. Stomach acid is an antimicrobial mechanism in the digestive system. The normal gastrointestinal flora provides competition, making it hard for pathogenic bacteria to grow in the gut. Complement is a set of proteins in the blood that can create holes in bacteria.
2. Professional antigen-presenting cells include macrophages, dendritic cells in the skin, some B-cells, and certain activated epithelial cells.
3. MHC-I is found in all nucleated cells and presents proteins created within the cell (endogenous antigens); this can allow for detection of cells infected with intracellular pathogens (especially viruses). MHC-II is only found in antigen-presenting cells and presents proteins that result from the digestion of extracellular pathogens that have been brought in by endocytosis (exogenous antigens).
4. Natural killer cells are activated by cells that do not present MHC (such as virally infected cells and cancer cells). Neutrophils are activated by bacteria, especially

those that have been opsonized (tagged with an antibody on their surface). Eosinophils are activated by invasive parasites and allergens. Basophils and mast cells are activated by allergens.

8.3

1. Plasma cells form from B-cells exposed to antigen and produce antibodies. Memory B-cells also form from B-cells exposed to antigen and lie in wait for a second exposure to a given antigen to be able to mount a rapid, robust response. Helper T-cells coordinate the immune system through lymphokines and respond to antigen bound to MHC-II. Cytotoxic T-cells directly kill virally infected cells and respond to antigen bound to MHC-I. Suppressor (regulatory) T-cells quell the immune response after a pathogen has been cleared and promote self-tolerance. Memory T-cells, like memory B-cells, lie in wait until a second exposure to a pathogen to be able to mount a rapid, robust response.
2. Circulating antibodies can mark a pathogen for destruction by phagocytic cells (opsonization), cause agglutination of the pathogen in insoluble complexes that can be taken up by phagocytic cells, or neutralize the pathogen by preventing its ability to invade tissues.
3. B-cells originally mature in the bone marrow and have some specificity at that point; however, antibodies that can respond to a given antigen undergo hypermutation, or rapid mutation of their antigen-binding sites. Only those B-cells that have the highest affinity for the antigen survive and proliferate, increasing the specificity for the antigen over time.
4. Positive selection occurs when T-cells in the thymus that are able to respond to antigen presented on MHC are allowed to survive (those that do not respond undergo apoptosis). Negative selection occurs when T-cells that respond to self-antigens undergo apoptosis before leaving the thymus.
5. Memory cells allow the immune system to carry out a much more rapid and robust secondary response.
6. Active immunity refers to the stimulation of the immune system to produce antibodies against a pathogen. Passive immunity refers to the transfer of antibodies to prevent infection, without stimulation of the plasma cells that produce these antibodies.

8.4

1. Fluid would be unable to return from the lower leg, and edema would result. This infection leads to *elephantiasis*, severe swelling of the limb with thickening of the skin.
2. The thoracic duct carries lymphatic fluid into the left subclavian vein.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. In DiGeorge syndrome, the thymus can be completely absent. The absence of the thymus would leave an individual unable to mount specific defenses against which of the following types of pathogens?

A. Viruses
B. Bacteria
C. Parasites
D. Fungi

2. Which of the following are NOT involved in cell-mediated immunity?

A. Memory cells
B. Plasma cells
C. Cytotoxic cells
D. Suppressor cells

3. The lymphatic system:

A. transports hormones throughout the body.
B. transports chylomicrons to the circulatory system.
C. causes extravasation of fluid into tissues.
D. is the site of mast cell activation.

4. Which of the following are involved in antibody production?

A. Plasma cells
B. Memory cells
C. Helper T-cells
D. Cytotoxic cells

5. Which of the following is NOT an example of a nonspecific defense mechanism?

A. Skin provides a physical barrier against invasion.
B. Macrophages engulf and destroy foreign particles.
C. An inflammatory response is initiated in response to physical damage.
D. Cytotoxic T-cells destroy cells displaying foreign antigens.

6. Which of the following is an example of adaptive immunity?

A. PRRs recognize that a pathogen is an invasive parasite and eosinophils are recruited to the area.
B. Complement is activated, causing osmotic instability in a bacterium.
C. Memory B-cells generated through vaccination are activated when their antigen is encountered.
D. Dendritic cells sample bacteria within a laceration and travel to the lymph nodes to present the antigen.

7. Which of the following is true regarding passive and active immunity?

A. Active immunity requires weeks to build, whereas passive immunity is acquired immediately.
B. Active immunity is short-lived, whereas passive immunity is long-lived.
C. Active immunity may be acquired during pregnancy through the placenta.
D. Passive immunity may be acquired through vaccination.

8. Where are most self-reactive T-cells eliminated?

A. Spleen
B. Lymph nodes
C. Bone marrow
D. Thymus

9. What is the response of the immune system to downregulation of MHC molecules on somatic cells?

A. B-cells are activated and antibodies are released.
B. T-cells are activated, resulting in a cytotoxic response.
C. Natural killer cells induce apoptosis of affected cells.
D. Macrophages engulf the pathogen and display its antigens.

10. Which of the following correctly indicates the response of $CD8^+$ T-cells when activated?

A. Secretion of cytotoxic chemicals
B. Causing isotype switching
C. Presentation of antigens
D. Activation of B-cells

11. Lymphoma is cancer of the cells of the lymphoid lineage. These cells often reside within lymph nodes. What type of cell is NOT likely to cause a lymphoma?

A. $CD8^+$ T-cells
B. B-cells
C. Macrophages
D. T_h1 cells

12. Upon encountering an antigen, only T-cells with a specific T-cell receptor are activated. This is an example of:

A. innate immunity.
B. a cytotoxic T-cell response.
C. humoral immunity.
D. clonal selection.

13. Which cell type is a phagocyte that attacks bacterial pathogens in the bloodstream?

A. Neutrophils
B. Eosinophils
C. Basophils
D. Dendritic cells

14. What type of immunity is likely to be affected by removal of the spleen?

A. Cytotoxic immunity
B. Humoral immunity
C. Innate immunity
D. Passive immunity

15. Which of the following cell types is NOT a granulocyte?

A. Natural killer cell
B. Mast cell
C. Eosinophil
D. Basophil

Explanations to Discrete Practice Questions

1. A

T-lymphocytes, which mature in the thymus, are the only specific defense against intracellular pathogens. While some bacteria, fungi, and parasites can live intracellularly, viruses—by definition—must replicate within cells. The absence of T-cells would leave an individual unable to fight viral infections with specific defenses.

2. B

The lymphocytes involved in cell-mediated immunity are the T-lymphocytes, or T-cells. There are four types of T-cells, each playing a different role in cell-mediated immunity: cytotoxic T-cells, helper T-cells, memory T-cells, and suppressor T-cells. Thus, from the answer choices, the only cells not involved in cell-mediated immunity are the plasma cells, which are differentiated immunoglobulin-secreting B-lymphocytes involved in humoral immunity. **Choice (B)** is therefore the correct answer.

3. B

The main function of the lymphatic system is to collect excess interstitial fluid and return it to the circulatory system, maintaining the balance of body fluids. However, this is not one of the answer choices. In addition, the lymphatic system accepts chylomicrons from the small intestine and delivers them to the cardiovascular circulation. Transport of hormones is a function of the cardiovascular system, eliminating **choice (A)**. The lymphatic system absorbs fluid that has been pushed into tissues, but does not cause the extravasation of the fluid, eliminating **choice (C)**. Mast cells reside in (and are activated in) the skin and mucous membranes, eliminating **choice (D)**.

4. A

Antibodies are produced by plasma cells derived from B-lymphocytes. The other cells are all types of T-lymphocytes, although memory B-cells can also exist. Still, memory B-cells do not produce antibodies; plasma cells do.

5. D

The body employs a number of nonspecific defense mechanisms against foreign invasion. The skin and mucous membranes provide a physical barrier against bacterial invasion. In addition, sweat contains enzymes that attack bacterial cell walls. Certain passages, such as the respiratory tract, are lined with ciliated mucus-coated epithelia, which filter and trap foreign particles. Macrophages engulf and destroy foreign particles. The inflammatory response is initiated in response to physical damage. The only choice that is not a nonspecific defense mechanism is **choice (D)**, the correct answer. Cytotoxic T-cells are involved in (specific) cell-mediated immunity.

6. C

Adaptive immunity involves the activation of B-cells and T-cells specific to the encountered antigen. Any choice that conforms to this paradigm will be correct. **Choice (C)** indicates that B-cells are activated. Pattern recognition receptors, or PRRs, in **choice (A)** recognize patterns common to certain pathogens, but do not identify the specific pathogen. Complement is an example of a blood-borne nonspecific defense against bacteria, eliminating **choice (B)**. Dendritic cells traveling to the lymph nodes in **choice (D)** are a part of the interaction between the innate and adaptive immune systems, but the dendritic cells themselves are nonspecific.

7. A

Active immunity refers to the production of antibodies during an immune response. Active immunity may be conferred by vaccination, such as when an individual is injected with a weakened, inactive, or modified form of a particular antigen that stimulates the immune system to produce antibodies. Active immunity may require weeks to build. Passive immunity, on the other hand, involves the transfer of antibodies either passively or by injection. An example would be during pregnancy, when some maternal antibodies cross the placenta and enter fetal circulation, conferring passive immunity to the fetus. Although passive immunity is acquired immediately, it is very short-lived, lasting only as long as the antibodies circulate in blood.

8. D

T-cells mature in the thymus, where they are "educated." This education involves the elimination of T-cells with improper binding to MHC–antigen complexes (positive selection) and self-reactive T-cells (negative selection). Thus, self-reactive T-cells are eliminated in the thymus.

9. C

Healthy cells exhibit MHC class I molecules. Natural killer cells monitor the expression of MHC molecules on the surface of cells. Viral infection and cancer often cause a reduction in the expression of MHC class I molecules on the cell surface. Natural killer cells detect this lack of MHC and induce apoptosis in the affected cells.

10. A

$CD8^+$ T-cells are largely responsible for the cytotoxic immune response. By releasing toxic chemicals into virally infected cells, $CD8^+$ T-cells are able to kill these cells in an effort to contain viral infections. Isotype switching refers to changes in the isotype of antibody produced, which is not caused by $CD8^+$ cells, eliminating **choice (B)**. Antigens are presented by macrophages, dendritic cells, certain epithelial cells, and some B-cells, eliminating **choice (C)**. B-cells are not activated by cytotoxic T-lymphocytes, eliminating **choice (D)**.

11. C

Lymphocytes arise from the lymphoid lineage, which includes B-cells and T-cells. Thus, all types of B- and T-cells are capable of causing lymphoma. Macrophages, however, are not lymphocytes and are not likely to cause lymphoma.

12. D

When the adaptive immune system encounters an antigen, only the cells with receptors (antibodies or T-cell receptors) specific to that antigen are activated. This is known as clonal selection. While a T-cell response may be a cytotoxic response, it could also be the activation of helper T-cells; plus, this does not explain the specificity of the response, eliminating **choice (B)**.

13. A

The only phagocytes that attack bacteria on this list are neutrophils and dendritic cells. Dendritic cells are able to sample and present any type of material, and reside in the skin. Neutrophils, on the other hand, are present in the bloodstream and can attack bacteria present there or in tissues. Eosinophils and basophils are involved in the formation of allergies; eosinophils also defend against parasites.

14. B

The spleen is a location where B-cells mature and proliferate. Therefore, removal of the spleen is likely to result in a reduction of humoral immunity. In fact, many people receive vaccinations prior to removal of the spleen in order to bolster their immunity.

15. A

Granulocytes are cells with granules in their cytoplasm. These granules are released in immune responses to attack a pathogen. Granulocytes include neutrophils, basophils, eosinophils, and mast cells. Natural killer cells are agranulocytes, which include lymphocytes (B-, T-, and NK cells) and monocytes/macrophages.

Concept Summary 328

Introduction

As we continue our survey of organ systems, we come to the digestive system. As with our previous reviews of other organ systems, we will start with a basic anatomical overview of the organs of digestion (including the accessory organs) and then move on to discuss how these organs function to provide nutrition to the individual. The food we eat is complex, composed of meats, grains, vegetables and fruits, dairy products, and sugars. The job of the digestive system is to take these complex foods—composed of polysaccharides, fats, and proteins—and turn these large macromolecules into smaller, simpler monosaccharides, fatty acids, and amino acids. In order to cleave all of these bonds, the body requires a complex system of mechanical and chemical agents. These compounds can then be absorbed from the gut, transported to the tissues by the circulatory system, and used by cells. In this chapter, we will consider the organs that make up the digestive system as well as the processes by which the foods we eat become the fuel we need for energy, growth, development, and maintenance of other essential activities.

9.1 Anatomy of the Digestive System ★

There are two types of digestion that occur. First, **intracellular digestion**, as a part of **metabolism**, involves the oxidation of glucose and fatty acids for energy. However, our diets do not consist of pure glucose and fatty acids; rather, these substances must be extracted from our food. The process by which these nutrients are obtained from food occurs within the lumen of the **alimentary canal** and is known as **extracellular digestion**. This is technically "outside" the body, as it is outside the cell borders. The alimentary canal runs from the **mouth** to the **anus** and is sectioned off by **sphincters**, or circular smooth muscles around the canal that can contract to allow compartmentalization of function.

The human digestive tract has specialized sections with different functional roles. The most basic functional distinction is between digestion and absorption. **Digestion** involves the breakdown of food into its constituent organic molecules: starches and other carbohydrates into monosaccharides, lipids (fats) into free fatty acids and glycerol, and proteins into amino acids. Digestion can be subdivided into mechanical and chemical processes. **Mechanical digestion** is the physical breakdown of large food particles into smaller food particles, but does not involve breaking chemical bonds. **Chemical digestion** is the enzymatic cleavage of chemical bonds, such as the peptide bonds of proteins or the glycosidic bonds of starches. **Absorption** involves the transport of products of digestion from the digestive tract into the circulatory system for distribution to the body's tissues and cells.

The digestive tract, shown in Figure 9.1, begins with the **oral cavity** (mouth) followed by the **pharynx**, a shared pathway for both food entering the digestive system and air entering the respiratory system. From the pharynx, food enters the **esophagus**, which transports food to the **stomach**. From the stomach, food travels to the **small intestine**, and then the **large intestine**. Finally, waste products of digestion enter the **rectum**, where feces are stored until the appropriate time of release. In addition to the actual organs of the digestive tract, the **salivary glands**, **pancreas**, **liver**, and **gallbladder** help to provide the enzymes and lubrication necessary to aid the digestion of food.

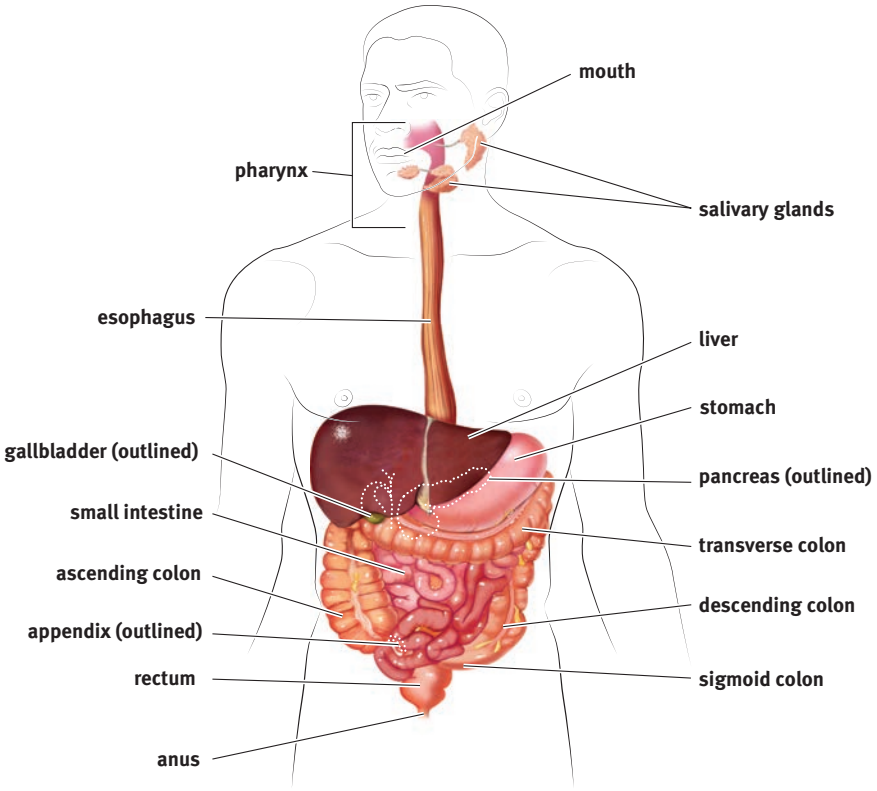

Figure 9.1. Anatomy of the Digestive System

The **enteric nervous system** is a collection of one hundred million neurons that govern the function of the gastrointestinal system. These neurons are present in the walls of the digestive tract and trigger **peristalsis**, or rhythmic contractions of the gut tube, in order to move materials through the system. This system can function independently of the brain and spinal cord, although it is heavily regulated by the autonomic nervous system. The parasympathetic division is involved in stimulation of digestive, activities, increasing secretions from exocrine glands and promoting peristalsis. The sympathetic division is involved in inhibition of these activities. The fact that so often we feel sleepy and lethargic after eating a big meal (often called a *food coma* colloquially) is due, in part, to parasympathetic activity. On the other hand, during periods of high sympathetic activity, blood flow is decreased to the digestive tract, and gut motility slows significantly.

Key Concept

All of the glands of the body (except sweat glands) are innervated by the parasympathetic nervous system.

MCAT Concept Check 9.1:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between mechanical and chemical digestion?
   - Mechanical digestion:

     _____
   - Chemical digestion:

     _____

2. Trace the path of food through the body, starting with ingestion and ending with excretion of feces:

   _____

   _____

   _____

3. What effect does the parasympathetic nervous system have on the digestive system? What effect does the sympathetic nervous system have?
   - Parasympathetic nervous system:

     _____
   - Sympathetic nervous system:

     _____

9.2 Ingestion and Digestion ★★★

To supply the body with nutrients, we must **ingest** (eat) food. Several hormones are involved with feeding behavior, including antidiuretic hormone (ADH or vasopressin), aldosterone, glucagon, ghrelin, leptin, and cholecystokinin. ADH and aldosterone trigger the sensation of thirst, encouraging the behavior of fluid consumption. Glucagon, secreted by the pancreas, and ghrelin, secreted by the stomach and pancreas, stimulate feelings of hunger. Leptin and cholecystokinin do the opposite, stimulating feelings of satiety. Digestion begins in the oral cavity and continues in the stomach and the first part of the small intestine, known as the duodenum.

ORAL CAVITY

The **oral cavity** plays a role in both mechanical and chemical digestion of food. Mechanical digestion in the mouth involves the breaking up of large food particles into smaller particles by using the teeth, tongue, and lips. This process is called **mastication** (chewing). Chewing helps to increase the surface-area-to-volume ratio of the food, allowing for more surface area for enzymatic digestion as it passes through the gut tube. It also moderates the size of food particles entering the lumen of the alimentary canal; food particles that are too large create an obstructive risk in the tract.

Chemical digestion begins the breakdown of chemical bonds in the macromolecules that make up food. This relies on enzymes from **saliva** produced by the three pairs of **salivary glands**. Saliva also aids mechanical digestion by moistening and lubricating food. The salivary glands, like all glands of the digestive tract, are innervated by the parasympathetic nervous system. The presence of food in the oral cavity triggers a neural circuit that ultimately leads to increased parasympathetic stimulation of these glands. Salivation can also be triggered by signals that food is near, such as smell or sight. Saliva contains *salivary amylase*, also known as *ptyalin*, and *lipase*. **Salivary amylase** is capable of hydrolyzing starch into smaller sugars (maltose and dextrins), while **lipase** catalyzes the hydrolysis of lipids. The amount of chemical digestion that occurs in the mouth is minimal, though, because the food does not stay in the mouth for long. Our muscular tongue forms the food into a **bolus**, which is forced back to the pharynx and swallowed.

PHARYNX

The **pharynx** is the cavity that leads from the mouth and posterior nasal cavity to the esophagus. The pharynx connects not only to the esophagus, but also to the larynx, which is a part of the respiratory tract. The pharynx can be divided into three parts:

Key Concept

The chemical digestion of carbohydrates is initiated in the mouth, but is completed in the small intestine. Salivary amylase (active in the mouth) and pancreatic amylase (active in the small intestine) have the same function.

Real World

There are three pairs of major salivary glands, called the parotid, submandibular, and sublingual glands. Other microscopic salivary glands are scattered throughout the upper digestive system. While the parasympathetic nervous system is responsible for promoting salivation, the sympathetic nervous system has some input into the glands as well. The sympathetic nervous system increases the viscosity of saliva, which is why dry mouth and even a tacky sensation in the mouth occurs during a fight-or-flight response.

the **nasopharynx** (behind the nasal cavity), the **oropharynx** (at the back of the mouth), and the **laryngopharynx** (above the vocal cords). Food is prevented from entering the larynx during swallowing by the **epiglottis**, a cartilaginous structure that folds down to cover the laryngeal inlet. Failure of this mechanism can lead to aspiration of food and choking.

ESOPHAGUS

The **esophagus** is a muscular tube that connects the pharynx to the stomach. The top third of the esophagus is composed of skeletal muscle, the bottom third is composed of smooth muscle, and the middle third is a mix of both. What does this mean in terms of nervous control? While the top of the esophagus is under somatic (voluntary) motor control, the bottom—and most of the rest of the gastrointestinal tract, for that matter—is under autonomic (involuntary) nervous control. The rhythmic contraction of smooth muscle that propels food toward the stomach is called **peristalsis**. Under normal circumstances, peristalsis proceeds down the digestive tract. However, certain conditions, such as exposure to chemicals, infectious agents, physical stimulation in the posterior pharynx, and even cognitive stimulation, can lead to reversal of peristalsis in the process of **emesis** (**vomiting**).

Swallowing is initiated in the muscles of the oropharynx, which constitute the **upper esophageal sphincter**. Peristalsis squeezes, pushes, and propels the bolus toward the stomach. As the bolus approaches the stomach, a muscular ring known as the **lower esophageal sphincter** (**cardiac sphincter**) relaxes and opens to allow the passage of food.

Real World

Weakness in the lower esophageal sphincter is a key feature of gastroesophageal reflux disease (GERD), which causes classic heartburn symptoms after eating. As food and acid reflux into the lower esophagus, they irritate the less-protected mucosa, stimulating pain receptors. These receptors localize pain poorly, so a general burning sensation is felt in the lower chest—leading to the common term *heartburn*.

STOMACH

There are three main energy sources: carbohydrates, fats, and proteins. As mentioned earlier, the chemical digestion of carbohydrates and fats is initiated in the mouth. No mechanical or chemical digestion takes place in the esophagus, except for the continued enzymatic activity initiated in the mouth by salivary enzymes. Thus, digestion that occurs prior to the entrance of the bolus into the stomach is minimal compared to the digestion that occurs in the stomach and small intestine.

The **stomach** is a highly muscular organ with a capacity of approximately two liters. In humans, the stomach is located in the upper left quadrant of the abdominal cavity, under the diaphragm. This organ uses hydrochloric acid and enzymes to digest food, creating a fairly harsh environment, and its mucosa is quite thick to prevent autodigestion. The stomach can be divided into four main anatomical divisions, as shown in Figure 9.2: the **fundus** and **body**, which

contain mostly gastric glands, and the **antrum** and **pylorus,** which contain mostly pyloric glands. The internal curvature of the stomach is called the **lesser curvature**; the external curvature is called the **greater curvature**. The lining of the stomach is thrown into folds called **rugae**.

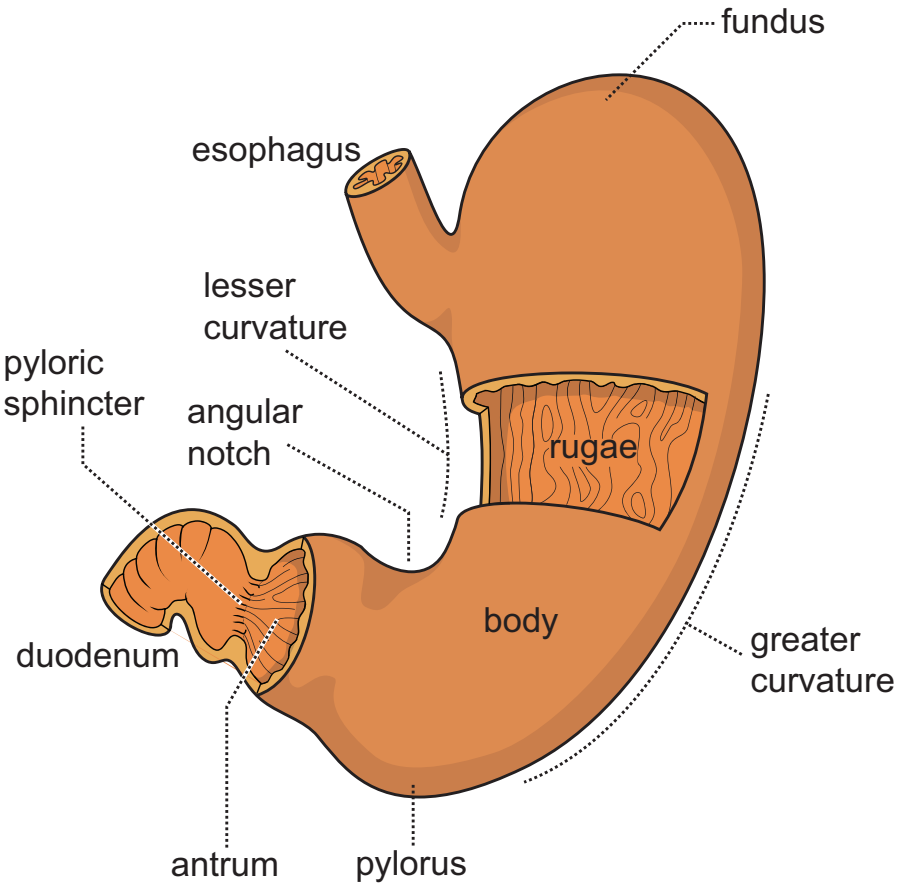

Figure 9.2. Anatomy of the Stomach

Real World

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, naproxen, and aspirin, are very common drugs. However, these drugs are not without side effects. One such side effect is the disruption of mucus production within the stomach. This leaves the mucosa of the stomach unprotected, and irritation results. This irritation can be in the form of *gastritis*, inflammation of the mucosa of the stomach, or *gastric ulcers*, deep wounds in the surface of the stomach.

The mucosa of the stomach contains gastric glands and pyloric glands. The **gastric glands** respond to signals from the **vagus nerve** of the parasympathetic nervous system, which is activated by the brain in response to the sight, taste, and smell of food. Gastric glands have three different cell types: mucous cells, chief cells, and parietal cells. **Mucous cells** produce the bicarbonate-rich mucus that protects the muscular wall from the harshly acidic (pH = 2) and proteolytic environment of the stomach.

Gastric juice is a combination of secretions from the other two cell types in the gastric glands. The **chief cells** secrete ***pepsinogen***. This is the inactive, **zymogen** form of *pepsin*, a proteolytic enzyme. Hydrogen ions in the stomach, secreted by **parietal cells** as hydrochloric acid, cleave pepsinogen to pepsin. **Pepsin** digests proteins by cleaving peptide bonds near aromatic amino acids, resulting in short

peptide fragments. Because pepsin is activated by the acidic environment, it follows that pepsin is most active at a low pH. This is a unique characteristic among human enzymes, as most human enzymes are most active at physiological pH. Stomach acid also kills most harmful bacteria (with the exception of *Helicobacter pylori*, infection with which is usually asymptomatic but can cause inflammation, ulcers, and even certain gastric cancers). The acidic environment also helps to denature proteins and can break down some intramolecular bonds that hold food together. In addition to HCl, parietal cells secrete **intrinsic factor**, a glycoprotein involved in the proper absorption of vitamin B_{12}.

The **pyloric glands** contain **G-cells** that secrete gastrin, a peptide hormone. **Gastrin** induces the parietal cells in the stomach to secrete more HCl and signals the stomach to contract, mixing its contents. The digestion of solid food in the stomach results in an acidic, semifluid mixture known as **chyme**. The combined mechanical and chemical digestive activities of the stomach result in a significant increase in the surface area of the now unrecognizable food particles, so when the chyme reaches the small intestine, the absorption of nutrients from it can be maximized. There are a few substances that are absorbed directly from the stomach (such as alcohol and aspirin), but the stomach is mainly an organ of digestion.

DUODENUM

The **small intestine** consists of three segments: the duodenum, the jejunum, and the ileum. The small intestine is quite long, up to seven meters. The duodenum is responsible for the majority of chemical digestion and has some minor involvement in absorption. However, most of the absorption in the small intestine takes place in the jejunum and ileum.

Food leaves the stomach through the **pyloric sphincter** and enters the duodenum. The presence of chyme in the duodenum causes the release of brush-border enzymes like *disaccharidases* (*maltase*, *isomaltase*, *lactase*, and *sucrase*) and *peptidases* (including *dipeptidase*). **Brush-border enzymes** are present on the luminal surface of cells lining the duodenum and break down dimers and trimers of biomolecules into absorbable monomers. The duodenum also secretes *enteropeptidase*, which is involved in the activation of other digestive enzymes from the accessory organs of digestion. Finally, it secretes hormones like secretin and cholecystokinin (CCK) into the bloodstream.

The **disaccharidases** digest disaccharides. **Maltase** digests maltose, **isomaltase** digests isomaltose, **lactase** digests lactose, and **sucrase** digests sucrose. Lack of a particular disaccharidase causes an inability to break down the corresponding disaccharide. Then bacteria in the intestines are able to hydrolyze that disaccharide,

Key Concept

The stomach secretes six products:

1. HCl (kills microbes, denatures proteins, and converts pepsinogen into pepsin)
2. Pepsinogen (cleaved to pepsin in the stomach; an enzyme that partially digests proteins)
3. Mucus (protects mucosa)
4. Bicarbonate (protects mucosa)
5. Water (dissolves and dilutes ingested material)
6. Intrinsic factor (required for normal absorption of vitamin B_{12})

Real World

Zollinger–Ellison syndrome is a rare disease resulting from a gastrin-secreting tumor (gastrinoma). Typically, this tumor is found in the pancreas. The excess gastrin leads to excessive HCl production by parietal cells. Not surprisingly, one of the most common signs of Zollinger–Ellison syndrome is the presence of intractable ulcer disease.

producing methane gas as a byproduct. In addition, undigested disaccharides can have an osmotic effect, pulling water into the stool and causing diarrhea. This is why people who are lactose intolerant have symptoms of bloating, flatulence, and possibly diarrhea after ingesting dairy products.

Peptidases break down proteins (or peptides, as the name implies). **Aminopeptidase** is a peptidase secreted by glands in the duodenum that removes the N-terminal amino acid from a peptide. **Dipeptidases** cleave the peptide bonds of dipeptides to release free amino acids. Unlike carbohydrates, which must be broken down into monosaccharides for absorption, di- and even tripeptides can be absorbed across the small intestine wall.

Enteropeptidase (formerly called ***enterokinase***) is an enzyme critical for the activation of ***trypsinogen***, a pancreatic protease, to ***trypsin***. Trypsin then initiates an activation cascade, as described later in this chapter. Enteropeptidase can also activate ***procarboxypeptidases A*** and ***B*** to their active forms.

Secretin is a peptide hormone that causes pancreatic enzymes to be released into the duodenum. It also regulates the pH of the digestive tract by reducing HCl secretion from parietal cells and increasing bicarbonate secretion from the pancreas. Secretin is also an **enterogastrone**, a hormone that slows motility through the digestive tract. Slowing of motility allows increased time for digestive enzymes to act on chyme—especially fats.

Finally, **cholecystokinin** (**CCK**) is secreted in response to the entry of chyme (specifically, amino acids and fat in the chyme) into the duodenum. This peptide hormone stimulates the release of both bile and pancreatic juices and also acts in the brain, where it promotes satiety. **Bile** is a complex fluid composed of bile salts, pigments, and cholesterol. **Bile salts** are derived from cholesterol. They are not enzymes and therefore do not directly perform chemical digestion (the enzymatic cleavage of chemical bonds). However, bile salts serve an important role in the mechanical digestion of fats and ultimately facilitate the chemical digestion of lipids. Bile salts have hydrophobic and hydrophilic regions, allowing them to serve as a bridge between aqueous and lipid environments. In fact, bile salts are much like the common soaps and detergents we use to wash our hands, clothes, and dishes. In the small intestine, bile salts **emulsify** fats and cholesterol into **micelles**. Without bile, fats would spontaneously separate out of the aqueous mixture in the duodenum and would not be accessible to *pancreatic lipase*, which is water-soluble. In addition, these micelles increase the surface area of the fats, increasing the rate at which lipase can act. Ultimately, proper fat digestion depends on both bile and lipase. Bile gets the fats into the solution and increases their surface area by placing them in micelles (mechanical digestion). Then, lipase can come in to hydrolyze the ester bonds holding the lipids together (chemical digestion).

Real World

Celiac disease results from an immune reaction against gluten, a protein found in grains, especially wheat. In this condition, the immune system develops antibodies against certain components of gluten. These antibodies then cross-react with elements of the small intestine, causing damage to the mucosa. This results in diarrhea and discomfort. Sometimes, this condition also results in malabsorptive syndromes, including the inability to absorb fat and fat-soluble vitamins. Contrary to popular belief, celiac disease and gluten sensitivity are immune responses, but not true allergies.

CCK also promotes the secretion of pancreatic juices into the duodenum, as shown in Figure 9.3. **Pancreatic juices** are a complex mixture of several enzymes in a bicarbonate-rich alkaline solution. This bicarbonate helps to neutralize acidic chyme, as well as provide an ideal working environment for each of the digestive enzymes, which are most active around pH 8.5. Pancreatic juices contain enzymes that can digest all three types of nutrients: carbohydrates, fats, and proteins. The identities and functions of these enzymes will be discussed in the next section of this chapter.

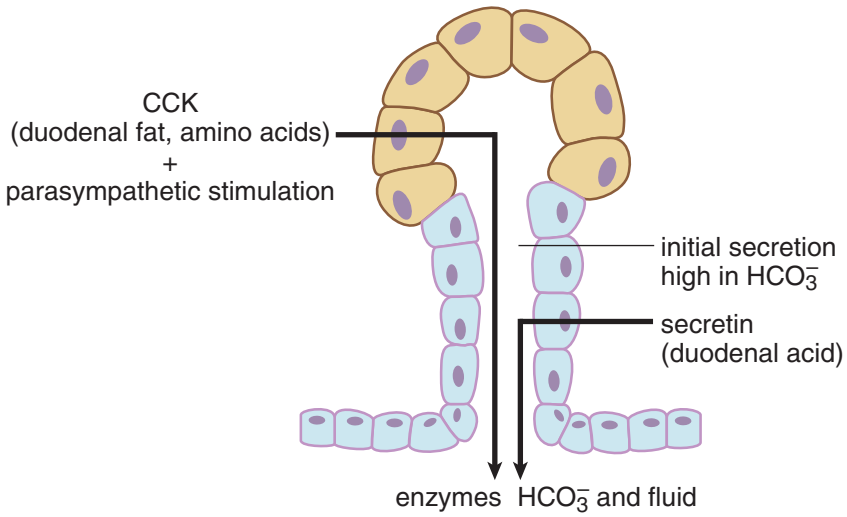

Figure 9.3. Hormonal Control of the Exocrine Pancreas

MCAT Concept Check 9.2:

Before you move on, assess your understanding of the material with these questions.

1. What two main enzymes are found in saliva? What do these enzymes do?
   - _____
   - _____

2. For each of the cell types below, list the major secretions of the cell and the functions of these secretions.

Cell	Secretions	Functions
Mucous cell		
Chief cell		
Parietal cell		
G-cell		

Bridge

The acidic environment of the stomach and basic environment of the duodenum point out the important correlation between pH and enzyme activity. Pepsin is active in the stomach and works best at pH 2. Pancreatic enzymes are active in the duodenum and work best at pH 8.5. pH, temperature, and salinity can all affect enzyme function, as highlighted in Chapter 2 of *MCAT Biochemistry Review*.

3. For each of the following substances, determine whether it is a digestive enzyme or a hormone and briefly summarize its functions.

Substance	Enzyme or Hormone?	Functions
Sucrase		
Secretin		
Dipeptidase		
Cholecystokinin		
Enteropeptidase		

4. How do bile and pancreatic lipase work together to digest fats?

_____

_____

9.3 Accessory Organs of Digestion ★★★

Digestion is a complex process that requires the release of enzymes not only from the cells directly lining the alimentary canal, but also from the pancreas, liver, and gallbladder. Collectively, these organs—which all originate as outgrowths of endoderm from the gut tube during development—are called **accessory organs of digestion**.

PANCREAS

The pancreas serves two quite different roles in the body, reflecting its exocrine and endocrine functions. As discussed in Chapter 5 of *MCAT Biology Review*, the endocrine functions of the pancreas include the release of insulin, glucagon, and somatostatin—peptide hormones necessary for the maintenance of proper blood sugar levels. The hormonal function of the pancreas is limited to cells residing in islets of Langerhans scattered throughout the organ. The bulk of the pancreas, however, is made of exocrine cells called **acinar cells** that produce pancreatic juices. As mentioned earlier, pancreatic juices are bicarbonate-rich alkaline secretions containing many digestive enzymes that work on all three classes of biomolecules. ***Pancreatic amylase*** breaks down large polysaccharides into small disaccharides and is therefore responsible for carbohydrate digestion. The pancreatic peptidases (***trypsinogen***, ***chymotrypsinogen***, and ***carboxypeptidases A*** and ***B***) are released in their zymogen form, but once activated are responsible for protein digestion. Enteropeptidase, produced by the duodenum, is the master switch. It activates trypsinogen to trypsin, which can then activate the other zymogens, and also activates procarboxypeptidases A and B to their active forms. Finally, the pancreas secretes **pancreatic lipase**, which is capable of breaking down fats into free fatty acids and glycerol.

Pancreatic juices are transferred to the duodenum via a duct system that runs along the middle of the pancreas, as shown in Figure 9.4. Like all exocrine cells, acinar cells secrete their products into ducts. These ducts then empty into the duodenum through the **major** and **minor duodenal papillae**.

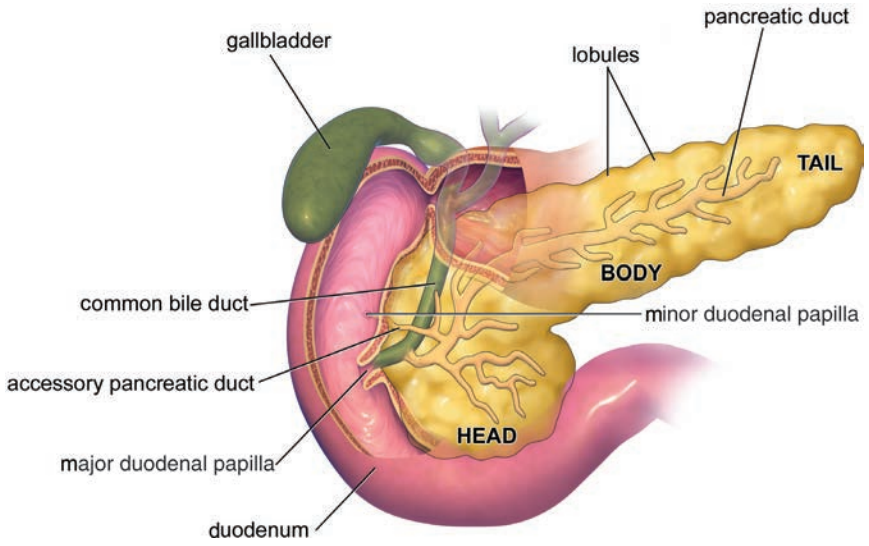

Figure 9.4. Anatomy of the Pancreas

LIVER

The **liver** is located in the upper right quadrant of the abdomen and contains two unique structures for communicating with the digestive system. First, **bile ducts** connect the liver with both the gallbladder and small intestine. Bile is produced in the liver and travels down these bile ducts where it may be stored in the gallbladder or secreted into the duodenum. The liver also receives all blood draining from the abdominal portion of the digestive tract through the **hepatic portal vein**. This nutrient-rich blood can be processed by the liver before draining into the inferior vena cava on its way to the right side of the heart. For example, the liver takes up excess sugar to create **glycogen**, the storage form of glucose, and stores fats as **triacylglycerols**. The liver can also reverse these processes, producing glucose for the rest of the body through glycogenolysis and **gluconeogenesis** and mobilizing fats in **lipoproteins**. The liver detoxifies both endogenous compounds (those made in the body) and exogenous compounds (those brought in from the environment). For example, the liver modifies ammonia, a toxic waste product of amino acid metabolism, to urea, which can be excreted by the kidneys. The liver also detoxifies and metabolizes alcohol and medications. Some drugs actually require activation by the enzymes of the liver. In addition, some drugs cannot be taken orally because modification of these drugs by the liver renders the drugs inactive.

Real World

Pancreatitis, or inflammation of the pancreas, is usually caused by gallstones or excessive consumption of alcohol. Regardless of the cause, pancreatitis results from premature activation of pancreatic enzymes and autodigestion of the pancreatic tissue. This is a very painful condition that may result in a long hospital stay and long-term consequences such as diabetes and the reduced digestion of proteins and fats.

Key Concept

The functions of the liver include processing of nutrients (glycogenesis and glycogenolysis, storage and mobilization of fats, gluconeogenesis), production of urea, detoxification of chemicals, production of bile, and synthesis of albumin and clotting factors.

Key Concept

The major components of bile are bile salts, which emulsify fats; pigments (especially bilirubin, from the breakdown of hemoglobin); and cholesterol.

Real World

Cirrhosis of the liver can occur from many different processes, including chronic alcohol consumption, hepatitis C infection, autoimmune hepatitis, and fatty liver disease. However, the outcome is the same. Cirrhosis is scarring of the liver, and this scar tissue builds up, creating increased resistance within the portal vein, resulting in portal hypertension. This causes a backup of fluid within the portal system, resulting in swollen veins in the digestive system, especially the esophagus, which may rupture and cause life-threatening bleeding. This often manifests as *hematemesis*, or vomiting of blood. Cirrhosis also causes bleeding disorders because production of clotting factors is disrupted. The inability to properly dispose of ammonia results in increased ammonia in the blood, which affects mentation. Finally, cirrhosis may also cause hepatocellular carcinoma, or cancer of the liver.

Bridge

Stone formation is nothing more than precipitation of a solid once its concentration has reached the K_{sp} of the compound. This is particularly common in the gallbladder because bile is concentrated there. Solubility and K_{sp} are discussed in Chapter 9 of *MCAT General Chemistry Review*.

Bile production is one of the most significant jobs of the liver *vis-à-vis* the digestive system. As mentioned earlier, bile is composed of bile salts, pigments, and cholesterol. Bile salts are amphipathic molecules that can emulsify fat in the digestive system. The major pigment in bile is **bilirubin**, which is a byproduct of the breakdown of hemoglobin. Bilirubin travels to the liver, where it is **conjugated** (attached to a protein) and secreted into the bile for excretion. If the liver is unable to process or excrete bilirubin (from liver damage, excessive red blood cell destruction, or blockage of the bile ducts), **jaundice** or yellowing of the skin may occur.

In addition to bile production, processing of nutrients, and detoxification and drug metabolism, the liver also synthesizes certain proteins necessary for proper body function. These proteins include **albumin**, a protein that maintains plasma oncotic pressure and also serves as a carrier for many drugs and hormones, as well as **clotting factors** used during blood coagulation.

GALLBLADDER

The **gallbladder** is located just beneath the liver and both stores and concentrates bile. Upon release of CCK, the gallbladder contracts and pushes bile out into the **biliary tree**. The bile duct system merges with the pancreatic duct, as shown in Figure 9.3 earlier, before emptying into the duodenum.

The gallbladder is a common site of cholesterol or bilirubin stone formation. This painful condition causes inflammation of the gallbladder. The stones may also travel into the bile ducts and may get stuck in the biliary tree. In some cases, stones can get caught just before entering the duodenum, resulting in blockage of not only the biliary tree, but the pancreatic duct as well, causing pancreatitis.

The functions of the various digestive enzymes (and bile) are summarized in Table 9.1.

Nutrient	Enzyme	Site of Production	Site of Function	Function
Carbohydrates	**Salivary amylase (ptyalin)**	**Salivary glands**	**Mouth**	**Hydrolyzes starch to maltose and dextrins**
	Pancreatic amylase	Pancreas (acinar cells)	Duodenum	Hydrolyzes starch to maltose and dextrins
	Maltase	**Intestinal glands**	**Duodenum**	**Hydrolyzes maltose to two glucose molecules**
	Isomaltase	Intestinal glands	Duodenum	Hydrolyzes isomaltose to two glucose molecules
	Sucrase	**Intestinal glands**	**Duodenum**	**Hydrolyzes sucrose to glucose and fructose**
	Lactase	Intestinal glands	Duodenum	Hydrolyzes lactose to glucose and galactose
Proteins	**Pepsin(ogen)**	**Gastric glands (chief cells)**	**Stomach**	**Hydrolyzes specific peptide bonds; activated by HCl**
	Trypsin(ogen)	Pancreas (acinar cells)	Duodenum	Hydrolyzes specific peptide bonds; converts chymotrypsin-ogen to chymotrypsin; activated by enteropeptidase
	Chymotrypsin (ogen)	**Pancreas (acinar cells)**	**Duodenum**	**Hydrolyzes specific peptide bonds; activated by trypsin**
	(Pro)carboxy peptidases A and B	Pancreas (acinar cells)	Duodenum	Hydrolyzes terminal peptide bond at carboxy end; activated by enteropeptidase
	Aminopeptidase	**Intestinal glands**	**Duodenum**	**Hydrolyzes terminal peptide bond at amino end**
	Dipeptidases	Intestinal glands	Duodenum	Hydrolyzes pairs of amino acids
	Enteropeptidase	**Intestinal glands**	**Duodenum**	**Converts trypsinogen to trypsin and procarboxypeptidases A and B to carboxypeptidases A and B**
Lipids	Bile*	Liver (stored in gallbladder)	Duodenum	Emulsifies fat
	Lipase	**Pancreas (acinar cells)**	**Duodenum**	**Hydrolyzes lipids**

*Note: Bile is not an enzyme, but is involved in mechanical digestion of fats.

Table 9.1. Digestive Enzymes

A summary of the digestion of each major class of biomolecules is provided in Figure 9.5.

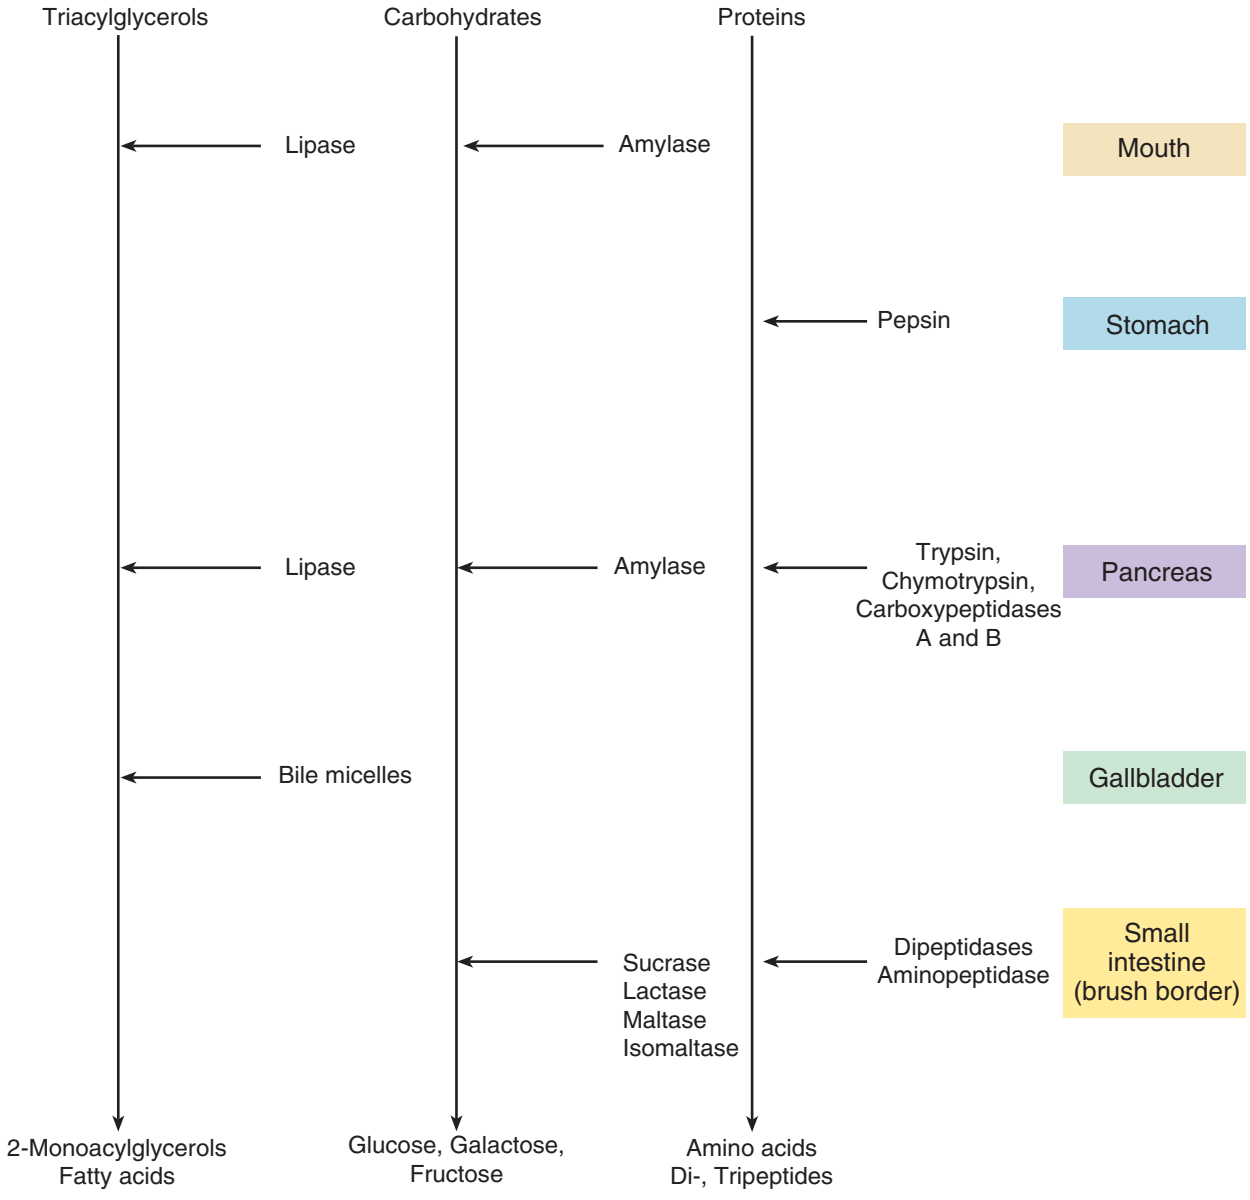

Figure 9.5. Summary of Digestive Processes

MCAT Concept Check 9.3:

Before you move on, assess your understanding of the material with these questions.

1. List at least one pancreatic enzyme that digests each of the three major classes of biomolecules:
   - Carbohydrates:

     _____
   - Proteins:

     _____
   - Fats:

     _____
2. What are the main components of bile?

   _____

   _____
3. Where is bile synthesized? Where is bile stored? Where does bile carry out its digestive function?
   - Synthesized:

     _____
   - Stored:

     _____
   - Carries out function:

     _____
4. List at least four functions of the liver:
   - _____
   - _____
   - _____
   - _____
5. The accessory organs of digestion originate from which primary germ layer?

   _____

9.4 Absorption and Defecation ★★

Absorption of nutrients primarily occurs in the small intestine, especially in the jejunum and ileum. The large intestine largely absorbs water.

JEJUNUM AND ILEUM

Mnemonic

Segments of the small intestine:
Dow **J**ones **I**ndustrial
- **D**uodenum
- **J**ejunum
- **I**leum

The small intestine consists of three segments: the duodenum, the jejunum, and the ileum. As discussed previously, the **duodenum** is primarily involved in digestion. The **jejunum** and **ileum** are involved in the absorption of nutrients. The small intestine is lined with **villi**, which are small, fingerlike projections from the epithelial lining, as shown in Figure 9.6. Each villus has many **microvilli**, drastically increasing the surface area available for absorption. In addition, at the middle of each villus is both a capillary bed for the absorption of water-soluble nutrients and a **lacteal**, a lymphatic channel that takes up fats for transport into the lymphatic system.

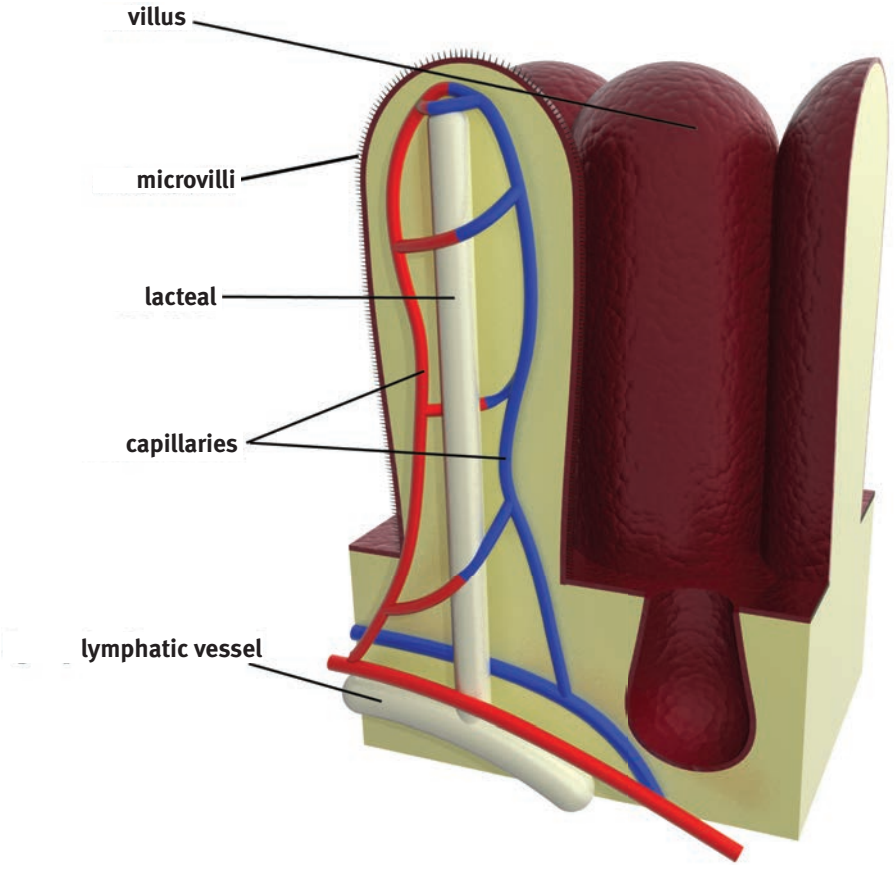

Figure 9.6. Structure of a Villus

Simple sugars, such as glucose, fructose, and galactose, and amino acids are absorbed by secondary active transport and facilitated diffusion into the epithelial cells lining the small intestine, as shown in Figure 9.7. Then, these substances move across the epithelial cells into the intestinal capillaries. Blood is constantly passing by the epithelial cells in the capillaries, carrying the carbohydrate and amino acid molecules away from the epithelial cells. This creates a concentration gradient such that the blood always has a lower concentration of monosaccharides and amino acids than inside the epithelial cells. Thus, simple carbohydrates and amino acids diffuse from the epithelial cells into the capillaries. The absorbed molecules then go to the liver via the hepatic portal circulation.

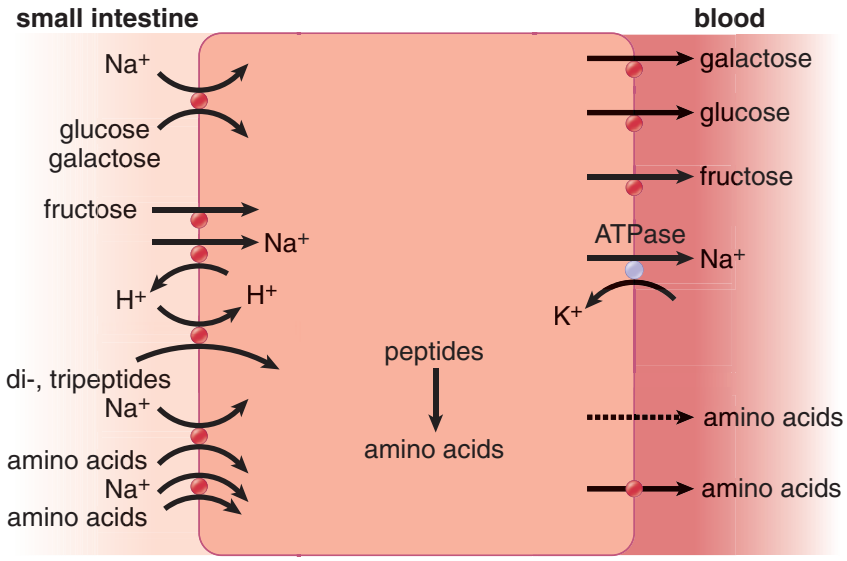

Figure 9.7. Absorption of Carbohydrates and Amino Acids in the Small Intestine

What about fats? Small fatty acids will follow the same process as carbohydrates and amino acids by diffusing directly into the intestinal capillaries. These fatty acids do not require transporters because they are nonpolar, so they can easily traverse the cellular membrane. Larger fats, glycerol, and cholesterol move separately into the

intestinal cells but then reform into triglycerides, as shown in Figure 9.8. The triglycerides and esterified cholesterol molecules are packaged into **chylomicrons**. Rather than entering the bloodstream, chylomicrons enter the lymphatic circulation through **lacteals**, small vessels that form the beginning of the lymphatic system. These lacteals converge and enter the venous circulation through the **thoracic duct** in the base of the neck, which empties into the left subclavian vein.

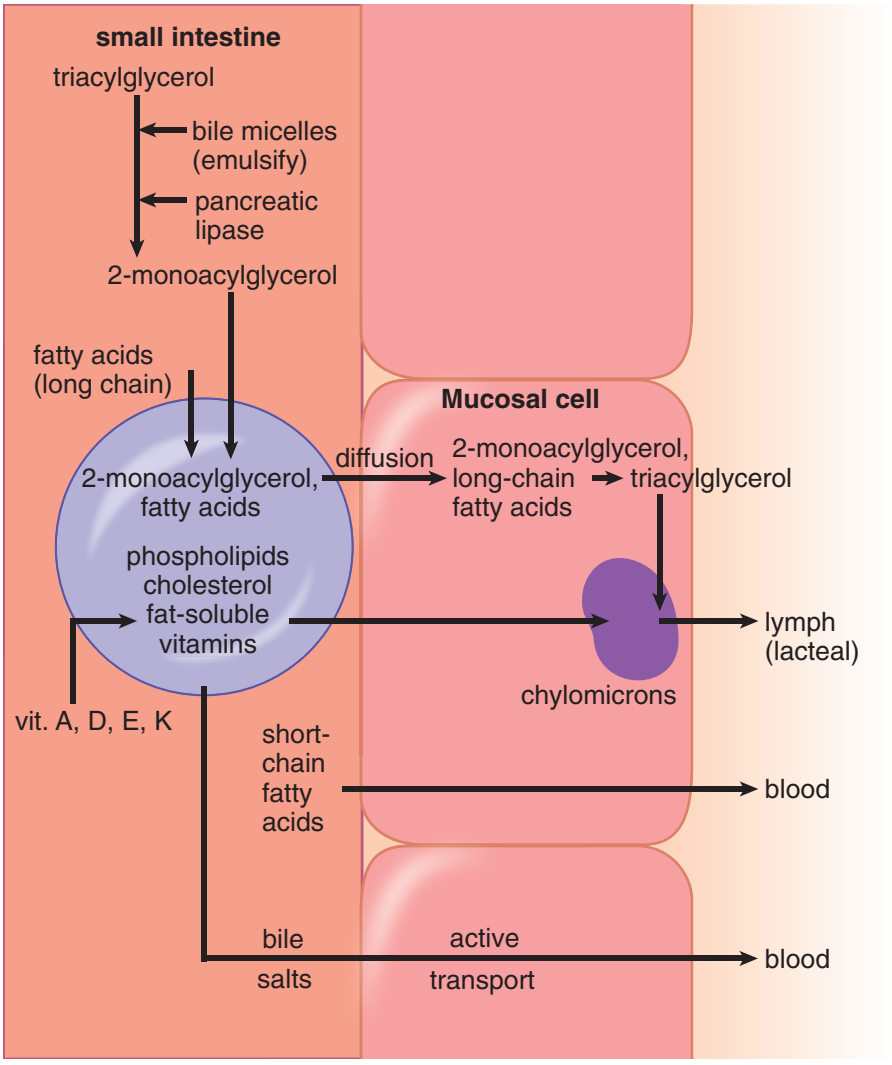

Figure 9.8. Absorption of Lipids

Vitamins are also absorbed in the small intestine. Vitamins can be categorized as either fat-soluble or water-soluble. Because there are only four **fat-soluble vitamins** (A, D, E, and K), these can be easily memorized. All other vitamins (B complex and C) are water-soluble. Fat-soluble vitamins dissolve directly into chylomicrons to enter the body. Failure to digest and absorb fat properly, which can be due to pathologies in the liver, gallbladder, pancreas, or small intestine, may lead

to deficiencies of fat-soluble vitamins. The **water-soluble vitamins** are absorbed, along with water, amino acids, and carbohydrates, across the endothelial cells of the small intestine, passing directly into the plasma.

In addition to fats, carbohydrates, amino acids, and vitamins, the small intestine also absorbs water. Much of the water in chyme is actually the result of secretions. The average person may consume up to two liters of fluid per day, but secretions into the upper gastrointestinal tract may total up to seven liters of fluid per day. In order to maintain proper fluid levels within the body, much of this fluid must be reabsorbed by osmosis. As solutes are absorbed into the bloodstream, water is drawn with it, eventually reaching the capillaries. Water passes not only **transcellularly** (across the cell membrane), but also **paracellularly** (squeezing between cells) to reach the blood.

LARGE INTESTINE

The final part of the gastrointestinal tract is the **large intestine**. It is primarily involved in water absorption. The large intestine has a larger diameter but shorter length than the small intestine. It is divided into three major sections: the cecum, the colon, and the rectum. The **cecum** is simply an outpocketing that accepts fluid exiting the small intestine through the **ileocecal valve** and is the site of attachment of the **appendix**. The appendix is a small fingerlike projection that was once thought to be **vestigial**, although recent evidence suggests that it may have a role in warding off certain bacterial infections and repopulating the large intestine with normal flora after episodes of diarrhea. Inflammation of the appendix (appendicitis) is a surgical emergency; in fact, it is the most common reason for an unscheduled surgery in the United States.

The **colon** itself is divided into the ascending, transverse, descending, and sigmoid colons. Its main function is to absorb water and salts (such as sodium chloride) from the undigested material left over from the small intestine. The small intestine actually absorbs much more water than the colon, so the colon primarily concentrates the remaining material to form **feces**. Too little or too much water absorption can cause diarrhea or constipation, respectively.

Finally, the rectum serves as a storage site for feces, which consists of indigestible material, water, bacteria (*E. coli* and others), and certain digestive secretions that are not reabsorbed (enzymes and some bile). The **anus** is the opening through which wastes are eliminated and consists of two sphincters: the **internal** and **external anal sphincters**. The external sphincter is under voluntary control (somatic), but the internal sphincter is under involuntary control (autonomic).

Bridge

Note the similarity between the muscles that control voiding of urine and feces. In both cases, there is an internal sphincter under autonomic control (internal urethral sphincter and internal anal sphincter) and an external sphincter under somatic control (external urethral sphincter and external anal sphincter). Urination is discussed in Chapter 10 of *MCAT Biology Review*.

The large intestine—and even the small intestine—is home to many different species of bacteria. In fact, 30 percent of the dry matter in stool consists of bacteria. Most of these bacteria are anaerobes, but the cecum is also home to many aerobic bacteria. This relationship is symbiotic: the bacteria are provided with a steady source of food, and the byproducts produced by the bacteria are beneficial to humans. For example, bacteria in the gut produce vitamin K, which is essential for the production of clotting factors, and biotin (vitamin B_7), which is a coenzyme for many metabolic enzymes.

MCAT Concept Check 9.4:

Before you move on, assess your understanding of the material with these questions.

1. What are the two circulatory vessels in a villus? What biomolecules are absorbed into each?
   - _____
   - _____
2. What are the four fat-soluble vitamins?

   _____
3. What are the three sections of the small intestine, in order? What are the three sections of the large intestine, in order?
   - Small intestine: _____, _____, _____
   - Large intestine: _____, _____, _____
4. *Vibrio cholera* causes a severe infection in the intestines, leading to massive volumes of watery diarrhea—up to 20 liters per day. Given these symptoms, does cholera likely impact the small intestine or the large intestine?

   _____

Conclusion

In this chapter, we have reviewed a lot of information about the digestive system that we can use to our advantage on Test Day. We began with an overview of the anatomy, keeping in mind that the system is designed to carry out extracellular digestion. Considering that all our foodstuffs are made up of fats, proteins, and carbohydrates, these compounds have to be broken down to their simplest molecular forms before they can be absorbed and distributed to the tissues and cells of the body.

As we moved through the gastrointestinal tract, we discussed whether each organ was a site of absorption, digestion, or both. We spent a good bit of time discussing each of the enzymes involved in digestion and their specific purposes. While digestion occurs primarily in the oral cavity, stomach, and duodenum, absorption occurs primarily in the jejunum and ileum, where the method of transport into the circulatory system is slightly different depending on the compound. Finally, we discussed the three segments of the large intestine and their roles in water and salt absorption, as well as the temporary storage of waste products. Although the amount of information about the digestive system may seem overwhelming, the underlying concepts are relatively straightforward, and a systematic approach (like charts, tables, or flashcards) will help you manage this content.

In the end, the digestive system's main purpose is to break down energy-containing compounds and get them into the circulation so they can be used by the rest of the body. Equally as important are the systems the body has for getting rid of compounds from the blood. Buildup of waste products like ammonia, urea, potassium, and hydrogen ions can lead to serious pathology. For instance, hyperammonemia (buildup of ammonia in the blood) can lead to severe, permanent neurological damage. Hyperkalemia (buildup of potassium in the blood) can quickly cause a fatal heart attack. Temperature regulation is similarly important; both hyperthermia and hypothermia can lead to organ dysfunction and, ultimately, death. In the next chapter, we turn our attention to these regulatory systems: the renal system and the skin.

CONCEPT SUMMARY

Anatomy of the Digestive System

- **Intracellular digestion** involves the oxidation of glucose and fatty acids to make energy. **Extracellular digestion** occurs in the lumen of the **alimentary canal**.
  - **Mechanical digestion** is the physical breakdown of large food particles into smaller food particles.
  - **Chemical digestion** is the enzymatic cleavage of chemical bonds, such as the peptide bonds of proteins or the glycosidic bonds of starches.
- The pathway of the digestive tract is: oral cavity → pharynx → esophagus → stomach → small intestine → large intestine → rectum
- The **accessory organs of digestion** are the salivary glands, pancreas, liver, and gallbladder.
- The **enteric nervous system** is in the wall of the alimentary canal and controls peristalsis. Its activity is upregulated by the parasympathetic nervous system and downregulated by the sympathetic nervous system.

Ingestion and Digestion

- Multiple hormones regulate feeding behavior, including antidiuretic hormone (ADH or vasopressin) and aldosterone, which promote thirst; glucagon and ghrelin, which promote hunger; and leptin and cholecystokinin, which promote satiety.
- In the **oral cavity**, **mastication** starts the mechanical digestion of food, while **salivary amylase** and **lipase** start the chemical digestion of food. Food is formed into a **bolus** and swallowed.
- The **pharynx** connects the mouth and posterior nasal cavity to the esophagus.
- The **esophagus** propels food to the stomach using peristalsis. Food enters the stomach through the **lower esophageal** (**cardiac**) **sphincter**.
- The stomach has four parts: **fundus**, **body**, **antrum**, and **pylorus**. The stomach has a **lesser** and **greater curvature** and is thrown into folds called **rugae**. Numerous secretory cells line the stomach.
  - **Mucous cells** produce bicarbonate-rich mucus to protect the stomach.
  - **Chief cells** secrete **pepsinogen**, a protease activated by the acidic environment of the stomach.
  - **Parietal cells** secrete hydrochloric acid and **intrinsic factor**, which is needed for vitamin B_{12} absorption.
  - **G-cells** secrete **gastrin**, a peptide hormone that increases HCl secretion and gastric motility.

- After mechanical and chemical digestion in the stomach, the food particles are now called **chyme**. Food passes into the duodenum through the **pyloric sphincter**.
- The **duodenum** is the first part of the small intestine and is primarily involved in chemical digestion.
  - **Disaccharidases** are brush-border enzymes that break down maltose, isomaltose, lactose, and sucrose into monosaccharides.
  - Brush-border **peptidases** include **aminopeptidase** and **dipeptidases**.
  - **Enteropeptidase** activates trypsinogen and procarboxypeptidases, initiating an activation cascade.
  - **Secretin** stimulates the release of pancreatic juices into the digestive tract and slows motility.
  - **Cholecystokinin** stimulates bile release from the gallbladder, release of pancreatic juices, and satiety.

Accessory Organs of Digestion

- **Acinar cells** in the pancreas produce pancreatic juices that contain bicarbonate, **pancreatic amylase**, pancreatic peptidases (**trypsinogen**, **chymotrypsinogen**, **carboxypeptidases A** and **B**), and **pancreatic lipase**.
- The **liver** synthesizes **bile**, which can be stored in the gallbladder or secreted into the duodenum directly.
  - Bile emulsifies fats, making them soluble and increasing their surface area.
  - The main components of bile are **bile salts**, pigments (especially **bilirubin** from the breakdown of hemoglobin), and cholesterol.
- The liver also processes nutrients (through glycogenesis and glycogenolysis, storage and mobilization of fats, and gluconeogenesis), produces urea, detoxifies chemicals, activates or inactivates medications, produces bile, and synthesizes albumin and clotting factors.
- The **gallbladder** stores and concentrates bile.

Absorption and Defecation

- The **jejunum** and **ileum** of the small intestine are primarily involved in absorption.
  - The small intestine is lined with **villi**, which are covered with **microvilli**, increasing the surface area available for absorption.
  - Villi contain a capillary bed and a **lacteal**, a vessel of the lymphatic system.
  - Water-soluble compounds, such as monosaccharides, amino acids, water-soluble vitamins, small fatty acids, and water, enter the capillary bed.
  - Fat-soluble compounds, such as fats, cholesterol, and fat-soluble vitamins, enter the lacteal.

- The **large intestine** absorbs water and salts, forming semisolid feces.
  - The **cecum** is an outpocketing that accepts fluid from the small intestine through the **ileocecal valve** and is the site of attachment of the **appendix**.
  - The **colon** is divided into ascending, transverse, descending, and sigmoid portions.
  - The **rectum** stores feces, which are then excreted through the **anus**.
  - Gut bacteria produce vitamin K and biotin (vitamin B_7).

ANSWERS TO CONCEPT CHECKS

9.1

1. Mechanical digestion, such as chewing, physically breaks food into smaller pieces. Chemical digestion involves hydrolysis of bonds and breakdown of food into smaller biomolecules.
2. Oral cavity (mouth) → pharynx → esophagus → stomach → small intestine → large intestine → rectum → anus
3. The parasympathetic nervous system increases secretions from all of the glands of the digestive system and promotes peristalsis. The sympathetic nervous system slows peristalsis.

9.2

1. Saliva contains salivary amylase (ptyalin), which digests starch into smaller sugars (maltose and dextrin), and lipase, which digests fats.

2.

Cell	Secretions	Functions
Mucous cell	Mucus	Protects lining of stomach, increases pH (bicarbonate)
Chief cell	Pepsinogen	Digests proteins, once activated by H^+
Parietal cell	HCl, intrinsic factor	HCl: decreases pH, kills microbes, denatures proteins, some chemical digestion; intrinsic factor: absorption of vitamin B_{12}
G-cell	Gastrin	Increases HCl production, increases gastric motility

3.

Substance	Enzyme or Hormone?	Functions
Sucrase	Enzyme	Brush-border enzyme; breaks down sucrose into monosaccharides
Secretin	Hormone	Increases pancreatic secretions, especially bicarbonate, reduces HCl secretion, decreases motility
Dipeptidase	Enzyme	Brush-border enzyme; breaks dipeptides into free amino acids
Cholecystokinin	Hormone	Recruits secretions from gallbladder and pancreas; promotes satiety
Enteropeptidase	Enzyme	Activates trypsinogen, which initiates an activation cascade

4. Bile accomplishes mechanical digestion of fats, emulsifying them and increasing their surface area. Pancreatic lipase accomplishes chemical digestion of fats, breaking their ester bonds.

9.3

1. Carbohydrates: pancreatic amylase; proteins: trypsin, chymotrypsin, carboxypeptidases A and B; fats: pancreatic lipase
2. Bile is composed of bile salts (amphipathic molecules derived from cholesterol that emulsify fats), pigments (especially bilirubin from the breakdown of hemoglobin), and cholesterol.
3. Bile is synthesized in the liver, stored in the gallbladder, and serves its function in the duodenum.
4. The liver processes nutrients (through glycogenesis and glycogenolysis, storage and mobilization of fats, and gluconeogenesis), produces urea, detoxifies chemicals, activates or inactivates medications, produces bile, and synthesizes albumin and clotting factors.
5. As outgrowths of the gut tube, the accessory organs of digestion arise from embryonic endoderm.

9.4

1. The two circulatory vessels are capillaries and lacteals. The capillary absorbs water-soluble nutrients, like monosaccharides, amino acids, small fatty acids, water-soluble vitamins, and water itself. The lacteal absorbs fat-soluble nutrients, like fats, cholesterol, and fat-soluble vitamins.
2. The fat-soluble vitamins are A, D, E, and K.
3. The small intestine consists of the duodenum, jejunum, and ileum. The large intestine consists of the cecum, colon, and rectum.
4. While the large intestine's main function is to absorb water, the small intestine actually absorbs a much larger volume of water. Thus, massive volumes of watery diarrhea are more likely to arise from infections in the small intestine than the large intestine.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following associations correctly matches a gastric cell with a compound it secretes?

A. G-cells—HCl
B. Chief cells—pepsinogen
C. Parietal cells—alkaline mucus
D. Mucous cells—intrinsic factor

2. Which of the following is NOT part of the small intestine?

A. Ileum
B. Cecum
C. Jejunum
D. Duodenum

3. In an experiment, enteropeptidase secretion was blocked. As a direct result, levels of all of the following active enzymes would likely be affected EXCEPT:

A. trypsin.
B. aminopeptidase.
C. chymotrypsin.
D. carboxypeptidase A.

4. Which of the following INCORRECTLY pairs a digestive hormone with its function?

A. Trypsin—hydrolyzes specific peptide bonds
B. Lactase—hydrolyzes lactose to glucose and galactose
C. Pancreatic amylase—hydrolyzes starch to maltose
D. Lipase—emulsifies fats

5. Which of the following correctly lists two organs in which proteins are digested?

A. Mouth and stomach
B. Stomach and large intestine
C. Stomach and small intestine
D. Small intestine and large intestine

6. Which of the following choices INCORRECTLY pairs a digestive enzyme with its site of secretion?

A. Sucrase—salivary glands
B. Carboxypeptidase—pancreas
C. Trypsin—pancreas
D. Lactase—duodenum

7. A two-week-old male infant is brought to the emergency room. His mother reports that he has been unable to keep any milk down; shortly after he nurses, he has sudden projectile vomiting. During exam, an olive-shaped mass can be felt in his upper abdomen. It is determined that there is a constriction in the digestive system that prevents food from reaching the small intestine from the stomach. Which structure is most likely the site of the problem?

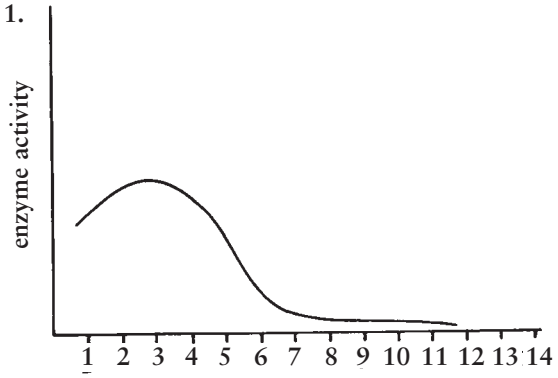
A. Cardiac sphincter
B. Pyloric sphincter
C. Ileocecal valve
D. Internal anal sphincter

8. Many medications have anticholinergic side effects, which block the activity of parasympathetic neurons throughout the body. Older individuals may be on many such medications simultaneously, exacerbating the side effects. Which of the following would NOT be expected in an individual taking medications with anticholinergic activity?

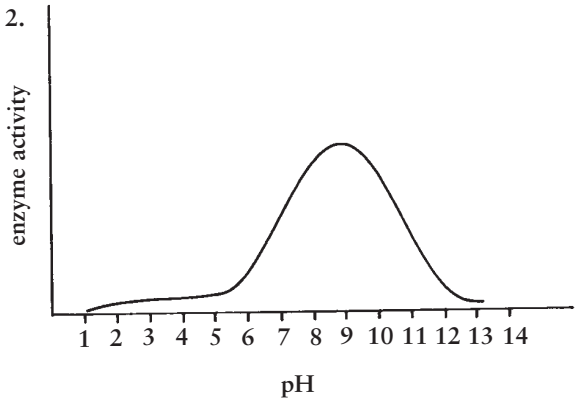
A. Dry mouth
B. Diarrhea
C. Slow gastric emptying
D. Decreased gastric acid production

9. The two graphs below show the relative activities of two enzymes in solutions of varying pH. Which of the following choices correctly identifies the two enzymes?

1.



2.



A. 1—chymotrypsin; 2—pepsin
B. 1—pepsin; 2—carboxypeptidase B
C. 1—lactase; 2—aminopeptidase
D. 1—enteropeptidase; 2—amylase

10. Which of the following would NOT likely lead to elevated levels of bilirubin in the blood?

A. Cholangiocarcinoma, a cancer of the bile ducts that can ultimately lead to full occlusion of the duct lumen
B. Autoimmune hemolytic anemia, a disease in which the red blood cells are attacked by antibodies and are lysed
C. Ménétrier's disease, in which rugae thicken and overlying glands lose secretory ability
D. Acetaminophen (Tylenol) overdose, in which the accumulation of toxic metabolites can cause rapid liver failure

11. Which of the following correctly pairs the molecule with its primary site of absorption?

A. Chylomicrons—lacteals
B. Amino acids—large intestine
C. Vitamins A and E—stomach
D. Cholesterol—ascending colon

12. Starch is hydrolyzed into maltose by enzymes from the:

I. salivary glands.
II. brush border.
III. pancreas.

A. I only
B. I and III only
C. II and III only
D. I, II, and III

13. Which of the following biomolecules does NOT drain to the liver before arriving at the right side of the heart?

A. Cholecalciferol (Vitamin D)
B. Threonine (an amino acid)
C. Fructose (a monosaccharide)
D. Pantothenic acid (vitamin B_5)

14. Which of the following hormones increases feeding behavior?

A. Leptin
B. Cholecystokinin
C. Ghrelin
D. Gastrin

15. Which of the following is likely to be seen in a patient with liver failure?

A. High concentrations of urea in the blood
B. High concentrations of albumin in the blood
C. Low concentrations of ammonia in the blood
D. Low concentrations of clotting factors in the blood

Explanations to Discrete Practice Questions

1. B

Chief cells secrete pepsinogen, a protease secreted as a zymogen that is activated by the acidic environment of the stomach. G-cells secrete gastrin, parietal cells secrete hydrochloric acid and intrinsic factor, and mucous cells secrete alkaline mucus, eliminating the other answer choices.

2. B

The small intestine is divided into three sections: the duodenum, the jejunum, and the ileum. The cecum is part of the large intestine, making **choice (B)** the correct answer.

3. B

Aminopeptidase is a brush-border peptidase secreted by the cells lining the duodenum; it does not require enteropeptidase for activation. Both trypsinogen and procarboxypeptidases A and B are activated by enteropeptidase, eliminating **choices (A)** and **(D)**. Once activated, trypsin can activate chymotrypsinogen; if trypsinogen cannot be activated, then chymotrypsinogen will not be activated either, eliminating **choice (C)**.

4. D

Lipase is involved in the digestion of fats, but its function is not to emulsify fats—this is the job of bile. Rather, lipase chemically digests fats in the duodenum, allowing them to be brought into duodenal cells and packaged into chylomicrons. The other associations given here are all correct.

5. C

Protein digestion begins in the stomach, where pepsin (secreted as pepsinogen) hydrolyzes specific peptide bonds. Protein digestion continues in the small intestine as trypsin (secreted as trypsinogen), chymotrypsin (secreted as chymotrypsinogen), carboxypeptidases A and B (secreted as procarboxypeptidases A and B), aminopeptidase, and dipeptidases hydrolyze specific parts of the peptide. No protein digestion occurs in the mouth or large intestine.

6. A

Sucrase is a brush-border enzyme found on duodenal cells and is not secreted by the salivary glands. This enzyme hydrolyzes sucrose (a disaccharide) to form glucose and fructose (monosaccharides). The other associations are all correct.

7. B

The question is basically asking us to identify the structure that lies between the stomach and the small intestine. This is the pyloric sphincter; the presentation given in the question is a classic example of what is called pyloric stenosis, in which the pyloric sphincter is thickened and cannot relax to permit chyme through. The cardiac sphincter, **choice (A)**, lies between the esophagus and the stomach. The ileocecal valve, **choice (C)**, lies between the ileum of the small intestine and the cecum of the large intestine. The internal anal sphincter, **choice (D)**, lies at the end of the rectum.

8. B

The parasympathetic nervous system has many roles in the digestive system. It promotes motility of the gut tube and secretion from glands. Therefore, blocking the parasympathetic nervous system would likely result in dry mouth (from reduced secretion of saliva), slow gastric emptying (from decreased peristalsis), and decreased gastric acid production (from reduced HCl secretion from the parietal cells in the gastric glands), eliminating **choices (A)**, **(C)**, and **(D)**.

Choice (B) is the correct answer because we would be more likely to expect constipation in such an individual, not diarrhea: slowed motility through the colon would lead to increased water reabsorption, making the feces too firm and causing constipation.

9. B

The first graph shows maximal activity at a very acidic pH, implying that this is an enzyme acting in the stomach. The second graph shows maximal activity around pH 8.5, implying that this is an enzyme acting in the duodenum. The only choice that matches the first graph with a stomach enzyme (pepsin) and the second with a duodenal enzyme (carboxypeptidase B) is **choice (B)**.

10. C

Elevated bilirubin implies a blockage to bile flow, increased production of bilirubin (from massive hemoglobin release), or an inability of the liver to produce bile. If the bile duct were occluded, as in **choice (A)**, then bile would not be able to flow into the digestive tract and would build up, increasing bilirubin levels in the blood. If many red blood cells were lysed, as in **choice (B)**, then bilirubin levels would rise in accordance with the increased hemoglobin release. If liver failure occurred, as in **choice (D)**, then it would be unable to produce bile, and bilirubin would again build up. **Choice (C)** refers to a pathology in the stomach—the key word given here is rugae, which are the folds in the stomach wall. Lack of gastric function would have no effect on bilirubin levels, making this the correct choice.

11. A

Chylomicrons contain triacylglycerols, cholesteryl esters, and fat-soluble vitamins and are secreted by intestinal cells into lacteals. Amino acids, fat-soluble vitamins (like vitamins A and E), and cholesterol are all absorbed in the small intestine.

12. B

Starch is hydrolyzed to maltose by two enzymes: salivary amylase (secreted by the salivary glands) in the mouth and pancreatic amylase (secreted by the pancreas) in the duodenum. Brush-border disaccharidases can further break down maltose, but do not break down starch.

13. A

While the capillaries from the intestine come together to form the portal vein, which drains to the liver, the lacteals come together to form the thoracic duct, which drains directly into the left subclavian vein. Therefore, fat-soluble compounds do not pass through the liver before reaching the right heart. Only **choice (A)**, vitamin D, is fat-soluble.

14. C

Ghrelin promotes a sensation of hunger, increasing feeding behavior. Both leptin and cholecystokinin promote satiety, decreasing feeding behavior—eliminating **choices (A)** and **(B)**. Gastrin increases acid production and gastric motility, but does not have any significant relationship with feeding behavior, eliminating **choice (D)**.

15. D

The liver serves many functions, including metabolic processes (glycogenesis and glycogenolysis, fat storage, and gluconeogenesis), detoxification or activation of medications, and synthesis of bile. Germane to this question are the roles of converting ammonia into urea through the urea cycle and synthesis of proteins, including albumin and clotting factors. A patient with liver failure would thus not be able to convert ammonia into urea and would have high concentrations of ammonia and low concentrations of urea in the blood, eliminating **choices (A)** and **(C)**. With decreased synthetic activity, both albumin and clotting factor concentrations would be low, eliminating **choice (B)** and making **choice (D)** the correct answer.

Introduction

Have a headache? Pop an ibuprofen. Backache? Works for that, too. Ibuprofen, which has been around for over 50 years, is an inexpensive, over-the-counter, nonsteroidal anti-inflammatory drug (NSAID). Because of its ability to relieve pain, ibuprofen is known as an analgesic. When used in moderation, ibuprofen carries relatively little risk. However, taking multiple doses for many years can profoundly affect the kidneys. Years of analgesic use (usually as self-therapy) can lead to kidney failure, known as analgesic nephropathy. If untreated, kidney failure is universally fatal.

If detected, however, dialysis (or a kidney transplant) could save such an individual's life. How does dialysis save a patient with kidney failure? Dialyzing fluid has many of the same solutes as blood, in strategic concentrations, and it is separated from blood by a semipermeable membrane. As blood is filtered through the dialysis machine, fluid and solutes diffuse down their concentration gradients, limited only by size (as determined by the membrane). The dialysis machine therefore performs filtration to purify the blood and excrete wastes, a crucial function that the kidneys would normally perform.

In this chapter, we'll learn more about filtration, as well as reabsorption and secretion. These processes are collectively responsible for osmoregulation. Osmoregulation is just one mechanism that the body uses to maintain homeostasis in its fluids and tissues. We'll also discuss the skin, which plays a significant role in temperature homeostasis (thermoregulation).

10.1 The Excretory System

The **excretory system** serves many functions, including the regulation of blood pressure, blood osmolarity, acid–base balance, and removal of nitrogenous wastes. The kidneys play an essential role in these functions.

ANATOMY OF THE EXCRETORY SYSTEM

The excretory system consists of the kidneys, ureters, bladder, and urethra, as shown in Figure 10.1. The kidneys are two bean-shaped structures located behind the digestive organs at the level of the bottom rib. The functional unit of the kidney is the nephron; each kidney has approximately 1 million nephrons. All of the nephrons eventually empty into the renal pelvis, which narrows to form the the ureter. Urine travels through the ureter to the bladder. From the bladder, urine is transported through the urethra to exit the body.

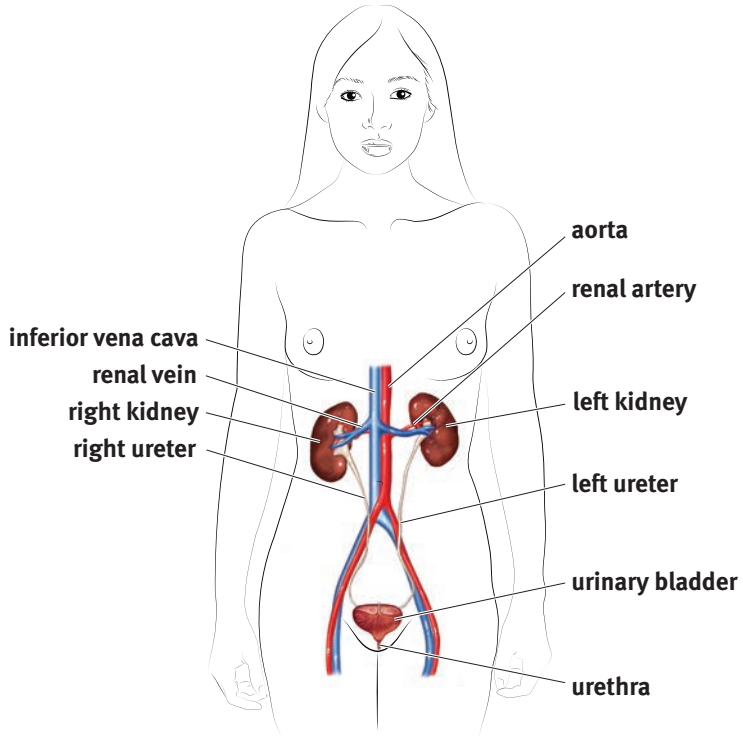

Figure 10.1. The Excretory System
Once it leaves the kidneys, urine moves through the ureters to be stored in the urinary bladder until it is excreted through the urethra.

Kidney Structure

Each kidney is subdivided into a cortex and a medulla, as shown in Figure 10.2. The **cortex** is the kidney's outermost layer, while the **medulla** of the kidney sits within the cortex. Each kidney also has a renal **hilum**, which is a deep slit in the

center of its medial surface. The widest part of the ureter, the **renal pelvis**, spans almost the entire width of the renal hilum. The **renal artery**, **renal vein**, and **ureter** enter and exit through the renal hilum.

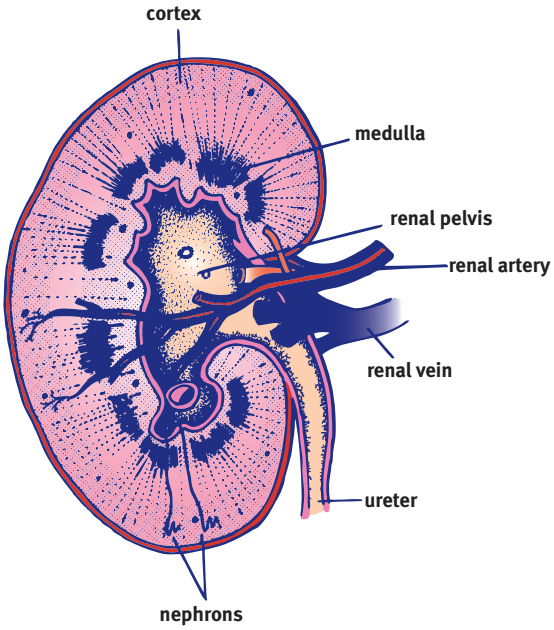

Figure 10.2. Gross Anatomy of the Kidney

The kidney has one of the few portal systems in the body. A **portal system** consists of two capillary beds in series through which blood must travel before returning to the heart. The renal artery branches out, passes through the medulla, and enters the cortex as **afferent arterioles**. The highly convoluted capillary tufts derived from these afferent arterioles are known as **glomeruli**. After blood passes through a glomerulus, the **efferent arterioles** then form a second capillary bed. These capillaries surround the loop of Henle and are known as **vasa recta**. The renal vascular system is shown in Figure 10.3.

Bridge

The portal system in the kidney is one of three major portal systems in the body. The other two are the hypophyseal portal system, which connects the hypothalamus and the anterior pituitary (discussed in Chapter 5 of *MCAT Biology Review*), and the hepatic portal system, which connects the gut tube and the liver (discussed in Chapter 9 of *MCAT Biology Review*). In each case, blood passes through two capillary beds before returning to the heart.

Bridge

Our discussion of neurons in Chapter 4 of *MCAT Biology Review* used some of the same terms as those that describe the organization of blood vessels in the kidney. Afferent neurons carry sensory information toward the central nervous system much as afferent arterioles carry blood toward the glomeruli. Efferent neurons relay signals away from the central nervous system just as efferent arterioles carry blood away from the glomerulus.

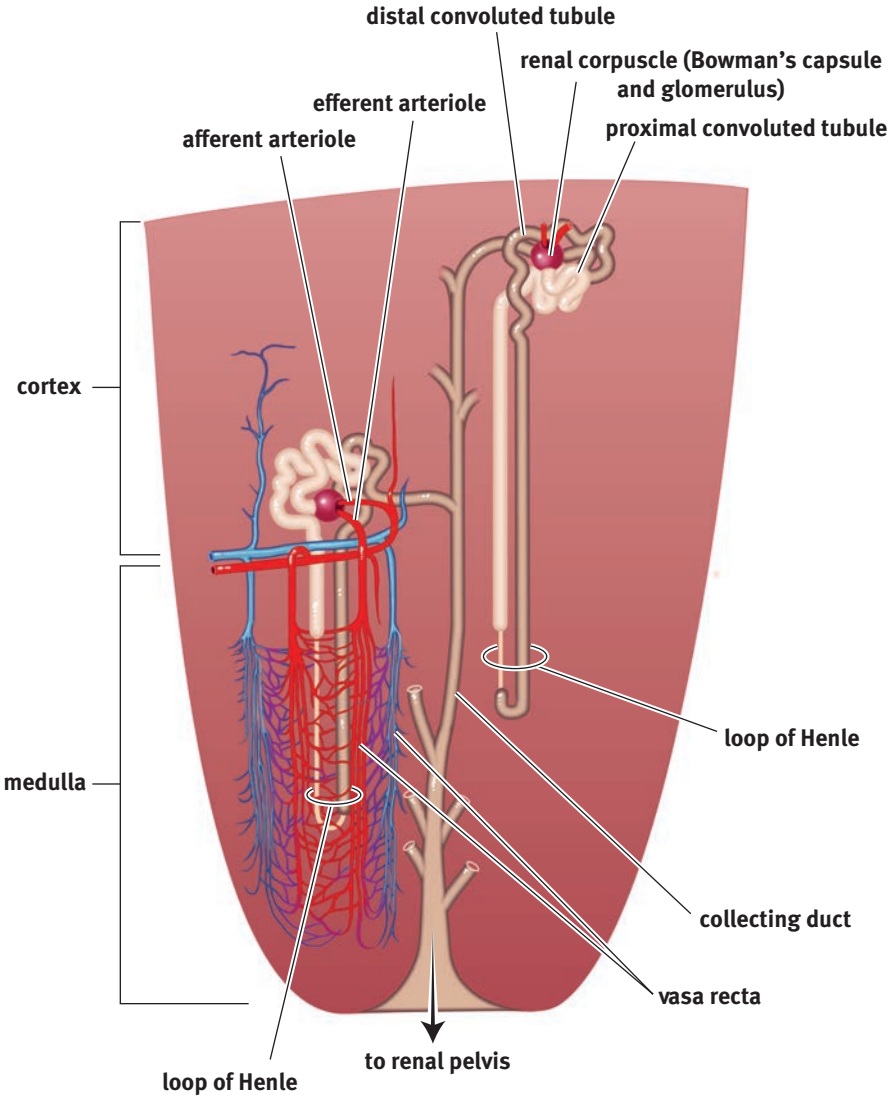

Figure 10.3. Microanatomy of the Renal Vascular System and the Nephron

Also visible in Figure 10.3 is the structure of the nephron. Around the glomerulus is a cuplike structure known as **Bowman's capsule**. Bowman's capsule leads to a long tubule with many distinct areas; in order, these are the proximal convoluted tubule, descending and ascending limbs of the Loop of Henle, distal convoluted tubule, and collecting duct. The kidney's ability to excrete waste is intricately tied to the specific placement of these structures and their physiology.

Bladder Structure

The bladder has a muscular lining known as the **detrusor muscle**. Parasympathetic activity causes the detrusor muscle to contract. However, in order to leave the body, urine must pass through two sphincters—the internal and external urethral sphincters. The **internal urethral sphincter**, consisting of smooth muscle, is

contracted in its normal state. Because the internal sphincter is made of smooth muscle, it is under involuntary control. The **external urethral sphincter** consists of skeletal muscle and is under voluntary control. When the bladder is full, stretch receptors convey to the nervous system that the bladder requires emptying. This causes parasympathetic neurons to fire, and the detrusor muscle contracts. This contraction also causes the internal sphincter to relax. This reflex is known as the **micturition reflex**. The next step is up to the individual. The person can choose to relax the external sphincter to urinate, or can maintain the tone of the external sphincter to prevent urination. This can cause a few moments of discomfort, but the reflex usually dissipates in a few minutes. However, if the bladder is not emptied, then the process will begin anew shortly thereafter. Urination itself is facilitated by the contraction of the abdominal musculature, which increases pressure within the abdominal cavity, resulting in compression of the bladder and increased urine flow rate.

OSMOREGULATION

The kidney filters the blood to form urine. The composition and quantity of urine is determined by the present state of the body. For example, if blood volume is low and blood osmolarity is high, then it is most beneficial to the body to maximally retain water. This results in low-volume, highly concentrated urine. Likewise, a patient receiving large amounts of intravenous fluids is likely to produce a larger volume of less concentrated urine. Thus, the primary job of the kidneys is to regulate blood volume and osmolarity. In order to do this, kidney function may be divided into the three different processes: filtration, secretion, and reabsorption.

Filtration

The nephron's first function is **filtration**. In the kidneys, approximately 20 percent of the blood that passes through the glomerulus is filtered as fluid into Bowman's space. The collected fluid is known as the **filtrate**. The movement of fluid into Bowman's space is governed by **Starling forces**, which account for the pressure differentials in both hydrostatic and oncotic pressures between the blood and Bowman's space, as shown in Figure 10.4. The hydrostatic pressure in the glomerulus is significantly higher than that in Bowman's space, which causes fluid to move into the nephron. On the other hand, the osmolarity of blood is higher than that of Bowman's space, resulting in pressure opposing the movement of fluid into the nephron. However, the hydrostatic pressure is much larger than the oncotic pressure, so the net flow is still from blood into the nephron.

Bridge

Like the electromotive force discussed in Chapter 6 of *MCAT Physics and Math Review*, Starling *forces* are really a misnomer. Rather than forces, it is a pressure differential that causes the net movement of fluid from the glomerulus to Bowman's space. Pressure is discussed in Chapter 4 of *MCAT Physics and Math Review*.

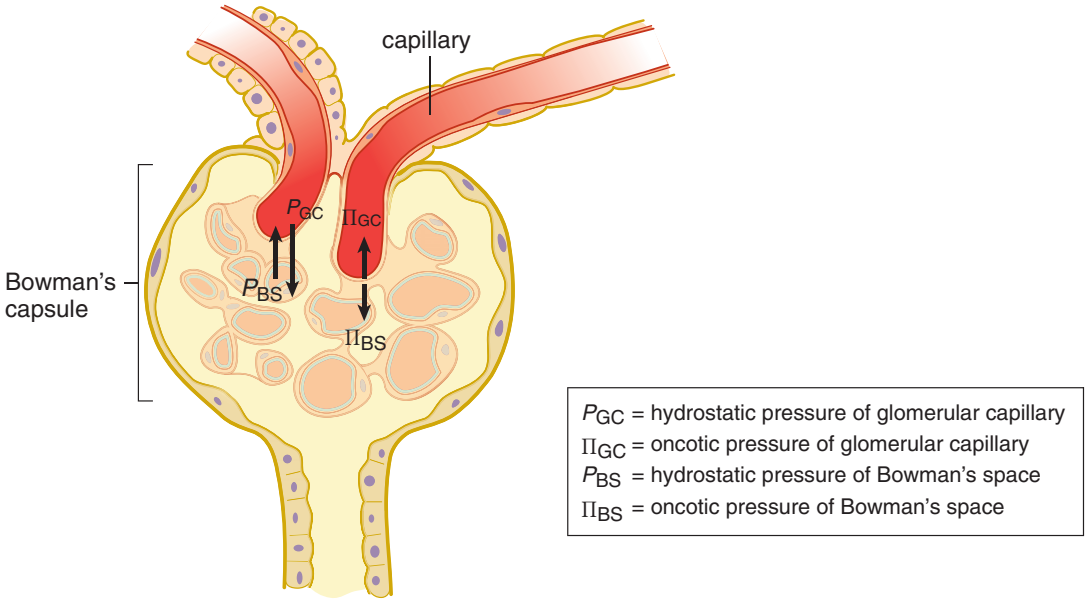

Figure 10.4. Starling Forces
The relative hydrostatic and oncotic pressure gradients determine the direction and rate of filtration.

Under most circumstances, fluid will flow from the glomerulus into Bowman's space. However, various pathologies can cause derangements of this flow. Consider what might happen if the ureter was obstructed by a kidney stone. An obstruction would result in a buildup of urine behind the stone. Eventually, enough fluid will build up and cause distention of the renal pelvis and the nephrons. What will happen to filtration in this case? The hydrostatic pressure in Bowman's space would increase to the point that filtration could no longer occur because there would be excessive pressure opposing movement of fluid into the nephron.

Key Concept

Imagine that the glomerulus is like a sieve or colander. Small molecules dissolved in the blood will pass through the tiny pores (such as glucose, which is later reabsorbed), whereas large molecules such as proteins and blood cells will not. If blood cells or proteins are found in the urine, this indicates a health problem at the level of the glomerulus.

The filtrate is similar in composition to blood but does not contain cells or proteins due to the filter's ability to select based on size. In other words, molecules or cells that are larger than glomerular pores will remain in the blood. As described earlier, the blood remaining in the glomerulus then travels into the efferent arterioles, which empty into the vasa recta. The filtrate is isotonic to blood so that neither the capsule nor the capillaries swell. Our kidneys filter about 180 liters per day, which is approximately 36 times our blood volume. This means that the entire volume of a person's blood is filtered about every 40 minutes.

Secretion

In addition to filtering blood, the nephrons are able to **secrete** salts, acids, bases, and urea directly into the tubule by either active or passive transport. The quantity and identity of the substances secreted into the nephron are directly related to the needs of the body at that time. For example, a diet heavy in meat results

in the intake of large amounts of protein, which contains a significant amount of nitrogen. Ammonia (NH_3) is a byproduct of the metabolism of nitrogen-containing compounds and, as a base, can disturb the pH of blood and cells. The liver converts the ammonia to **urea**, a neutral compound, which travels to the kidney and is secreted into the nephron for excretion with the urine. The kidneys are capable of eliminating ions or other substances when present in relative excess in the blood, such as potassium cations, hydrogen ions, or metabolites of medications. Secretion is also a mechanism for excreting wastes that are simply too large to pass through glomerular pores.

Reabsorption

Some compounds that are filtered or secreted may be taken back up for use via **reabsorption**. Certain substances are almost always reabsorbed, such as glucose, amino acids, and vitamins. In addition, hormones such as antidiuretic hormone (ADH or vasopressin) and aldosterone can alter the quantity of water reabsorbed within the kidney in order to maintain blood pressure.

Key Concept

- Filtration: movement of solutes from blood to filtrate at Bowman's capsule
- Secretion: movement of solutes from blood to filtrate anywhere besides Bowman's capsule
- Reabsorption: movement of solutes from filtrate to blood

NEPHRON FUNCTION

The kidney uses mechanisms such as filtration, secretion, and reabsorption to produce urine and to regulate the blood volume and osmolarity. However, the function of the nephron isn't quite that simple. In fact, renal physiology is often considered one of the most difficult topics covered in medical school.

In order to simplify this topic, it is important to understand that the kidney has two main goals: keep what the body needs and lose what it doesn't, and concentrate the urine to conserve water. The kidney allows the human body to reabsorb certain materials for reuse, while also selectively eliminating waste. For example, glucose and amino acids are not usually present in the urine because the kidney is able to reabsorb these substances for later use. On the contrary, waste products like hydrogen and potassium ions, ammonia, and urea remain in the filtrate and are excreted. Finally, water is reabsorbed in large quantities in order to maintain blood pressure and adequate hydration.

Key Concept

Anything that makes it into the filtrate and that is not reabsorbed will be lost from the body in the urine.

In order to understand this complex organ, we will study the nephron piece-by-piece, discussing exactly what is occurring in each segment. Follow along with the nephron diagram shown in Figure 10.5. As a theme, note that segments that are horizontal in the diagram (Bowman's capsule, the proximal convoluted tubule, and the distal convoluted tubule) are primarily focused on the *identity* of the particles in the urine (*keep what the body needs and lose what it doesn't*). In contrast, the segments that are vertical in the diagram (the loop of Henle and collecting duct) are primarily focused on the volume and concentration of the urine (*concentrate the urine to conserve water*).

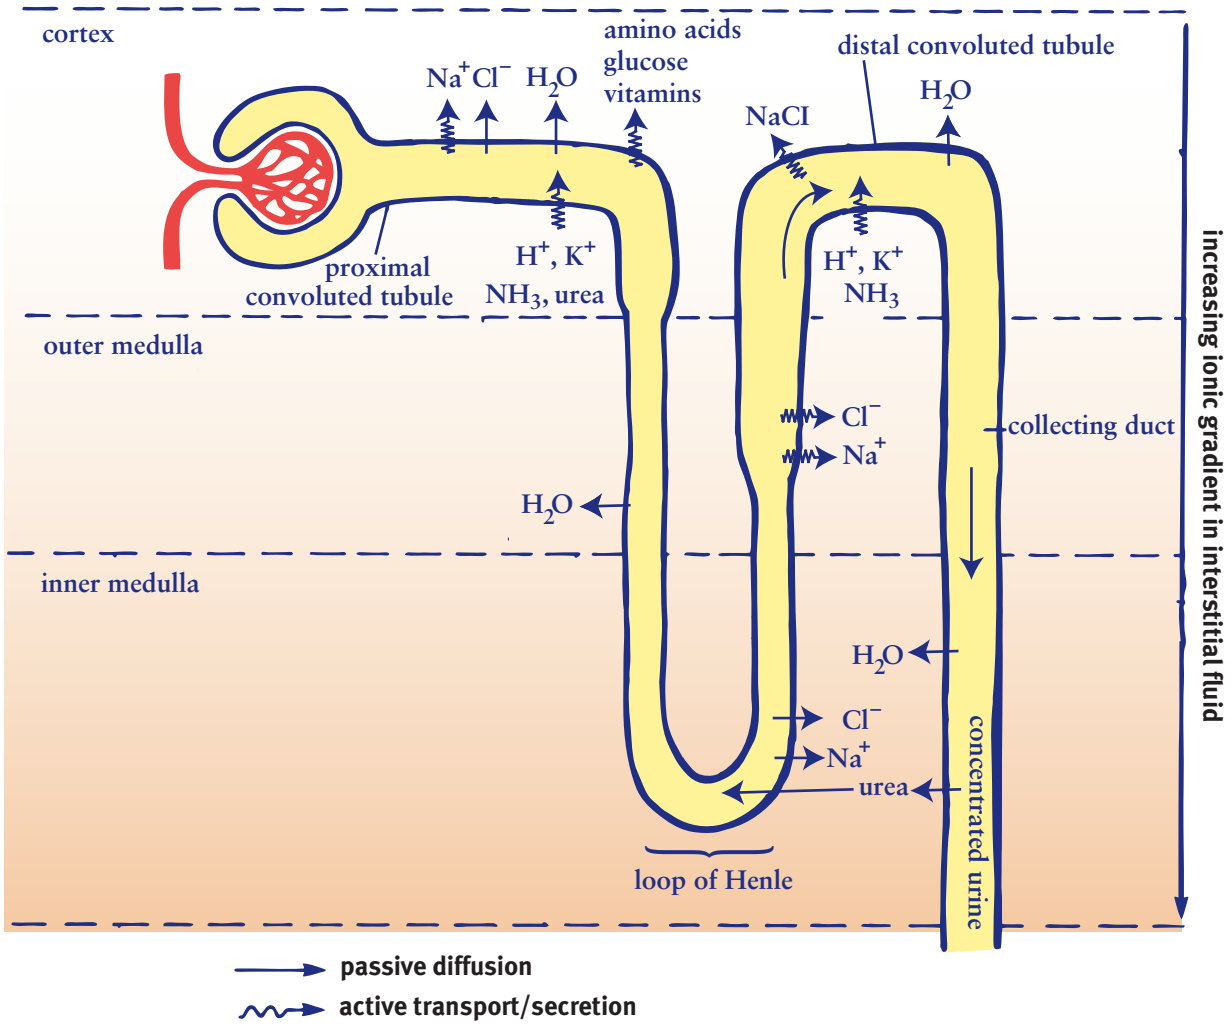

Figure 10.5. Reabsorption and Secretion in the Nephron

Mnemonic

Major waste products excreted in the urine: **Dump** the **HUNK**

- **H**$^+$
- **U**rea
- **N**H_3
- **K**$^+$

Proximal Convoluted Tubule

The filtrate first enters the **proximal convoluted tubule** (**PCT**). In this region, amino acids, glucose, water-soluble vitamins, and the majority of salts are reabsorbed along with water. Almost 70 percent of filtered sodium will be reabsorbed here, but the filtrate remains isotonic to the interstitium, as other solutes and a large volume of water are also reabsorbed. Solutes that enter the **interstitium**—the connective tissue surrounding the nephron—are picked up by the vasa recta to be returned to the bloodstream for reuse within the body. The PCT is also the site of secretion for a number of waste products, including hydrogen ions, potassium ions, ammonia, and urea.

Loop of Henle

Filtrate from the proximal convoluted tubule then enters the **descending limb of the loop of Henle**, which dives deep into the medulla before turning around

to become the **ascending limb of the loop of Henle**. The descending limb is permeable only to water, and the medulla has an ever-increasing osmolarity as the descending limb travels deeper into it. Think for a moment how this would affect the flow of water. As the descending limb traverses deeper into the medulla, the increasing interstitial concentration favors the outflow of water from the descending limb, which is reabsorbed into the vasa recta.

The kidney is capable of altering the osmolarity of the interstitium. This creates a gradient that, coupled with selective permeability of the nephron, allows maximal reabsorption and conservation of water. In the normal physiological state, the osmolarity in the cortex is approximately the same as that of the blood and remains at that level. Deeper in the medulla, the osmolarity in the interstitium can range from isotonic with blood (when trying to excrete water) to four times as concentrated (when trying to conserve water). Water will move out of the tubule, into the interstitium, and eventually back into the blood. If the concentration is the same in the tubule and in the interstitium, there is no driving force (gradient), and the water will be lost in urine.

Together, the vasa recta and nephron create a **countercurrent multiplier system**. What is meant by this is that the flow of filtrate through the loop of Henle is in the opposite direction from the flow of blood through the vasa recta. If the two flowed in the same direction, they would quickly reach equilibrium and the kidney would be unable to reabsorb as much water. By making the two flow in opposite directions, the filtrate is constantly being exposed to hypertonic blood, which allows maximal reabsorption of water.

As the descending limb transitions to become the ascending limb of the loop of Henle, a change in permeability occurs. The ascending limb is only permeable to salts and is impermeable to water. Here the opposite occurs: at the deeper parts of the medulla, salt concentrations are high, but decrease as the ascending limb rises. Thus, increasing amounts of salt are removed from the filtrate as it travels up the loop of Henle.

At the transition from the inner to outer medulla, the loop of Henle becomes thicker in what is termed the **diluting segment**. This is not because the lumen within the tube has enlarged, but because the cells lining the tube are larger. These cells contain large amounts of mitochondria, which allow the reabsorption of sodium and chloride by active transport. Indeed, because so much salt is reabsorbed while water is stuck in the nephron, the filtrate actually becomes hypotonic compared to the interstitium. While we tend to focus on the concentrating abilities of the nephron, this segment is noteworthy because it is the only portion of the nephron that can produce urine that is more dilute than the blood.

This is important during periods of *overhydration* and provides a mechanism for eliminating excess water.

At the beginning of the loop of Henle, the filtrate is isotonic to the interstitium. Thus, from the beginning of the loop of Henle to the end, there is a slight degree of dilution. Far more important, however, is the fact that the volume of the filtrate has been significantly reduced, demonstrating a net reabsorption of a large volume of water.

Distal Convoluted Tubule

Next, the filtrate enters the **distal convoluted tubule** (**DCT**). The DCT responds to aldosterone, which promotes sodium reabsorption. Because sodium ions are osmotically active particles, water will follow the sodium, concentrating the urine and decreasing its volume. The DCT is also the site of waste product secretion, like the PCT.

Collecting Duct

The final concentration of the urine will depend largely on the permeability of the collecting duct, which is responsive to both aldosterone and antidiuretic hormone (ADH or vasopressin). As permeability of the collecting duct increases, so too does water reabsorption, resulting in further concentration of the urine. The reabsorbed water enters the interstitium and makes its way to the vasa recta, where it reenters the bloodstream to once again become part of the plasma. The collecting duct almost always reabsorbs water, but the amount is variable. When the body is very well hydrated, the collecting duct will be fairly impermeable to salt and water. When in conservation mode, ADH and aldosterone will each act to increase reabsorption of water in the collecting duct, allowing for greater water retention and more concentrated urine output.

Ultimately, anything that does not leave the tubule by the end of the collecting duct will be excreted; the collecting duct is the point of no return. After that, there are no further opportunities for reabsorption. As the filtrate leaves the tubule, it collects in the renal pelvis. The fluid, which carries mostly urea, uric acid, and excess ions (sodium, potassium, magnesium, and calcium), flows through the ureter to the bladder where it is stored until voiding.

Real World

In certain conditions, such as congestive heart failure, the body accumulates excess fluid in the lungs or peripheral tissues (edema). The judicious use of a diuretic drug can help the body get rid of excess fluids. Diuretics typically inhibit the reabsorption of sodium in one or more regions of the nephron, thereby increasing sodium excretion. As an osmotically active particle, sodium will pull water with it, thereby relieving the body of some of its excess fluid.

FUNCTIONS OF THE EXCRETORY SYSTEM

The kidneys use osmolarity gradients and selective permeability to filter, secrete, and reabsorb materials in the process of making urine. However, these processes have larger implications for the human body has a whole. The selective elimination of water and solutes allows the kidneys, in conjunction with the endocrine, cardiovascular, and respiratory systems, to control blood pressure, blood osmolarity, and acid–base balance.

Blood Pressure

In Chapter 5 of *MCAT Biology Review*, we discussed two hormones that are very important for maintenance of proper blood pressure: aldosterone and antidiuretic hormone (ADH or vasopressin).

Aldosterone is a steroid hormone that is secreted by the adrenal cortex in response to decreased blood pressure. Decreased blood pressure stimulates the release of **renin** from **juxtaglomerular cells** in the kidney. Renin then cleaves **angiotensinogen**, a liver protein, to form **angiotensin I**. This peptide is then metabolized by **angiotensin-converting enzyme** in the lungs to form **angiotensin II**, which promotes the release of aldosterone from the adrenal cortex.

Aldosterone works by altering the ability of the distal convoluted tubule and collecting duct to reabsorb sodium. Remember that water does not move on its own, but rather travels down an osmolarity gradient. Thus, if we reabsorb more sodium, water will flow with it. This reabsorption of isotonic fluid has the net effect of increasing blood volume and therefore blood pressure. Aldosterone will also increase potassium and hydrogen ion excretion.

Antidiuretic hormone (**ADH**, also known as **vasopressin**) is a peptide hormone synthesized by the hypothalamus and released by the posterior pituitary in response to high blood osmolarity. It directly alters the permeability of the collecting duct, allowing more water to be reabsorbed by making the cell junctions of the duct leaky. Increased concentration in the interstitium (hypertonic to the filtrate) will then cause the reabsorption of water from the tubule. Alcohol and caffeine both inhibit ADH release and lead to the frequent excretion of dilute urine.

In addition to the kidneys, the cardiovascular system can also vasoconstrict or vasodilate in order to maintain blood pressure. Constriction of the afferent arteriole will lead to a lower pressure of blood reaching the glomeruli, which are adjacent to the juxtaglomerular cells. Therefore, this vasoconstriction will secondarily lead to renin release, which will also help raise blood pressure.

Osmoregulation

The osmolarity of the blood must be tightly controlled to ensure correct oncotic pressures within the vasculature. A note on terminology: **osmotic pressure** is the "sucking" pressure that draws water into the vasculature caused by all dissolved particles. **Oncotic pressure**, on the other hand, is the osmotic pressure that is attributable to dissolved proteins specifically. Blood osmolarity is usually maintained at approximately 290 milliosmoles (mOsm) per liter. As described earlier, the kidneys control osmolarity by modulating the reabsorption of water and by filtering and secreting dissolved particles. When blood osmolarity

Real World

Aldosterone increases blood pressure by increasing the reabsorption of sodium. In medicine, we exploit this characteristic by using drugs that actually block angiotensin-converting enzyme or the angiotensin II receptor. In Chapter 5 of *MCAT Biology Review*, we mentioned the ACE inhibitors, which mostly end with *–pril*. The angiotensin II receptor blockers mostly end with *–sartan* (*losartan*, *valsartan*, *irbesartan*) Blocking this receptor limits aldosterone release, which limits salt and water reabsorption, and therefore results in lowered blood pressure.

Key Concept

ADH only governs water reabsorption and thus results in a lower blood osmolarity. Aldosterone causes both salt and water reabsorption and does not change blood osmolarity.

is low, excess water will be excreted, while solutes will be reabsorbed in higher concentrations. In contrast, when blood osmolarity is high, water reabsorption increases and solute excretion increases.

Acid–Base Balance

The **bicarbonate buffer system** is the major regulator of blood pH. Remind yourself of the buffer equation:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

In Chapter 6 of *MCAT Biology Review*, we talked about how the respiratory system can contribute to acid–base balance by increasing or decreasing the respiratory rate. If the blood pH is too low, then increasing the respiratory rate blows off more CO_2 and favors the conversion of H^+ and HCO_3^- to water and carbon dioxide, increasing the pH. If the blood pH is too high, then decreasing the respiratory rate causes the opposite effects. The respiratory system can react to derangements of pH quickly. What can the excretory system do to contribute? The kidneys are able to selectively increase or decrease the secretion of both hydrogen ions and bicarbonate. When blood pH is too low, the kidneys excrete more hydrogen ions and increase reabsorption of bicarbonate, resulting in a higher pH. Likewise, when blood pH is too high, the kidneys can excrete more bicarbonate and increase reabsorption of hydrogen ions. This is slower than the respiratory response, but it is a highly effective way for the body to maintain acid–base balance.

MCAT Concept Check 10.1:

Before you move on, assess your understanding of the material with these questions.

1. List the structures in the excretory pathway, from where filtrate enters the nephron to the excretion of urine from the body.

_____

_____

2. List the vessels in the renal vascular pathway, starting from the renal artery and ending at the renal vein.

_____

_____

3. What arm of the nervous system is responsible for contraction of the detrusor muscle?

_____

4. What are the three processes by which solutes are exchanged between the filtrate and the blood? What happens in each process?
   - _____
   - _____
   - _____

5. For each segment of the nephron listed below, what are its major functions?
   - Bowman's capsule:

     _____
   - Proximal convoluted tubule:

     _____
   - Descending limb of the loop of Henle:

     _____
   - Ascending limb of the loop of Henle:

     _____
   - Distal convoluted tubule:

     _____
   - Collecting duct:

     _____

10.2 Skin ★★★

By both weight and size, the **skin** (**integument**) is the largest organ in our bodies. It makes up about 16 percent of total body weight, on average. Skin is one of the major components of nonspecific immune defense, protecting us from exposure to the elements and invasion by pathogens.

STRUCTURE

The skin has several layers. Starting from the deepest layer and working outward, these layers are the **hypodermis** (**subcutaneous** layer), **dermis**, and **epidermis**, as shown in Figure 10.6. Skin is derived from the ectoderm.

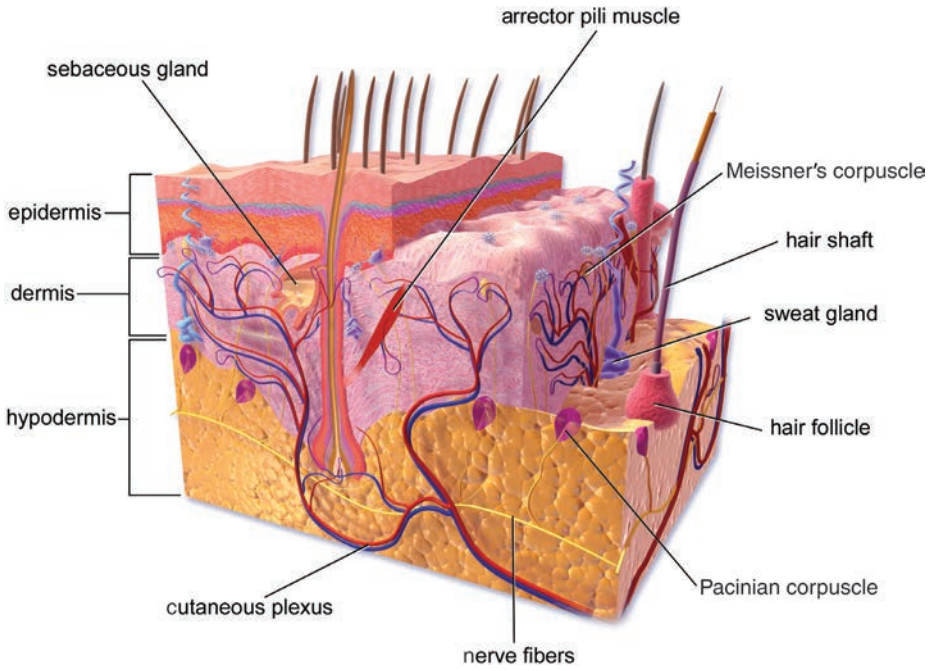

Figure 10.6. Anatomy of the Skin and Subcutaneous Tissue

The Epidermis

The **epidermis** is also subdivided into layers called **strata**. From the deepest layer outward, these are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum, as shown in Figure 10.7. The **stratum basale** contains stem cells and is responsible for proliferation of **keratinocytes**, the predominant cells of the skin that produce **keratin**. In the **stratum spinosum**, these cells become connected to each other; this layer is also the site of Langerhans cells, described below. In the **stratum granulosum**, the keratinocytes die and lose their nuclei. The **stratum lucidum** is only present in thick, hairless skin, such as the skin on the sole of the foot or the palms, and is nearly transparent. Finally, the **stratum corneum** contains up to several dozen layers of flattened keratinocytes, forming a barrier that prevents invasion by pathogens and that helps to prevent loss of fluids and salt. Hair projects above the skin, and there are openings for sweat and sebaceous glands.

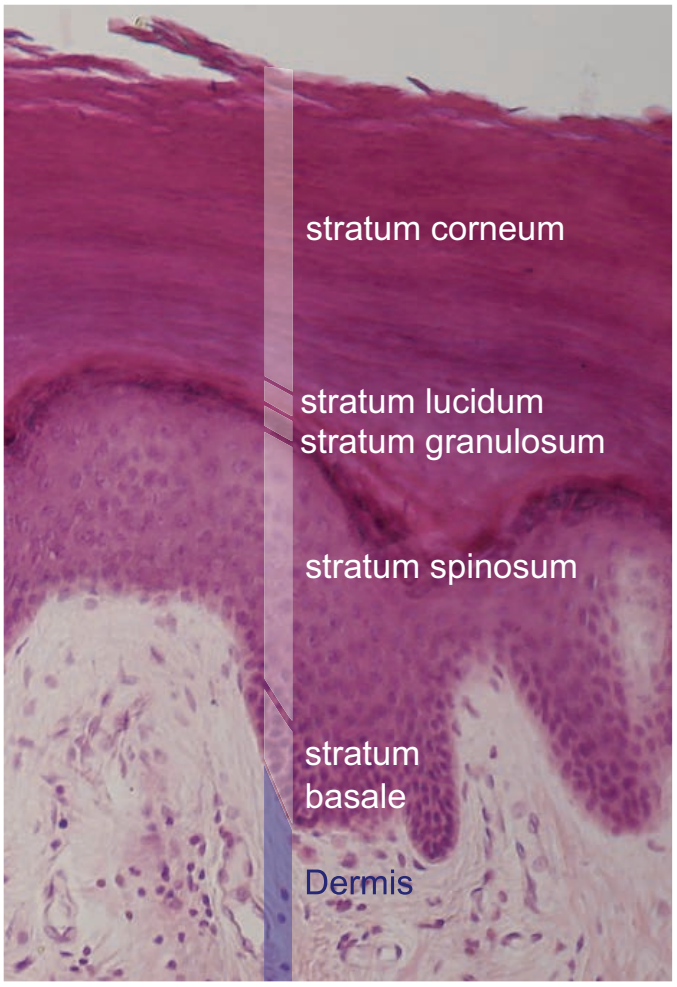

Figure 10.7. Layers of the Epidermis

Other Cells of the Epidermis

In the epidermis, the main cells are keratinocytes. Keratin, mentioned above, is resistant to damage and provides protection against injury, water, and pathogens. **Calluses** form from excessive keratin deposition in areas of repeated strain due to friction; they provide protection to avoid damage in the future. **Fingernails** and **hair** are also formed from keratin and are produced by specialized cells in the skin.

Melanocytes are a cell type derived from neural crest cells and found in the stratum basale. These cells produce **melanin**, a pigment that serves to protect the skin from DNA damage caused by ultraviolet radiation. Once produced, the pigment is passed to the keratinocytes. All humans actually have comparable numbers of melanocytes; skin color is caused by varying levels of activity of the melanocytes. More active melanocytes result in darker skin tones. Upon exposure to ultraviolet radiation, melanocytes increase activity, resulting in a darker skin color.

Mnemonic

Layers of the skin (superficial to deep):
Come, **L**et's **G**et **S**un **B**urned

- Stratum **c**orneum
- Stratum **l**ucidum
- Stratum **g**ranulosum
- Stratum **s**pinosum
- Stratum **b**asale

Real World

People who have albinism suffer from a genetic metabolic disorder characterized by the inability to synthesize melanin. Typically, albinism is inherited in an autosomal recessive fashion. As would be expected, patients with albinism are extremely sensitive to the harmful effects of the sun. Depigmentation can also occur in vitiligo, an autoimmune disorder in which melanocytes are killed by the individual's immune system.

Langerhans cells are actually special macrophages that reside within stratum spinosum. These cells are capable of presenting antigens to T-cells in order to activate the immune system.

The Dermis

The dermis also consists of multiple layers. The upper layer (right below the epidermis) is the **papillary layer**, which consists of loose connective tissue. Below the papillary layer is the denser **reticular layer**. Sweat glands, blood vessels, and hair follicles originate in the dermis.

Most sensory receptors are also located in the dermis. **Merkel cells** (**discs**), for example, are sensory receptors present at the epidermal–dermal junction. These cells are connected to sensory neurons and are responsible for deep pressure and texture sensation within the skin. Other sensory organs in the skin include free nerve endings, which respond to pain; **Meissner's corpuscles**, which respond to light touch; **Ruffini endings**, which respond to stretch; and **Pacinian corpuscles**, which respond to deep pressure and vibration.

The Hypodermis

Finally, the **hypodermis** is a layer of connective tissue that connects the skin to the rest of the body. This layer contains fat and fibrous tissue.

THERMOREGULATION

We have already mentioned that the skin protects us from the elements and microbes. It also has other functions, including ultraviolet protection (via melanin) and transduction of sensory information from the outside world. In this section, we look at another function of the skin: thermoregulation.

Thermoregulation is achieved by sweating, piloerection, vasodilation, and vasoconstriction. **Sweating** is an excellent cooling mechanism that is controlled by the autonomic nervous system. When body temperature rises above the set point determined by the hypothalamus, then thermoregulation processes must occur in order to rid the body of heat. Postganglionic sympathetic neurons that utilize acetylcholine innervate sweat glands and promote the secretion of water with certain ions onto the skin. Heat is then absorbed from the body as the molecules within the water undergo a phase change to evaporate. The production of sweat itself is not the main mechanism of cooling; it is the evaporation of water from the skin, which absorbs body heat. At the same time, arteriolar vasodilation occurs to maximize heat loss. This brings a large quantity of blood to the skin, which accelerates the evaporation of sweat by maximizing the heat energy available for the liquid–gas phase change.

In cold conditions, **arrector pili** muscles contract, causing the hairs of the skin to stand up on end (**piloerection**). This helps to trap a layer of heated air near the

Bridge

Evaporation is an endothermic process and, thus, absorbs energy from the surroundings to undergo this phase change. Further, the presence of dissolved solutes in sweat increases the boiling point of sweat slightly in comparison to pure water; this allows the absorption of even more heat energy. Boiling point elevation is a colligative property that is discussed in Chapter 9 of *MCAT General Chemistry Review*.

Bridge

The neurons that innervate sweat glands are actually very unusual. Unlike all other postganglionic sympathetic neurons, these neurons are cholinergic—not noradrenergic (that is, they release acetylcholine, not norepinephrine). All preganglionic neurons in the autonomic nervous system and postganglionic neurons in the parasympathetic nervous system are cholinergic as well. These neurons are discussed in Chapter 4 of *MCAT Biology Review*.

skin. The arterioles that feed the capillaries of the skin constrict, limiting the quantity of blood reaching the skin. Skeletal muscle may also begin to contract rapidly, causing shivering. **Shivering** requires a sizeable amount of ATP; however, a significant portion of the energy from ATP is converted into thermal energy. In addition to these mechanisms, humans possess a layer of fat just below the skin. This fat helps to insulate the body. In addition to this fat, which is called **white fat**, **brown fat** may also be present, especially in infants. Brown fat has a much less efficient electron transport chain, which means that more heat energy is released as fuel is burned.

The skin also helps to maintain the osmolarity of the body. This is because the skin is relatively impermeable to water. This prevents not only the entrance of water through the skin, but also the loss of water from the tissues. This becomes very important in cases such as burns or large losses of skin as dehydration of the tissues becomes a real threat to survival.

MCAT Concept Check 10.2:

Before you move on, assess your understanding of the material with these questions.

1. What is the predominant cell type in the epidermis?

_____

2. What are the layers of the epidermis, from superficial to deep?
   - _____
   - _____
   - _____
   - _____
   - _____

3. What are the layers of the dermis, from superficial to deep?
   - _____
   - _____

4. What are some mechanisms the body uses to cool itself? What are some mechanisms the body uses to retain heat?
   - Cooling:

     _____
   - Retaining heat:

     _____

Conclusion

Two main organ systems were discussed in this chapter: the excretory system and the skin. Both of these systems play an essential role in homeostasis. However, this chapter also covered a very MCAT-worthy concept: no system works alone. Multiple systems participate in homeostasis. While the kidneys are the major players in salt, water, and acid–base balance, their function depends on the endocrine system, circulatory system, and respiratory system. While the skin is an important immune organ, its function as a thermoregulatory organ is dependent on the nervous system; it also sends sensory signals to the nervous system. As you move onto the last organ system in the next chapter—the musculoskeletal system—notice how each system interacts with other systems in order to produce a fully functioning organism. The MCAT is far more focused on how you conceptualize the big picture, and not on how many trivial details you memorize. As you study, focus on understanding these systems and how each system influences the rest of the body.

CONCEPT SUMMARY

The Excretory System

- The **excretory system** serves many functions, including the regulation of blood pressure, blood osmolarity, acid–base balance, and removal of nitrogenous wastes.
- The **kidney** produces urine, which dumps into the **ureter** at the **renal pelvis**. Urine is then collected in the **bladder** until it is excreted through the **urethra**.
- The kidney contains a cortex and a medulla. Each kidney has a **hilum**, which contains a renal artery, renal vein, and ureter.
- The kidney contains a **portal system** with two capillary beds in series.
  - Blood from the renal artery flows into **afferent arterioles**, which form **glomeruli** in Bowman's capsule (the first capillary bed).
  - Blood then flows through the **efferent arteriole** to the **vasa recta**, which surround the nephron (the second capillary bed), before leaving the kidney through the renal vein.
- The bladder has a muscular lining known as the **detrusor muscle**, which is under parasympathetic control. It also has two muscular sphincters.
  - The **internal urethral sphincter** consists of smooth muscle and is under involuntary (parasympathetic) control.
  - The **external urethral sphincter** consists of skeletal muscle and is under voluntary control.
- The kidney participates in solute movement through three processes:
  - **Filtration** is the movement of solutes from blood to filtrate at Bowman's capsule. The direction and rate of filtration is determined by **Starling forces**, which account for the hydrostatic and oncotic pressure differentials between the glomerulus and Bowman's space.
  - **Secretion** is the movement of solutes from blood to filtrate anywhere other than Bowman's capsule.
  - **Reabsorption** is the movement of solutes from filtrate to blood.
- Each segment of the nephron has a specific function.
  - The **proximal convoluted tubule** (**PCT**) is the site of bulk reabsorption of glucose, amino acids, soluble vitamins, salt, and water. It is also the site of secretion for hydrogen ions, potassium ions, ammonia, and urea.
  - The **descending limb of the loop of Henle** is permeable to water but not salt; therefore, as the filtrate moves into the more osmotically concentrated renal medulla, water is reabsorbed from the filtrate. The vasa recta and nephron flow in opposite directions, creating a **countercurrent multiplier system** that allows maximal reabsorption of water.

- The **ascending limb of the loop of Henle** is permeable to salt but not water; therefore, salt is reabsorbed both passively and actively. The **diluting segment** is in the outer medulla; because salt is actively reabsorbed in this site, the filtrate actually becomes hypotonic compared to the blood.
- The **distal convoluted tubule** (**DCT**) is responsive to aldosterone and is a site of salt reabsorption and waste product excretion, like the PCT.
- The **collecting duct** is responsive to both aldosterone and antidiuretic hormone and has variable permeability, which allows reabsorption of the right amount of water depending on the body's needs.

- The kidney is under hormonal control. When blood pressure (and volume) are low, two different hormonal systems are activated.
  - **Aldosterone** is a steroid hormone regulated by the renin–angiotensin–aldosterone system that increases sodium reabsorption in the distal convoluted tubule and collecting duct, thereby increasing water reabsorption. This results in an increased blood volume (and pressure), but no change in blood osmolarity.
  - **Antidiuretic hormone** (**ADH** or **vasopressin**) is a peptide hormone synthesized by the hypothalamus and released by the posterior pituitary. Its release is stimulated not only by low blood volume but also by high blood osmolarity. It increases the permeability of the collecting duct to water, increasing water reabsorption. This results in an increased blood volume (and pressure) and a decreased blood osmolarity.
- The kidney can regulate pH by selective reabsorption or secretion of bicarbonate or hydrogen ions.

Skin

- The skin acts as a barrier, protecting us from the elements and invasion by pathogens.
- The skin is composed of three major layers: the **hypodermis** (**subcutaneous** layer), **dermis**, and **epidermis**.
  - The epidermis is composed of five layers: the **stratum basale**, **stratum spinosum**, **stratum granulosum**, **stratum lucidum**, and **stratum corneum**. The stratum basale contains stem cells that proliferate to form keratinocytes. Keratinocyte nuclei are lost in the stratum granulosum, and many thin layers form in the stratum corneum.
  - **Melanocytes** produce **melanin**, which protects the skin from DNA damage caused by ultraviolet radiation; melanin is passed to keratinocytes.
  - **Langerhans cells** are special macrophages that serve as antigen-presenting cells in the skin.

- The dermis is composed of two layers: the **papillary layer** and the **reticular layer**.
- Many sensory cells are located in the dermis, including **Merkel cells** (deep pressure and texture), free nerve endings (pain), **Meissner's corpuscles** (light touch), **Ruffini endings** (stretch), and **Pacinian corpuscles** (deep pressure and vibration).
- The hypodermis contains fat and connective tissue and connects the skin to the rest of the body.

- The skin is important for thermoregulation, or the maintenance of a constant internal temperature.
  - Cooling mechanisms include **sweating**, which absorbs heat from the body through evaporation of water from sweat, and vasodilation. Sweat glands are innervated by postganglionic cholinergic sympathetic neurons.
  - Warming mechanisms include piloerection, in which arrector pili muscles contract, causing hairs to stand on end (trapping a layer of warmed air around the skin), vasoconstriction, shivering, and insulation provided by fat.
- The skin also prevents dehydration and salt loss from the body.

ANSWERS TO CONCEPT CHECKS

10.1

1. Bowman's space → proximal convoluted tubule → descending limb of the loop of Henle → ascending limb of the loop of Henle → distal convoluted tubule → collecting duct → renal pelvis → ureter → bladder → urethra
2. Renal artery → afferent arteriole → glomerulus → efferent arteriole → vasa recta → renal vein
3. The parasympathetic nervous system causes contraction of the detrusor muscle.
4. Filtration is the movement of solutes from blood into filtrate at Bowman's capsule. Secretion is the movement of solutes from blood into filtrate anywhere besides Bowman's capsule. Reabsorption is the movement of solutes from filtrate into blood.
5. Bowman's capsule is the site of filtration, through which water, ions, amino acids, vitamins, and glucose pass (essentially everything besides cells and proteins). The proximal convoluted tubule controls solute identity, reabsorbing vitamins, amino acids, and glucose, while secreting potassium and hydrogen ions, ammonia, and urea. The descending limb of the loop of Henle is important for water reabsorption using the medullary concentration gradient. The ascending limb of the loop of Henle is important for salt reabsorption and allowing dilution of the urine in the diluting segment. The distal convoluted tubule is also important for solute identity by reabsorbing salts while secreting potassium and hydrogen ions, ammonia, and urea. The collecting duct is important for urine concentration; its variable permeability allows water to be reabsorbed based on the needs of the body.

10.2

1. Keratinocytes are the primary cells of the epidermis.
2. Stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, stratum basale
3. The papillary layer and the reticular layer
4. The body can cool itself through sweating and vasodilation. The body can warm itself through vasoconstriction, piloerection, and shivering.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following would most likely be filtered through the glomerulus into Bowman's space?

A. Erythrocytes
B. Monosaccharides
C. Platelets
D. Proteins

2. In which of the following segments of the nephron is sodium NOT actively transported out of the nephron?

A. Proximal convoluted tubule
B. Thin portion of the ascending limb of the loop of Henle
C. Distal convoluted tubule
D. Thick portion of the ascending limb of the loop of Henle

3. Which region of the kidney has the lowest solute concentration under normal physiological circumstances?

A. Cortex
B. Outer medulla
C. Inner medulla
D. Renal pelvis

4. Which of the following sequences correctly shows the passage of blood through the vessels of the kidney?

A. Renal artery → afferent arterioles → glomerulus → efferent arterioles → vasa recta → renal vein
B. Afferent arterioles → renal artery → glomerulus → vasa recta → renal vein → efferent arterioles
C. Glomerulus → renal artery → afferent arterioles → efferent arterioles → renal vein → vasa recta
D. Renal vein → efferent arterioles → glomerulus → afferent arterioles → vasa recta → renal artery

5. Which of the following statements is FALSE?

A. ADH increases water reabsorption in the kidney.
B. Aldosterone indirectly increases water reabsorption in the kidney.
C. ADH acts directly on the proximal convoluted tubule.
D. Aldosterone stimulates reabsorption of sodium from the collecting duct.

6. In the nephron, amino acids enter the vasa recta via the process of:

A. filtration.
B. secretion.
C. excretion.
D. reabsorption.

7. On a very cold day, a man waits for over an hour at the bus stop. Which of the following structures helps his body set and maintain a normal temperature?

A. Hypothalamus
B. Kidneys
C. Posterior pituitary
D. Brainstem

8. Glucose reabsorption in the nephron occurs in the:

A. loop of Henle.
B. distal convoluted tubule.
C. proximal convoluted tubule.
D. collecting duct.

9. Under normal physiological circumstances, the primary function of the nephron is to create urine that is:

A. hypertonic to the blood.
B. hypotonic to the blood.
C. isotonic to the filtrate.
D. hypotonic to the vasa recta.

10. Diabetic nephropathy is commonly detected by finding protein in the urine of a patient. In such a disease, where is the likely defect in the nephron?

A. Glomerulus
B. Proximal convoluted tubule
C. Loop of Henle
D. Collecting duct

11. A laceration cuts down into a layer of loose connective tissue in the skin. Which layer of the skin is this?

A. Stratum corneum
B. Stratum lucidum
C. Papillary layer
D. Reticular layer

12. When the pH of the blood is high, which substance is likely to be excreted in larger quantities in the urine?

A. Urea
B. Ammonia
C. Hydrogen ions
D. Bicarbonate ions

13. In which layer of the skin can the stem cells of keratinocytes be found?

A. Stratum lucidum
B. Stratum granulosum
C. Stratum basale
D. Stratum corneum

14. A drug is used that prevents the conversion of angiotensin I to angiotensin II. What is a likely effect of this drug?

A. Increased sodium reabsorption
B. Increased potassium reabsorption
C. Increased blood pressure
D. Increased blood pH

15. Sarin is a potent organophosphate that can be used in chemical warfare. As an inhibitor of acetylcholinesterase, sarin causes excessive buildup of acetylcholine in all synapses where it is the neurotransmitter. Which of the following symptoms would be most likely to be seen in an individual with sarin poisoning?

A. Increased urination and increased sweating
B. Increased urination and decreased sweating
C. Decreased urination and increased sweating
D. Decreased urination and decreased sweating

Explanations to Discrete Practice Questions

1. B

The glomerulus functions like a sieve; small molecules dissolved in the fluid will pass through the glomerulus, including glucose, which is later reabsorbed. Large molecules, such as proteins, and cells, such as erythrocytes and platelets, will not be able to pass through the glomerular filter.

2. B

Sodium is actively transported out of the nephron in the proximal and distal convoluted tubules, where the concentration of sodium outside of the nephron is higher than inside; thus, energy is required to transport the sodium molecules against their concentration gradient, eliminating **choices (A)** and **(C)**. In the inner medulla, however, sodium and other ions (such as chloride) diffuse passively down their concentration gradients from the thin ascending limb of the loop of Henle, making **choice (B)** the correct answer. The thick ascending limb of the loop of Henle *is* thick because its cells contain many mitochondria—which produce the ATP needed for active transport of sodium and chloride out of the filtrate, eliminating **choice (D)**.

3. A

The region of the kidney that has the lowest solute concentration is the cortex, where the proximal convoluted tubule and a part of the distal convoluted tubule are found. The solute concentration increases as one descends into the medulla, and concentrated urine can be found in the renal pelvis.

4. A

Blood enters the kidney through the renal artery, which divides into many afferent arterioles that run through the medulla and into the cortex. Each afferent arteriole branches into a convoluted network of capillaries called a glomerulus. Rather than converging directly into a vein, the capillaries converge into an efferent arteriole, which divides into a fine capillary network known as the vasa recta. The vasa recta capillaries enmesh the nephron tubule, where they reabsorb various ions, and then converge into the renal vein. This arrangement of tandem capillary beds is known as a portal system.

5. C

All of the answer choices describe ADH or aldosterone. These two hormones ultimately act to increase water reabsorption in the kidney; their respective mechanisms of action, however, are different. ADH increases water reabsorption by increasing the permeability of the collecting duct to water, whereas aldosterone stimulates reabsorption of sodium from the distal convoluted tubule and collecting duct. Using this knowledge, we can now attack the answer choices. **Choice (C)** is the correct answer because ADH does not act on the proximal convoluted tubule, but rather the collecting duct.

6. D

Essential substances, such as glucose, salts, amino acids, and water, are reabsorbed from the filtrate and returned to the blood in the vasa recta. In general, reabsorption refers to the movement of solutes from the filtrate back into the blood.

7. A

The hypothalamus functions as a thermostat that regulates body temperature. When it's cold outside, nervous stimulation

to the blood vessels in the skin is increased, causing the vessels to constrict. This constriction diminishes blood flow to the skin surface and prevents heat loss. Sweat glands are turned off to prevent heat loss through evaporation. Skeletal muscles are stimulated to shiver (rapidly contract), which increases the metabolic rate and produces heat. The hypothalamus is also involved in other processes, including the release of endocrine hormones, regulation of appetite, and circadian rhythms.

8. C

The filtrate enters Bowman's capsule and then flows into the proximal convoluted tubule, where virtually all glucose, amino acids, and other important organic molecules are reabsorbed via active transport.

9. A

The kidneys function to eliminate wastes such as urea, while reabsorbing various important substances such as glucose and amino acids for reuse by the body. Generation of a solute concentration gradient from the cortex to the medulla allows a considerable amount of water to be reabsorbed. Excretion of concentrated urine serves to limit water losses from the body and helps to preserve blood volume. Thus, the primary function of the nephron is to create urine that is hypertonic to the blood, making **choice (A)** the correct answer and eliminating **choices (B)** and **(D)**. Water should be reabsorbed from the filtrate, so urine should be hypertonic to the filtrate, eliminating **choice (C)**.

10. A

The glomerulus is the most likely location of pathology if large proteins are detected in the urine. This is because large proteins should not be able to pass through the filter of the glomerulus in the first place. Once large proteins are in the filtrate, no other nephron structure can reabsorb them. Thus, the only likely source of protein in the urine is glomerular pathology.

11. C

The layer of the skin that is predominantly loose connective tissue is the papillary layer of the dermis. The stratum corneum and stratum lucidum, **choices (A)** and **(B)**, contain dead keratinocytes, while the reticular layer, **choice (D)**, consists of dense connective tissue.

12. D

When the pH of the blood is high, this indicates that the blood is alkalemic. In order to correct the pH of the blood, the kidney will increase the excretion of a base, namely bicarbonate. Excretion of urea would have little effect on the pH, eliminating **choice (A)**. While ammonia is a base, it is quite toxic and is generally converted to urea before excretion, eliminating **choice (B)**. Excretion of hydrogen ions would result in exacerbation of the alkalemia, eliminating **choice (C)**.

13. C

The stratum basale contains the stem cells that proliferate to form keratinocytes, which then ascend through the other layers of skin until they are shed from the stratum corneum.

14. B

Normally, angiotensin II causes secretion of aldosterone from the adrenal cortex. Aldosterone serves to increase reabsorption of sodium, while promoting excretion of potassium and hydrogen ions. Thus, blocking the release of aldosterone should result in decreased reabsorption of sodium, while decreasing excretion of potassium and hydrogen ions. This eliminates **choices (A)** and **(D)** and makes **choice (B)** the correct answer. In the absence of aldosterone, less water reabsorption will occur, eliminating **choice (C)**.

15. A

An excess of acetylcholine will lead to activation of all parasympathetic neurons, preganglionic sympathetic neurons, and the postganglionic sympathetic neurons that innervate sweat glands. Because the parasympathetic nervous system causes contractions of the bladder, one would expect increased urination. The increased activation of sweat glands would lead to increased sweating as well.

Concept Summary 390

Introduction

Populations affected by large disasters or traumatic events like wars or earthquakes are often fertile ground for unique medical discoveries. During World War II, Nazi Germany bombed London for 57 consecutive days during the beginning of what came to be known as the *Blitzkrieg*, or eight-month Lightning War. Victims of the Blitz, as it is known in London, included those afflicted with a specific set of symptoms: pain and swelling with accompanying effects of depleted blood volume (shock, weakness, low blood pressure, and decreased urine output). Less obvious was acute kidney failure, which could lead quickly to death if left untreated.

What caused the Blitz victims to suffer from these symptoms? Extreme physical trauma to muscles—namely, compression—destroys skeletal muscle tissue. This condition is called *rhabdomyolysis* (*rhabdo–* refers to striation, *myo–* to muscle, and *–lysis* to breakdown).

The products of skeletal muscle destruction, some of which are toxic, circulate in the blood until they are filtered out. *Creatine kinase* is one of these products; in fact, rhabdomyolysis is diagnosed with a creatine kinase level five times the normal upper limit. Myoglobin is another. Much like hemoglobin, myoglobin uses heme to carry oxygen. It is not, however, housed within a red blood cell. Thus, an erythrocyte-free urine sample that tests positive for heme points compellingly toward rhabdomyolysis. Myoglobin oxygen reserves are just one of the specialized features of muscles, as we will see in this chapter.

Skeletal muscles are only able to exert an effect on the body by moving bony structures around joints. Bones are more than simply a support structure, however; they also provide protection to internal organs, serve as a storage reserve of calcium and other minerals, and are the site of hematopoiesis. Further, skeletal muscle isn't the only form of muscle in the body; smooth muscle plays roles in the cardiovascular,

respiratory, reproductive, and digestive systems, and cardiac muscle comprises the contractile tissue of the heart. In this chapter, we'll explore the biology of all of these tissues, completing our tour of systems anatomy and physiology!

11.1 The Muscular System ★★★

The muscular system is composed of not only skeletal muscle, but also smooth muscle and cardiac muscle. Skeletal muscle is essential for supporting the body and allowing for movement. The contraction of skeletal muscle also compresses venous structures and helps propel blood through the low-pressure venous system toward the heart, as well as lymph through the lymphatic system. Rapid muscle contraction also leads to shivering, which is important in thermoregulation. Smooth muscle is responsible for involuntary movement, such as the rhythmic contractions of smooth muscle in the digestive system called peristalsis. Smooth muscle also aids in the regulation of blood pressure by constricting and relaxing the vasculature. Cardiac muscle is a special type of muscle that is able to maintain rhythmic contraction of the heart without nervous system input. In this section, we will discuss each type of muscle as well as the physiology of muscles.

TYPES OF MUSCLE

Muscle can be divided into the three different subtypes: skeletal muscle, smooth muscle, and cardiac muscle. Each muscle type performs specific functions, although they share some similarities. All muscle is capable of contraction, which relies on calcium ions. All muscle is innervated, although—as we will see—the part of the nervous system that innervates the muscle and the ability of the muscle to contract without nervous input varies from type to type.

Skeletal Muscle

Skeletal muscle is responsible for voluntary movement and is therefore innervated by the somatic nervous system. Due to the arrangement of actin and myosin into repeating units called **sarcomeres**, it appears striped or **striated** when viewed microscopically. Skeletal muscle is multinucleated because it is formed as individual muscle cells fuse in long rods during development.

There are multiple different types of fibers within skeletal muscle. **Red fibers**, also known as **slow-twitch fibers**, have high myoglobin content and primarily derive their energy aerobically. **Myoglobin** is an oxygen carrier that uses iron in a heme group to bind oxygen, imparting a red color. Red fibers also contain many mitochondria to carry out oxidative phosphorylation. **White fibers**, also known as **fast-twitch fibers**, contain much less myoglobin. Because there is less

myoglobin, and therefore less iron, the color is lighter. These two types of fibers can be mixed in muscles. Muscles that contract slowly, but that can sustain activity (such as the muscles that support posture), contain a predominance of red fibers. Muscles that contract rapidly, but fatigue quickly, contain mostly white fibers.

Smooth Muscle

Smooth muscle is responsible for involuntary action. Thus, smooth muscle is controlled by the autonomic nervous system. It is found in the respiratory tree, digestive tract, bladder, uterus, blood vessel walls, and many other locations. Smooth muscle cells have a single nucleus located in the center of the cell. Just like skeletal muscle, smooth muscle cells contain actin and myosin, but the fibers are not as well-organized, so striations cannot be seen. Compared to skeletal muscle, smooth muscle is capable of more sustained contractions; a constant state of low-level contraction, as may be seen in the blood vessels, is called **tonus**. Smooth muscle can actually contract without nervous system input in what is known as **myogenic activity**. In this case, the muscle cells contract directly in response to stretch or other stimuli.

Cardiac Muscle

Cardiac muscle has characteristics of both smooth and skeletal muscle types. Cardiac muscle is primarily uninucleated, but cells may contain two nuclei. Like smooth muscle, cardiac muscle is involuntary and innervated by the autonomic nervous system. However, like skeletal muscle, cardiac muscle appears striated.

One of the unique characteristics of cardiac muscle is how each cardiac myocyte communicates. Cardiac muscle cells are connected by **intercalated discs**, which contain many **gap junctions**. These gap junctions are connections between the cytoplasm of adjacent cells, allowing for the flow of ions directly between cells. This allows for rapid and coordinated muscle cell depolarization and efficient contraction of cardiac muscle.

Cardiac muscle cells are able to define and maintain their own rhythm through myogenic activity. Starting at the **sinoatrial** (**SA**) **node**, depolarization spreads using conduction pathways to the **atrioventricular** (**AV**) **node**. From there, the depolarization spreads to the **bundle of His** and its branches, and then to the **Purkinje fibers**. The gap junctions allow for progressive depolarization to spread via ion flow across the gap junctions between cells. The nervous and endocrine systems also play a role in the regulation of cardiac muscle contraction. The vagus nerve provides parasympathetic outflow to the heart and slows the heart rate. Norepinephrine from sympathetic neurons or epinephrine from the adrenal medulla binds to adrenergic receptors in the heart, causing an increased heart rate

Real World

Poultry provides a great example of the difference between red and white fibers. Most muscles of support, such as the thigh, are considered dark meat and contain a high concentration of red fibers. Active muscles, like the pectoral muscles (breast meat), are considered white meat and have a high concentration of white fibers.

MCAT Expertise

The MCAT loves to test the fact that both smooth and cardiac muscle exhibit myogenic activity. These muscle cells will respond to nervous input, but do not require external signals to undergo contraction.

and greater contractility. One of the ways epinephrine does this is by increasing intracellular calcium levels within cardiac myocytes. Ultimately, cardiac contraction—like that of all types of muscle—relies on calcium.

The main characteristics of each muscle type are summarized in Table 11.1.

Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Striated	Striated	Nonstriated
Voluntary	Involuntary	Involuntary
Somatic innervation	Autonomic innervation	Autonomic innervation
Many nuclei per cell	1–2 nuclei per cell	1 nucleus per cell
Ca^{2+} required for contraction	Ca^{2+} required for contraction	Ca^{2+} required for contraction

Table 11.1. Types of Muscle

MICROSCOPIC STRUCTURE OF SKELETAL MUSCLE

Each type of muscle has a specific microscopic structure. However, the MCAT tends to focus on the contractile elements and microscopic structure of skeletal muscle. In order to accurately answer those questions on Test Day, let's take a moment to discuss skeletal muscle in detail.

The Sarcomere

The **sarcomere** is the basic contractile unit of skeletal muscle. Sarcomeres are made of **thick** and **thin filaments**. The thick filaments are organized bundles of **myosin**, whereas the thin filaments are made of **actin** along with two other proteins: **troponin** and **tropomyosin**. These proteins help to regulate the interaction between the actin and myosin filaments. Another protein, **titin**, acts as a spring and anchors the actin and myosin filaments together, preventing excessive stretching of the muscle.

Mnemonic

To remember which filament is associated with **t**roponin and **t**ropomyosin, remember that ac**t**in has a **T** in it.

Each sarcomere is divided into different lines, zones, and bands, as shown in Figure 11.1. **Z-lines** define the boundaries of each sarcomere. The **M-line** runs down the center of the sarcomere, through the middle of the myosin filaments. The **I-band** is the region containing exclusively thin filaments, whereas the **H-zone** contains only thick filaments. The **A-band** contains the thick filaments in their entirety, including any overlap with thin filaments. During contraction, the H-zone, I-band, the distance between Z-lines, and the distance between M-lines all become smaller, whereas the A-band's size remains constant.

Mnemonic

To remember which is the thin and thick filament, remember **acthin**: **actin** filaments are **thin** (while myosin filaments are thick).

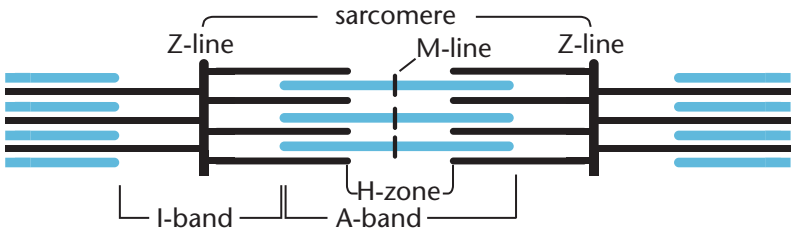

Figure 11.1. The Sarcomere
Sarcomeres are the functional units of striated muscle.

Gross Structure of Myocytes

Sarcomeres are attached end-to-end to form **myofibrils**. Myofibrils are surrounded by a covering known as the **sarcoplasmic reticulum** (**SR**), a modified endoplasmic reticulum that contains a high concentration of Ca^{2+} ions. The **sarcoplasm** is a modified cytoplasm located just outside the sarcoplasmic reticulum. The cell membrane of a myocyte is known as the **sarcolemma**. The sarcolemma is capable of propagating an action potential and can distribute the action potential to all sarcomeres in a muscle using a system of **transverse tubules** (**T-tubules**) that are oriented perpendicularly to the myofibrils, as shown in Figure 11.2. Each **myocyte**, or muscle cell, contains many myofibrils arranged in parallel and can also be called a **muscle fiber**. The nuclei, of which there are many, are usually found at the periphery of the cell. Finally, many myocytes in parallel form a muscle.

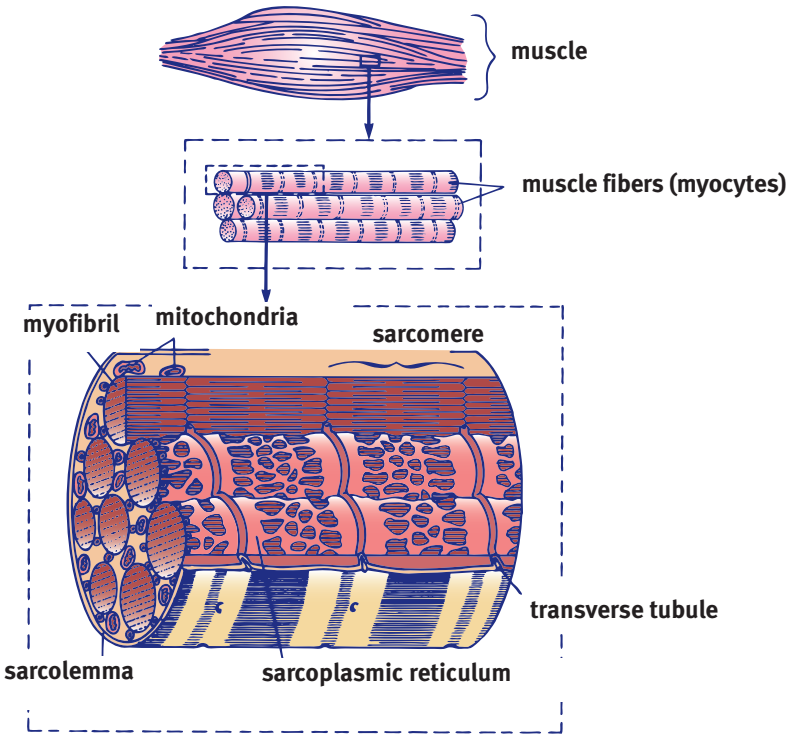

Figure 11.2. Architecture of Skeletal Muscle
A muscle is composed of parallel myocytes (muscle fibers), which are composed of parallel myofibrils.

Mnemonic

Parts of the sarcomere:

- **Z**—**Z** is the end of the alphabet, and the end of the sarcomere
- **M**—**M**iddle of the **m**yosin filaments
- **I**—**I** is a **thin** letter (**thin** filaments only)
- **H**—**H** is a **thick** letter (**thick** filaments only)
- **A**—**A**ll of the thick filament, whether or not it is overlapping

Key Concept

The sarcoplasmic reticulum is just a fancy name for the specialized endoplasmic reticulum in muscle cells.

Key Concept

A myofibril is an arrangement of many sarcomeres in series. A muscle fiber (or myocyte, or muscle cell) contains many myofibrils within it, arranged in parallel. A muscle is made up of parallel muscle fibers. These names are very similar; pay careful attention to terminology when reading about muscle structure!

MUSCLE CONTRACTION

Contraction of muscle requires a series of coordinated steps that are repeated to induce further shortening. This process depends on both ATP and calcium.

Initiation

Contraction starts at the **neuromuscular junction**, where the nervous system communicates with muscles via **motor** (**efferent**) **neurons**. This signal travels down the neuron until it reaches the **nerve terminal** (**synaptic bouton**), where acetylcholine is released into the synapse. In the case of the neuromuscular junction, the nerve terminal can also be called the **motor end plate**. Acetylcholine binds to receptors on the sarcolemma, causing depolarization. Each nerve terminal controls a group of myocytes; together, the nerve terminal and its myocytes constitute a **motor unit**.

Depolarization triggers an action potential, which spreads down the sarcolemma to the T-tubules. The T-tubules travel into the muscle tissues to the sarcoplasmic reticulum. When the action potential reaches the sarcoplasmic reticulum, Ca^{2+} is ultimately released. The calcium ions bind to a regulatory subunit in troponin, triggering a change in the confirmation of tropomyosin, to which troponin is bound. This change exposes the **myosin-binding sites** on the actin thin filament, as shown in Figure 11.3.

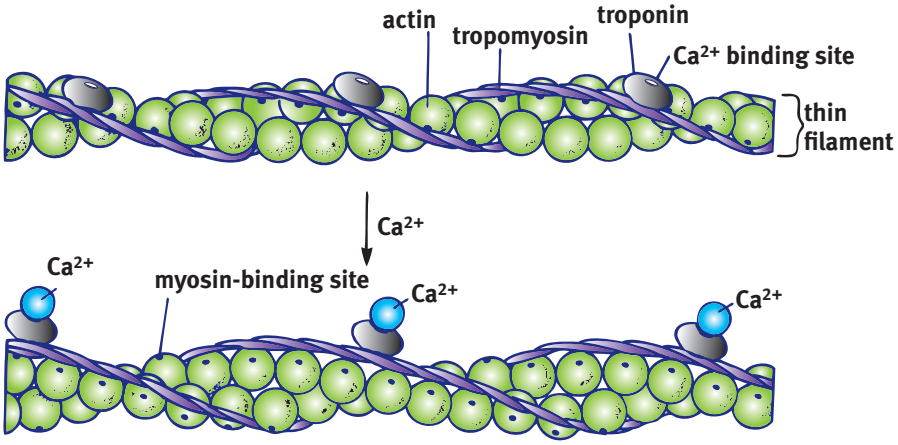

Figure 11.3. Regulation of Contraction with Calcium
Calcium binds to troponin, leading to a conformational change in tropomyosin, which exposes the myosin-binding sites of actin.

Shortening of the Sarcomere

The free globular heads of the myosin molecules move toward and bind with the exposed sites on actin. The newly formed actin–myosin cross bridges then allow myosin to pull on actin, which draws the thin filaments toward the M-line, resulting in shortening of the sarcomere. The actin–myosin cross-bridge cycle is illustrated in Figure 11.4.

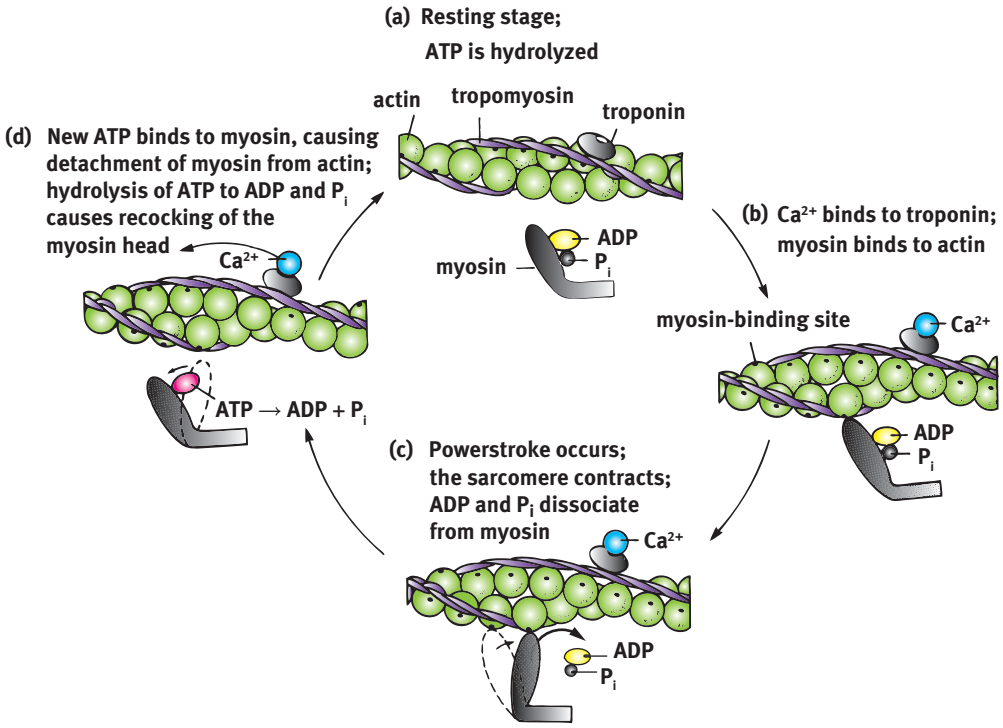

Figure 11.4. The Actin–Myosin Cross-Bridge Cycle
Calcium and ATP are essential for muscle contraction and relaxation.

Starting at the top of the diagram, myosin carrying hydrolyzed ATP (ADP and an inorganic phosphate, P_i) is able to bind with the myosin-binding site. The release of the inorganic phosphate and ADP in rapid succession provides the energy for the powerstroke and results in sliding of the actin filament over the myosin filament. Then, ATP binds to the myosin head, releasing it from actin. This ATP is hydrolyzed to ADP and P_i, which **recocks** the myosin head so that it is in position to initiate another cross-bridge cycle. The repetitive binding and releasing of myosin heads on actin filaments allows for the thin filament to slide along the thick filament, causing sequential shortening of the sarcomere. This is known as the **sliding filament model**, as shown in Figure 11.5.

Key Concept

The binding of ATP is required for releasing the myosin head from the actin filament. It is the dissociation of ADP and P_i from myosin that is responsible for the powerstroke, not the hydrolysis of ATP.

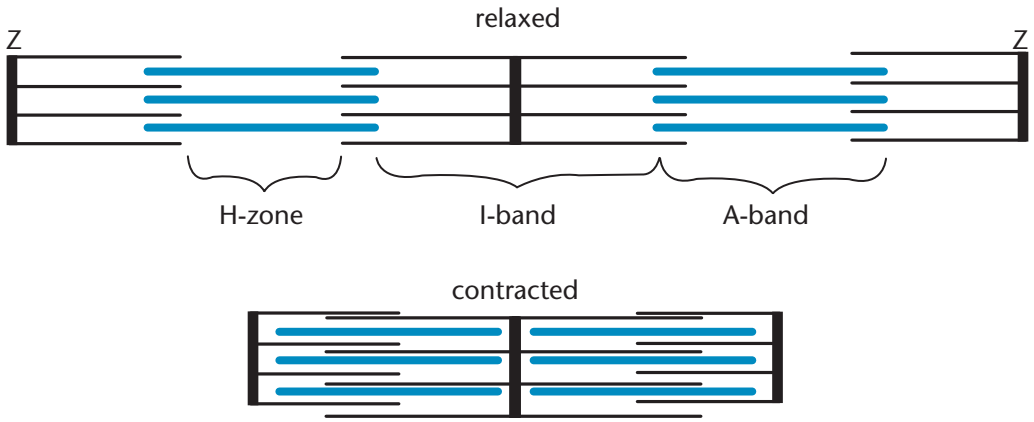

Figure 11.5. Sarcomere Contraction
When a sarcomere contracts, both the H-zone and I-band shorten while the A-band is unchanged.

Relaxation

Acetylcholine is degraded in the synapse by the enzyme known as ***acetylcholinesterase***. This results in termination of the signal at the neuromuscular junction and allows the sarcolemma to repolarize. As the signal decays, calcium release ceases, and the SR takes up calcium from the sarcoplasm. The SR tightly controls intracellular calcium concentrations so that muscles are contracted only when necessary. ATP binds to the myosin heads, freeing them from actin. Once the myosin and actin disconnect, the sarcomere can return to its original width. Without calcium, the myosin-binding sites will be covered by tropomyosin and contraction will be prevented.

Real World

After death, ATP production ceases. Myosin heads cannot detach from actin, making it impossible for muscles to relax and lengthen. This condition is known as rigor mortis.

STIMULATION, SUMMATION, AND MUSCLE FATIGUE

Muscle cells, like neurons, exhibit an all-or-nothing response; either they respond completely to a stimulus or not at all. For muscle cells to respond, stimuli must reach a threshold value. The strength of a response from one muscle cell cannot be changed because the only options are all or nothing. Rather, nerves control overall force by the number of motor units they recruit to respond. Maximal response occurs when all fibers within a muscle are stimulated to contract simultaneously.

Bridge

Why do muscle fibers contract in an all-or-nothing fashion? Because they are innervated by neurons that deliver signals using action potentials, which are all-or-nothing phenomena as well. Action potentials are discussed in Chapter 4 of *MCAT Biology Review*.

Simple Twitch

A simple twitch is the response of a single muscle fiber to a brief stimulus at or above threshold, as shown in Figure 11.6a. It consists of a latent period, contraction period, and relaxation period. The **latent period** is the time between reaching threshold and the onset of contraction. It is during this time that the action potential spreads along the muscle and allows for calcium to be released from the sarcoplasmic reticulum. The muscle then contracts, and, assuming calcium is cleared from the sarcoplasm, it then relaxes.

Summation and Tetanus

If a muscle fiber is exposed to frequent and prolonged stimulation, it will have insufficient time to relax. The contractions will combine, become stronger and more prolonged. This is known as **frequency summation**, as shown in Figure 11.6b. If the contractions become so frequent that the muscle is unable to relax at all, this is known as **tetanus**. Prolonged tetanus will result in muscle fatigue, explained below. Note that tetanus (the disease) includes tetanus (the physiological phenomenon) as one of its primary clinical features, but that tetanic physiology also occurs under normal circumstances with multiple simple twitches in succession.

Real World

The disease *tetanus* is caused by a bacterium called *Clostridium tetani* that releases the toxin *tetanospasmin*. Tetanospasmin blocks the release of GABA from the neurons that *inhibit* motor neurons, making the motor neurons overexcitable. This leads to constant contraction of muscles, which can be so strong as to fracture bones. Tetanus can usually be prevented after exposure by administration of a tetanus toxoid vaccine or tetanus immunoglobulin.

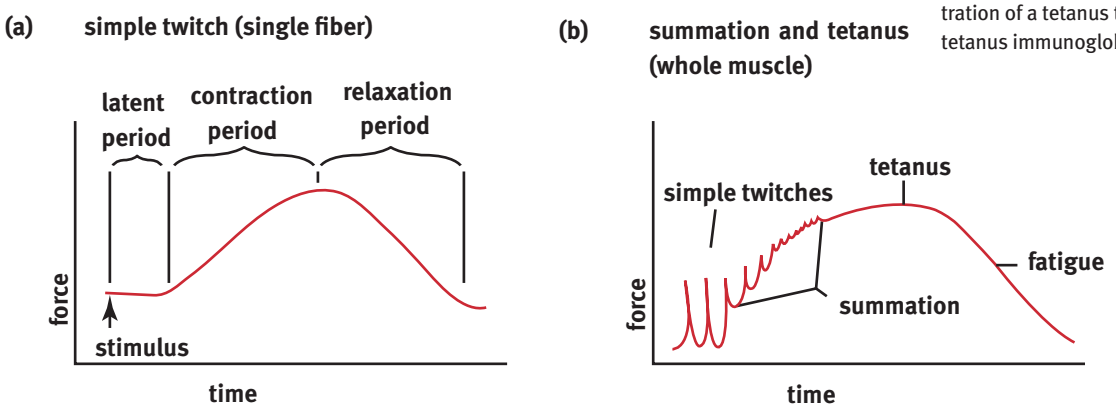

Figure 11.6. Force of Muscle Contraction Due to a Simple Twitch and Tetanus
(a) A simple twitch contraction; (b) Summation of frequent simple twitches can lead to tetanus.

Oxygen Debt and Muscle Fatigue

Muscles require ATP to function. Slow-twitch (red) muscle fibers have high levels of mitochondria and thus use oxidative phosphorylation to make ATP. However, this means that high concentrations of oxygen are required to generate the large amounts of ATP muscle cells need. There are two supplemental energy reserves in muscle. **Creatine phosphate** is created by transferring a phosphate group from ATP to creatine during times of rest. This reaction can then be reversed during muscle use to quickly generate ATP from ADP:

$$\text{creatine} + \text{ATP} \rightleftharpoons \text{creatine phosphate} + \text{ADP}$$

Muscle also contains myoglobin, which binds oxygen with high affinity. As exercising muscles run out of oxygen, they use myoglobin reserves to keep aerobic metabolism going. Fast-twitch (white) muscle fibers have fewer mitochondria and must rely on glycolysis and fermentation to make ATP under most circumstances. When a person exercises, heart rate and respiratory rate increase in order to move more oxygen to actively respiring muscles. The oxyhemoglobin dissociation curve undergoes a right shift in the presence of increased carbon

dioxide concentration, increased hydrogen ion concentration (decreased pH), and increased temperature. However, even with these adaptations, muscle use can quickly overwhelm the ability of the body to deliver oxygen. Then, even red muscle fibers must switch to anaerobic metabolism and produce lactic acid, at which point the muscle begins to fatigue. The difference between the amount of oxygen needed by the muscles and the actual amount present is called the **oxygen debt**. After the cessation of strenuous exercise, the body must metabolize all of the lactic acid it has produced. Most lactic acid is converted back into pyruvate, which can enter the citric acid cycle. This process requires oxygen, and the amount of oxygen required to recover from strenuous exercise is equal to the oxygen debt.

MCAT Concept Check 11.1:

Before you move on, assess your understanding of the material with these questions.

1. What type(s) of muscle (skeletal, smooth, or cardiac) does each of the following describe? (Note: Circle the correct response(s) next to each item.)

• Striated:	Skeletal	Smooth	Cardiac
• Always uninucleated:	Skeletal	Smooth	Cardiac
• Always polynucleated:	Skeletal	Smooth	Cardiac
• Voluntary:	Skeletal	Smooth	Cardiac
• Innervated by the autonomic nervous system:	Skeletal	Smooth	Cardiac
• Exhibits myogenic activity:	Skeletal	Smooth	Cardiac

2. Which zone or band in the sarcomere does NOT change its length during muscle contraction? Why?

_____

3. What are the events that initiate muscle contraction, in order? Start with neurotransmitter release and trace the pathway to the point where myosin binds with actin.

_____

_____

_____

4. What role does the binding of ATP to the myosin head play in the cross-bridge cycle? What about the dissociation of ADP and inorganic phosphate from the myosin head?
   - Binding of ATP:

     _____
   - Dissociation of ADP and inorganic phosphate:

     _____

5. What is tetanus (the physiological phenomenon, not the disease)?

_____

_____

11.2 The Skeletal System ★★

There are two types of skeletons: exoskeletons and endoskeletons. **Exoskeletons** encase whole organisms and are usually found in arthropods, such as crustaceans and insects. Vertebrates, including humans, have **endoskeletons**. Endoskeletons are internal, but are not able to protect the soft tissue structures as well as exoskeletons. However, exoskeletons must be shed and regrown to accommodate growth. Endoskeletons are much better able to accommodate the growth of a larger organism.

SKELETAL STRUCTURE

The components of our skeletal system are divided into axial and appendicular skeletons. The **axial skeleton** consists of the skull, vertebral column, ribcage, and hyoid bone (a small bone in the anterior neck used for swallowing); it provides the basic central framework for the body. The **appendicular skeleton** consists of the bones of the limbs (humerus, radius and ulna, carpals, metacarpals, and phalanges in the upper limb; and femur, tibia and fibula, tarsals, metatarsals, and phalanges in the lower limb), the pectoral girdle (scapula and clavicle), and pelvis. Both skeleton types are covered by other structures (muscle, connective tissue, and vasculature). The structure of the skeleton is shown in Figure 11.7, with many of the bones labeled.

Real World

An adult human has 206 bones. Over 100 of these are in the hands and feet.

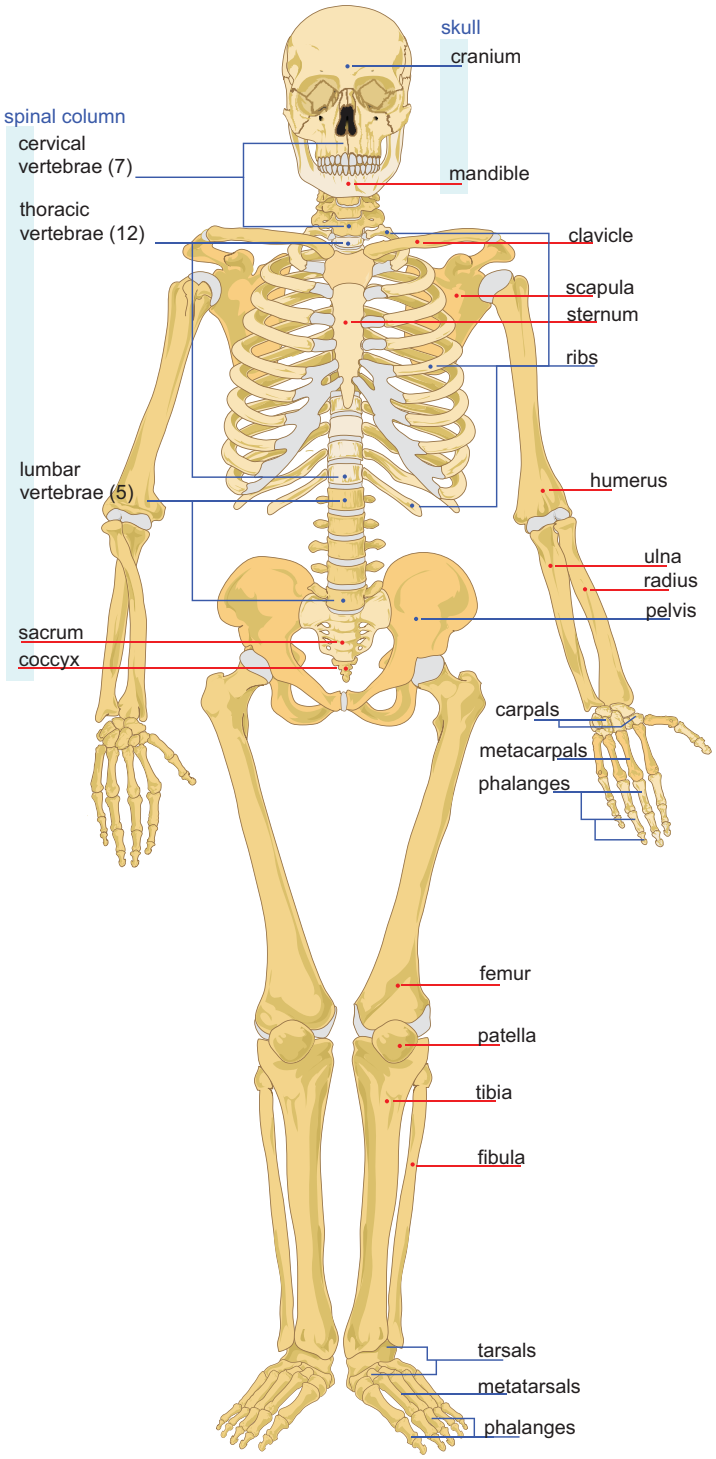

Figure 11.7. Anatomy of the Human Skeleton

The skeleton is created from two major components: bone and cartilage.

BONE COMPOSITION

Bone is a connective tissue derived from embryonic mesoderm. Bone is much harder than cartilage, but is relatively lightweight.

Macroscopic Bone Structure

The structure of bone can be seen in Figure 11.8.

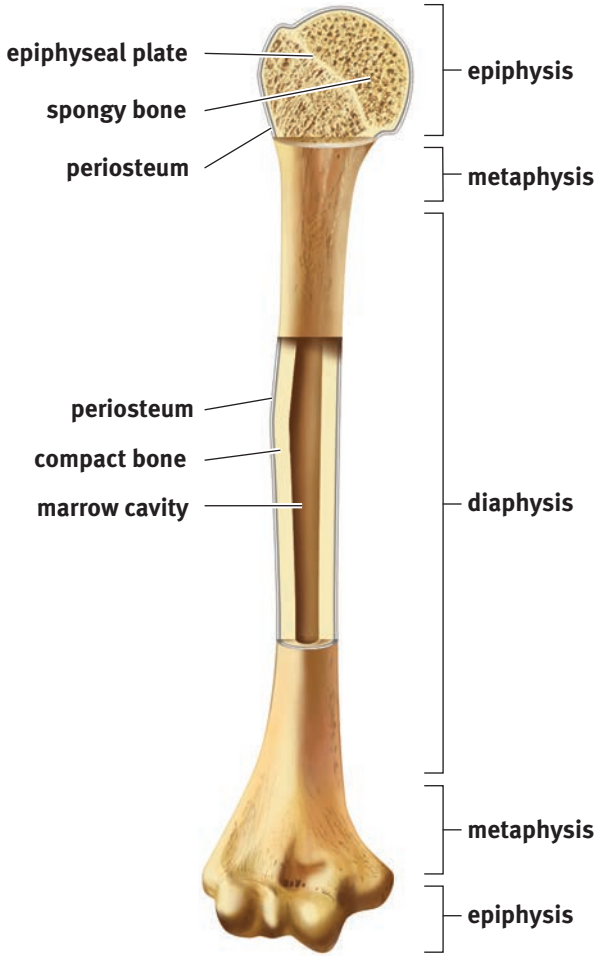

Figure 11.8. Anatomy of a Long Bone (Humerus)

Bone's characteristic strength comes specifically from **compact bone**. It lives up to its name, as it is both dense and strong. The other type of bone structure is **spongy** or **cancellous** bone. The lattice structure of spongy bone is visible under microscopy and consists of bony spicules (points) known as **trabeculae**. The cavities between trabeculae are filled with **bone marrow**, which may be either red or yellow. **Red marrow** is filled with hematopoietic stem cells, which are

responsible for generation of all the cells in our blood; **yellow marrow** is composed primarily of fat and is relatively inactive.

Bones in the appendicular skeleton are typically **long bones**, which are characterized by cylindrical shafts called **diaphyses** that swell at each end to form **metaphyses**, and that terminate in **epiphyses**. The outermost portions of bone are composed of compact bone, whereas the internal core is made of spongy bone. Long bone diaphyses and metaphyses are full of bone marrow. The epiphyses, on the other hand, use their spongy cores for more effective dispersion of force and pressure at the joints. At the internal edge of the epiphysis is an **epiphyseal** (**growth**) **plate**, which is a cartilaginous structure and the site of longitudinal growth. Prior to adulthood, the epiphyseal plate is filled with mitotic cells that contribute to growth; during puberty, these epiphyseal plates close and vertical growth is halted. Finally, a fibrous sheath called the **periosteum** surrounds the long bone to protect it as well as serve as a site for muscle attachment. Some periosteum cells are capable of differentiating into bone-forming cells; a healthy periosteum is necessary for bone growth and repair.

Structures in the musculoskeletal system are held together with dense connective tissue. **Tendons** attach muscle to bone and **ligaments** hold bones together at joints.

Bridge

The root *lig–* refers to a connection between two things. Think of *DNA ligase*, discussed in Chapter 6 of *MCAT Biochemistry Review*. Think of ligands in complex ions, discussed in Chapter 9 of *MCAT General Chemistry Review*. In this case, ligaments attach bones to each other to stabilize joints.

Microscopic Bone Structure

The strength of compact bone comes from the **bone matrix**, which has both organic and inorganic components. The organic components include collagen, glycoproteins, and other peptides. The inorganic components include calcium, phosphate, and hydroxide ions, which harden together to form **hydroxyapatite** crystals ($Ca_{10}(PO_4)_6(OH)_2$). Minerals such as sodium, magnesium, and potassium are also stored in bone.

Strong bones require uniform distribution of organic and inorganic materials. The bony matrix is ordered into structural units known as **osteons** or **Haversian systems**, as shown in Figure 11.9. Each of these osteons contains concentric circles of bony matrix called **lamellae** surrounding a central microscopic channel. Longitudinal channels (those with an axis parallel to the bone) are known as **Haversian canals**, while transverse channels (those with an axis perpendicular to the bone) are known as **Volkmann's canals**. These canals contain the blood vessels, nerve fibers, and lymph vessels that maintain the health of the bone. Between the lamellar rings are small spaces called **lacunae**, which house mature bone cells known as **osteocytes**. The lacunae are interconnected by tiny channels called **canaliculi** that allow for the exchange of nutrients and wastes between osteocytes and the Haversian and Volkmann's canals.

Key Concept

Bone appears to be rigid and static, but it is actually quite dynamic. It is both vascular and innervated, which is why it hurts so much to break a bone. In addition, bone remains in a vigorous equilibrium between construction and destruction, known as bone remodeling.

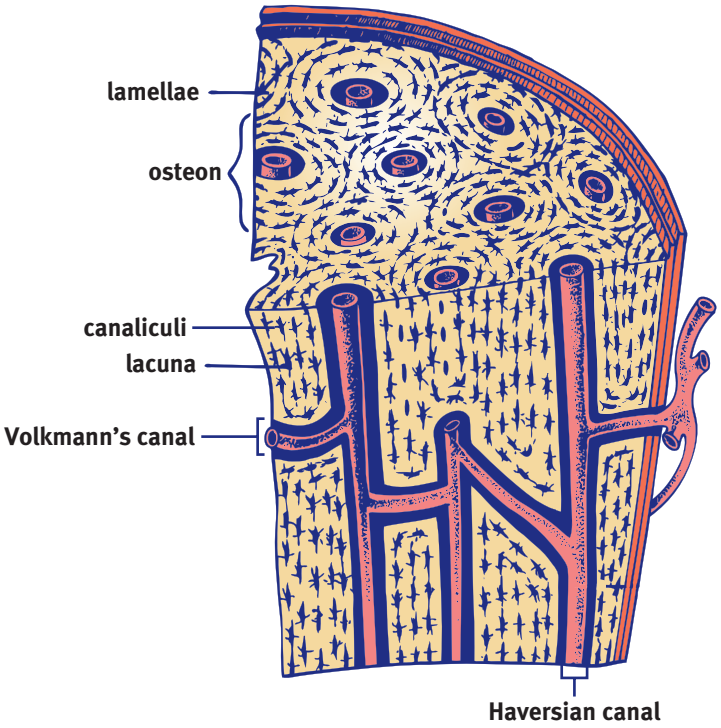

Figure 11.9. Bone Matrix
Cross-sectional and longitudinal views highlighting Haversian systems.

Bone Remodeling

Two cell types are largely responsible for building and maintaining strong bones: osteoblasts and osteoclasts. **Osteoblasts** build bone, whereas **osteoclasts**, polynucleated resident macrophages of bone, resorb it. These processes together contribute to the constant turnover of bone, as shown in Figure 11.10. During bone formation, essential ingredients such as calcium and phosphate are obtained from the blood. During bone resorption, these ions are released back into the bloodstream. Bone remodeling occurs in response to stress, and bone actually remodels in such as a way as to accommodate the repetitive stresses faced by the body. Endocrine hormones may also affect bone metabolism. **Parathyroid hormone**, a peptide hormone released by the parathyroid glands in response to low blood calcium, promotes resorption of bone, increasing the concentration of calcium and phosphate in the blood. **Vitamin D**, which is activated by parathyroid hormone, also promotes the resorption of bone. This may seem counterintuitive at first—isn't vitamin D used to promote bone strength? Indeed, the resorption of bone in response to vitamin D actually encourages the growth of new, stronger bone, thus overcompensating for the effect of resorbing bone in the first place. Finally, **calcitonin**, a peptide hormone released by the parafollicular cells of the thyroid in response to high blood calcium, promotes bone formation, lowering blood calcium levels.

Mnemonic

Osteo**b**lasts **b**uild bone. Osteo**c**lasts **c**hew bone.

Real World

Osteoporosis is the most common bone disease in the United States. It is thought to be the result of increased osteoclast resorption and some concomitant slowing of bone formation, both of which lead to loss of bone mass. Estrogen is believed to help prevent osteoporosis by stimulating osteoblast activity.

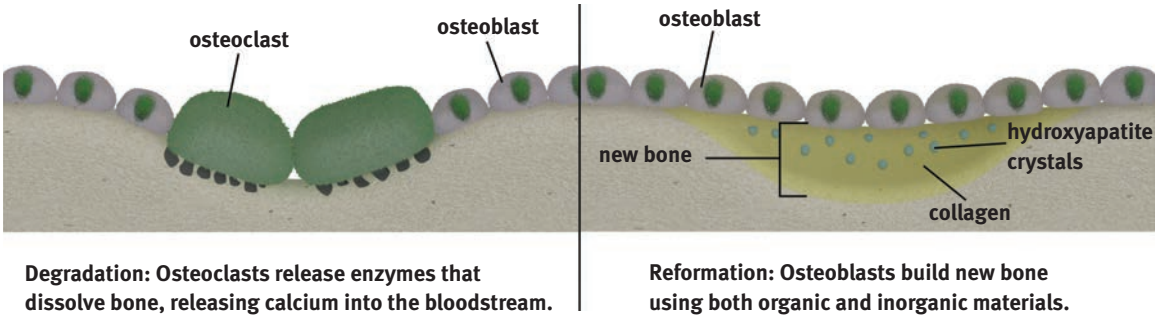

Figure 11.10. Bone Remodeling

CARTILAGE

Cartilage is softer and more flexible than bone. Cartilage consists of a firm but elastic matrix called **chondrin** that is secreted by cells called **chondrocytes**. Fetal skeletons are mostly made up of cartilage. This is advantageous because fetuses must grow and develop in a confined environment and then must traverse the birth canal. Adults have cartilage only in body parts that need a little extra flexibility or cushioning (external ear, nose, walls of the larynx and trachea, intervertebral discs, and joints). Cartilage also differs from bone in that it is avascular (without blood and lymphatic vessels) and is not innervated.

Most of the bones of the body are created by the hardening of cartilage into bone. This process is known as **endochondral ossification** and is responsible for the formation of most of the long bones of the body. Bones may also be formed through **intramembranous ossification**, in which undifferentiated embryonic connective tissue (**mesenchymal tissue**) is transformed into, and replaced by, bone. This occurs in bones of the skull.

JOINTS AND MOVEMENT

Like bone and cartilage, joints are also made of connective tissue and come in two major varieties: immovable and movable. **Immovable joints** consist of bones that are fused together to form **sutures** or similar fibrous joints. These joints are found primarily in the head, where they anchor bones of the skull together.

Movable joints, structures of which are in Figure 11.11, include hinge joints (like the elbow or knee), ball-and-socket joints (like the shoulder or hip), and others. They permit bones to shift relative to one another. Movable joints are strengthened by **ligaments**, which are pieces of fibrous tissue that connect bones to one another, and consist of a **synovial capsule**, which encloses the actual **joint cavity** (**articular cavity**). A layer of soft tissue called the **synovium** secretes **synovial fluid**, which lubricates the movement of structures in the joint space. The **articular cartilage**

Real World

Degradation of articular cartilage (cartilage in joints) can lead to medical issues like osteoarthritis. Osteoarthritis (or "arthritis" in the lay population) is painful because a lack of cartilage in joints leads to bones rubbing directly on one another.

contributes to the joint by coating the articular surfaces of the bones so that impact is restricted to the lubricated joint cartilage, rather than to the bones.

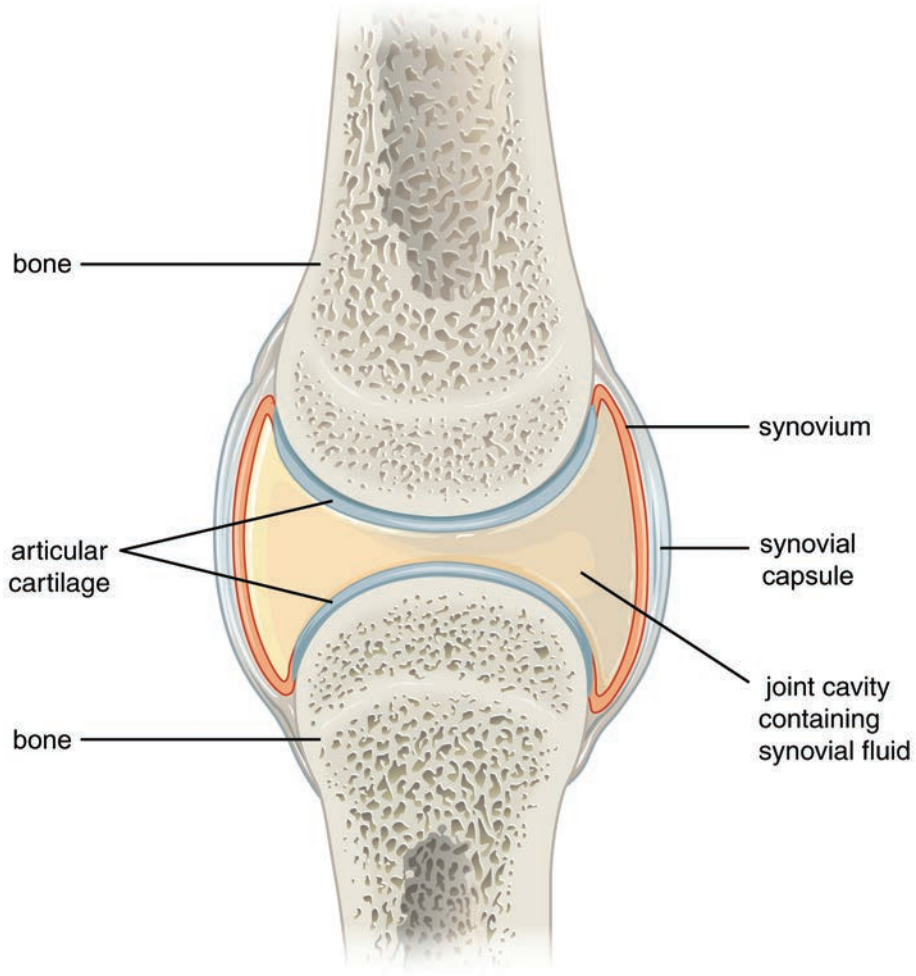

Figure 11.11. Structures in a Movable Joint

When a muscle is attached to two bones, its contraction will cause one of the bones to move. The end of the muscle with a larger attachment to bone (usually the proximal connection) is called the **origin**. The end with the smaller attachment to bone (usually the distal connection) is called the **insertion**. Often, our muscles work in **antagonistic pairs**; one relaxes while the other contracts. Such is the case in the arm, where the biceps brachii and triceps brachii work antagonistically, as shown in Figure 11.12. When the biceps contracts and the triceps relaxes, the elbow is flexed; when the triceps contracts and the biceps relaxes, the elbow is extended. Muscles can also be **synergistic**—working together to accomplish the same function.

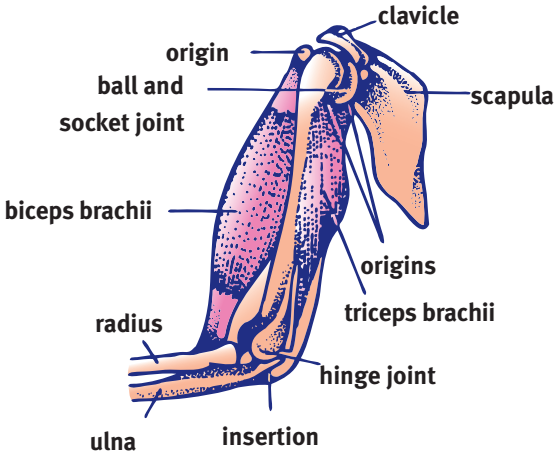

Figure 11.12. Antagonistic Muscle Pairs
The biceps brachii and triceps brachii are an example of a muscle pair that works antagonistically; the contraction of one causes the other to elongate.

Muscles may also be classified by the types of movements they coordinate. A **flexor** muscle decreases the angle across a joint (like the biceps brachii); an **extensor** increases or straightens this angle (like the triceps brachii). An **abductor** moves a part of the body away from the midline (like the deltoid); an **adductor** moves a part of the body toward the midline (like the pectoralis major). **Medial** and **lateral rotation** describe motions that occur in limbs; a medial rotator rotates the axis of the limb toward the midline (like the subscapularis), whereas a lateral rotator rotates the axis of the limb away from the midline (like the infraspinatus).

MCAT Concept Check 11.2:
Before you move on, assess your understanding of the material with these questions.

1. What is the difference between compact and spongy bone?
   - Compact bone:

     _____

   - Spongy bone:

     _____

2. What are the three structural parts of a bone? Which part contributes most to linear growth?

   _____

   _____

3. What chemical forms most of the inorganic component of bone?

   _____

4. What are the functions of osteoblasts, osteoclasts, and chondrocytes?
   - Osteoblast:

     _____

   - Osteoclast:

     _____

   - Chondrocyte:

     _____

5. What liquid provides the lubrication for movable joints? What tissue produces it?

   _____

Conclusion

One concept that has been emphasized throughout the past eight chapters focusing on anatomy and physiology is the notion that organ systems work together in order to achieve a desired effect. The musculoskeletal system is no different. Usually, we think of the musculoskeletal system as being responsible for movement, but to limit the musculoskeletal system to that function would be shortsighted. The bones are reservoirs of calcium and other minerals that can be released through hormonal signaling. They protect the internal organs and provide support for the body. Muscle tissue not only moves these bones, but pumps blood through the body and regulates the function of a number of other systems, including respiration, digestion, blood pressure and vascular tone, and reproduction and childbirth. As you continue reviewing anatomy and physiology and master the fundamentals of each organ system, be sure to pay special attention to how each organ system interacts with the others. While the MCAT expects you to understand each individual organ system, it will also challenge your knowledge by asking you to think critically about how one system impacts another. By spending some time in your studies looking at these interactions, you will be one step ahead on Test Day.

In our final chapter of *MCAT Biology Review*, we will switch gears and look at the transfer of information from generation to generation. This picks up on a discussion from the first three chapters of the book in which we explored the organization of cells and their genetic material, reproduction, and embryogenesis and development. In the next chapter, we'll describe classical (Mendelian) inheritance and conclude with a note on how the gene pool can change over time with the topic of evolution.

CONCEPT SUMMARY

The Muscular System

- There are three main types of muscle: skeletal muscle, smooth muscle, and cardiac muscle.
  - **Skeletal muscle** is involved in support and movement, propulsion of blood in the venous system, and thermoregulation. It appears **striated**, is under voluntary (somatic) control, is polynucleated, and can be divided into **red** (**slow-twitch**) **fibers** that carry out oxidative phosphorylation and **white** (**fast-twitch**) **fibers** that rely on anaerobic metabolism.
  - **Smooth muscle** is in the respiratory, reproductive, cardiovascular, and digestive systems. It appears nonstriated, is under involuntary (autonomic) control, and is uninucleated. It can display **myogenic activity**, or contraction without neural input.
  - **Cardiac muscle** comprises the contractile tissue of the heart. It appears striated, is under involuntary (autonomic) control, and is uninucleated (sometimes binucleated). It can also display myogenic activity. Cells are connected with **intercalated discs** that contain **gap junctions**.
- The **sarcomere** is the basic contractile unit of striated muscle.
  - Sarcomeres are made of thick (**myosin**) and thin (**actin**) filaments.
  - **Troponin** and **tropomyosin** are found on the thin filament and regulate actin–myosin interactions.
- The sarcomere can be divided into different lines, zones, and bands.
  - The boundaries of each sarcomere are defined by **Z-lines**.
  - The **M-line** is located in the middle of the sarcomere.
  - The **I-band** contains only thin filaments.
  - The **H-zone** consists of only thick filaments.
  - The **A-band** contains the thick filaments in their entirety. It is the only part of the sarcomere that maintains a constant size during contraction.
- Sarcomeres attach end-to-end to become **myofibrils**, and each **myocyte** (muscle cell or **muscle fiber**) contains many myofibrils.
  - Myofibrils are surrounded by the **sarcoplasmic reticulum**, a calcium-containing modified endoplasmic reticulum, and the cell membrane of a myocyte is known as the **sarcolemma**.
  - A system of **T-tubules** is connected to the sarcolemma and oriented perpendicularly to the myofibrils, allowing the incoming signal to reach all parts of the muscle.

- Muscle contraction begins at the **neuromuscular junction**, where the motor neuron releases acetylcholine that binds to receptors on the sarcolemma, causing depolarization.
  - This depolarization spreads down the sarcolemma to the T-tubules, triggering the release of calcium ions.
  - Calcium binds to troponin, causing a shift in tropomyosin and exposure of the myosin-binding sites on the actin thin filament.
  - Shortening of the sarcomere occurs as myosin heads bind to the exposed sites on actin, forming cross bridges and pulling the actin filament along the thick filament, resulting in contraction. This is known as the **sliding filament model**.
  - The muscle relaxes when acetylcholine is degraded by acetylcholinesterase, terminating the signal and allowing calcium to be brought back into the SR. ATP binds to the myosin head, allowing it to release from actin.
- Muscle cells exhibit an all-or-nothing response called a **simple twitch**.
  - Addition of multiple simple twitches before the muscle has an opportunity to fully relax is called **frequency summation**.
  - Simple twitches that occur so frequently as to not let the muscle relax at all can lead to **tetanus**, a more prolonged and stronger contraction.
- Muscle cells have additional energy reserves to reduce **oxygen debt** (the difference between the amount of oxygen needed and the amount present) and forestall fatigue.
  - **Creatine phosphate** can transfer a phosphate group to ADP, forming ATP.
  - **Myoglobin** is a heme-containing protein that is a muscular oxygen reserve.

The Skeletal System

- Internal skeletons (like those in humans) are called **endoskeletons**; external skeletons (like those in arthropods) are called **exoskeletons**.
- The human skeletal system can be divided into axial and appendicular skeletons.
  - The **axial skeleton** consists of structures in the midline such as the skull, vertebral column, ribcage, and hyoid bone.
  - The **appendicular skeleton** consists of the bones of the limbs, the pectoral girdle, and the pelvis.
- Bone is derived from embryonic mesoderm and includes both compact and spongy (cancellous) types.
  - **Compact bone** provides strength and is dense.
  - **Spongy** or **cancellous bone** has a lattice-like structure consisting of bony spicules known as **trabeculae**. The cavities are filled with bone marrow.

- Long bones contain shafts called **diaphyses** that flare to form **metaphyses** and that terminate in **epiphyses**. The epiphysis contains an **epiphyseal** (**growth**) **plate** that causes linear growth of the bone.
- Bone is surrounded by a layer of connective tissue called **periosteum**.
- Bones are attached to **muscles** by tendons and to each other by **ligaments**.

- **Bone matrix** has both organic components, like collagen, glycoproteins, and other peptides, and inorganic components, like **hydroxyapatite**.
  - Bone is organized into concentric rings called **lamellae** around a central **Haversian** or **Volkmann's canal**. This structural unit is called an **osteon** or **Haversian system**.
  - Between lamellar rings are **lacunae**, where osteocytes reside, which are connected with **canaliculi** to allow for nutrient and waste transfer.
- Bone remodeling is carried out by osteoblasts and osteoclasts. **Osteoblasts** build bone, while **osteoclasts** resorb bone.
  - **Parathyroid hormone** increases resorption of bone, increasing calcium and phosphate concentrations in the blood.
  - **Vitamin D** also increases resorption of bone, leading to increased turnover and, subsequently, the production of stronger bone.
  - **Calcitonin** increases bone formation, decreasing calcium concentrations in the blood.
- Cartilage is a firm, elastic material secreted by **chondrocytes**. Its matrix is called **chondrin**.
  - Cartilage is usually found in areas that require more flexibility or cushioning.
  - Cartilage is avascular and is not innervated.
- In fetal life, bone forms from cartilage through **endochondral ossification**. Some bones, especially those of the skull, form directly from undifferentiated tissue (**mesenchyme**) in **intramembranous ossification**.
- Joints may be classified as immovable or movable.
  - **Immovable joints** are fused together to form sutures or similar fibrous joints.
  - **Movable joints** are usually strengthened by ligaments and contain a **synovial capsule**.
  - **Synovial fluid**, secreted by the **synovium**, aids in motion by lubricating the joint.
  - Each bone in the joint is coated with **articular cartilage** to aid in movement and provide cushioning.
- Muscles that serve opposite functions come in **antagonistic pairs**; when one muscle contracts, the other lengthens.

ANSWERS TO CONCEPT CHECKS

11.1

1. Skeletal and cardiac muscle are striated. Smooth muscle is always uninucleated. Skeletal muscle is always polynucleated. Skeletal muscle is voluntary. Smooth and cardiac muscle are innervated by the autonomic nervous system. Smooth and cardiac muscle exhibit myogenic activity.
2. The A-band does not change length during muscle contraction because it is the entire length of the myosin filament. The filaments do not change length, but rather slide over each other; thus, the A-band should remain a constant length during contraction.
3. Release of acetylcholine from motor neuron → activation of acetylcholine receptors in sarcolemma → depolarization of sarcolemma → spreading of signal using T-tubules → release of calcium from sarcoplasmic reticulum (SR) → binding of calcium to troponin → conformational shift of tropomyosin → exposure of myosin-binding sites → myosin binds to actin
4. ATP binding allows the myosin filament to disconnect from actin. Dissociation of ADP and inorganic phosphate from myosin causes the powerstroke.
5. Tetanus is the summation of multiple simple twitches that occur too quickly for the muscle to relax. This leads to a stronger and more prolonged contraction of the muscle.

11.2

1. Compact bone is dense and is used for its strength; it forms most of the outer layers of a bone. Spongy (cancellous) bone has many spaces between bony spicules called trabeculae and is the site of marrow production. It is found in the interior core of the bone and also helps distribute forces or pressures on the bone.
2. The three parts of a bone are the diaphysis, metaphyses, and epiphyses. Growth plates are found in epiphyses and contribute to linear growth.
3. Most inorganic bone is composed of hydroxyapatite crystals.
4. Osteoblasts build bone. Osteoclasts chew bone (break it down). Chondrocytes form cartilage.
5. Synovial fluid, produced by the synovium, lubricates movable joints.

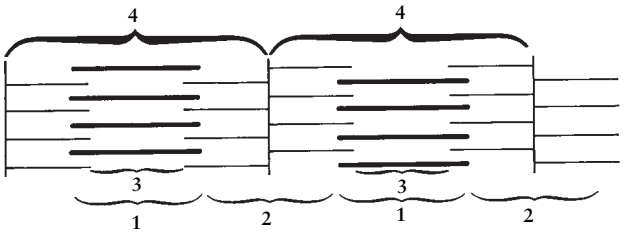
Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

Questions 1, 2, and 3 are based on the following diagram:



1. During muscle contraction, which of the following regions decrease(s) in length?

A. 1 only
B. 1 and 2 only
C. 3 and 4 only
D. 2, 3, and 4 only

2. Region 1 refers to:

A. the thick filaments only.
B. the thin filaments only.
C. the A-band.
D. the I-band.

3. Which region represents one sarcomere?

A. 1
B. 2
C. 3
D. 4

4. With which of the following molecules does Ca^{2+} bind after its release from the sarcoplasmic reticulum to regulate muscle contraction?

A. Myosin
B. Actin
C. Troponin
D. Tropomyosin

5. Which of the following cells is correctly coupled with its definition?

A. Osteoblasts—bone cells involved in the secretion of bone matrix
B. Osteoclasts—immature bone cells
C. Osteocytes—polynucleated cells actively involved in bone resorption
D. Chondrocytes—undifferentiated bone marrow cells

6. An X-ray of the right femur in a child shows that it is shorter than the opposite femur, and below the average length for a child of this age. Which region of the bone is most likely to have caused this abnormality?

A. Diaphysis
B. Metaphysis
C. Epiphysis
D. Periosteum

7. Which of the following INCORRECTLY pairs a type of muscle fiber with a characteristic of that fiber?

A. Red fibers—rich in mitochondria
B. Red fibers—high levels of myoglobin
C. White fibers—fast-twitching
D. White fibers—predominantly uses aerobic respiration

8. When the knee moves back and forth during walking, what prevents the surfaces of the leg bones from rubbing against each other?

A. Articular cartilage
B. Epiphyses
C. Synovial fluid
D. Smooth muscle

9. Which type(s) of muscle is/are always multinucleated?

I. Cardiac muscle
II. Skeletal muscle
III. Smooth muscle

A. I only
B. II only
C. III only
D. I and II only

10. Which type(s) of muscle has/have myogenic activity?

I. Cardiac muscle
II. Skeletal muscle
III. Smooth muscle

A. I only
B. II only
C. III only
D. I and III only

11. Red bone marrow is involved in erythrocyte formation. In contrast, yellow bone marrow:

A. is involved in leukocyte formation.
B. is responsible for drainage of lymph.
C. causes the formation of spicules.
D. contains predominantly adipose tissue.

12. Which of the following statements regarding the periosteum is INCORRECT?

A. The periosteum serves as a site of attachment of bone to muscle.
B. Cells of the periosteum may differentiate into osteoblasts.
C. The periosteum is a fibrous sheath that surrounds long bones.
D. The periosteum secretes fluid into the joint cavity.

13. Which of the following bones is NOT a part of the appendicular skeleton?

A. The triquetrum, one of the carpal bones
B. The calcaneus, which forms the heel
C. The ischium, one of the fused pelvic bones
D. The sternum, or breastbone

14. To facilitate the process of birth, an infant's head is somewhat flexible. This flexibility is given in part by the two fontanelles, which are soft spots of connective tissue in the infant's skull. With time, the fontanelles will close through a process known as:

A. endochondral ossification.
B. intramembranous ossification.
C. bone resorption.
D. longitudinal growth.

15. A young woman presents to the emergency room with a broken hip. She denies any recent history of trauma to the joint. Blood tests reveal a calcium concentration of 11.5 $\frac{mg}{dL}$ (normal: 8.4–10.2). Which tissue is likely responsible for these findings?

A. Thyroid
B. Cartilage
C. Parathyroid
D. Smooth muscle

Explanations to Discrete Practice Questions

1. D

We are given a diagram of a sarcomere and asked to determine which regions shorten during muscle contraction. All bands and zones of the sarcomere shorten during contraction except the A-band, which is the full length of the thick filaments. In this diagram, that is region 1. Thus, the remaining regions all shorten, making **choice (D)** the correct answer. Region 2 represents the I-band, region 3 represents the H-zone, and region 4 is the length of the sarcomere between Z-lines.

2. C

Region 1 contains both thick and thin filaments overlapping one over the other. This region refers to the A-band and is measured from one end of the thick filaments to the other. This is also the only portion of the sarcomere that does not change length during muscle contraction.

3. D

The sarcomere is the contractile unit in striated muscle cells. One sarcomere is represented by the area between the two vertical lines, referred to as the Z-lines. In addition, the Z-lines anchor the thin filaments. In the diagram, a sarcomere is therefore defined by region 4.

4. C

Calcium is released from the sarcoplasmic reticulum into the sarcoplasm. It binds the troponin molecules on the thin filaments, causing the strands of tropomyosin to shift, thereby exposing the myosin-binding sites on the thin filaments.

5. A

Let's quickly define each one of the four cells discussed in the answer choices. Osteoblasts are bone cells involved in the secretion of bone matrix, as **choice (A)** states. Osteoclasts are large, polynucleated cells involved in bone resorption. Osteocytes are mature bone cells that eventually become surrounded by their matrix; their primary role is bone maintenance. Finally, chondrocytes are cells that secrete chondrin, an elastic matrix that makes up cartilage.

6. C

This question is essentially asking where longitudinal growth occurs in bones. The most likely site of abnormalities in this child's femur is the epiphyseal plate, a disk of cartilaginous cells at the internal border of the epiphysis, because the epiphyseal plate is the site of longitudinal growth. Damage to the epiphysis (with or without metaphysis involvement) can imply damage to the epiphyseal plate.

7. D

Red fibers are slow-twitching fibers that have high levels of myoglobin and many mitochondria. They derive their energy from aerobic respiration and are capable of sustained vigorous activity. This eliminates **choices (A)** and **(B)**. White fibers, on the other hand, are fast-twitching fibers and contain lower levels of myoglobin and fewer mitochondria. Because of their composition, they derive more of their energy anaerobically and fatigue more easily. This eliminates **choice (C)** and makes **choice (D)** the correct answer.

8. A

The articular surfaces of the bones are covered with a layer of smooth articular cartilage. The epiphysis is a portion of the bone itself, eliminating **choice (B)**. Synovial fluid lubricates the movement in the joint space, but does not stop the bones from contacting one another; this is the job

of articular cartilage, eliminating **choice (C)**. There is no appreciable function for smooth muscle in the joint space, eliminating **choice (D)**.

9. B

The only type of muscle that is always multinucleated is skeletal muscle, making **choice (B)** the correct answer. Cardiac muscle may contain one or two centrally located nuclei, so statement I is incorrect. Smooth muscle, on the other hand, always has only one centrally located nucleus.

10. D

Myogenic activity refers to the ability of a muscle to contract without nervous stimulation in response to other stimuli like stretching. Smooth and cardiac muscle both possess myogenic activity.

11. D

Yellow marrow is largely inactive and is infiltrated by adipose tissue, making **choice (D)** the correct answer.

12. D

The periosteum, a fibrous sheath that surrounds long bones, is the site of attachment to muscle tissue. Some periosteum cells are capable of differentiating into bone-forming cells called osteoblasts. This eliminates **choices (A)**, **(B)**, and **(C)**. It is the synovium that secretes fluid into the joint cavity (joint space), not the periosteum, making **choice (D)** the correct answer.

13. D

The axial skeleton consists of the skull, vertebral column, rib cage, and hyoid bone. The sternum is a point of attachment of the rib cage and is thus a part of the axial, not appendicular, skeleton. The limb bones, pectoral girdle, and pelvis are all part of the appendicular skeleton.

14. B

Bones form in one of two ways: endochondral ossification and intramembranous ossification. Endochondral ossification is the replacement of a cartilaginous skeleton with bone and occurs mostly in long bones, eliminating **choice (A)**. Intramembranous ossification is the formation of bone from undifferentiated connective tissue cells (mesenchyme) and occurs mostly in the skull, making **choice (B)** the correct answer. Bone resorption is the breakdown of bone, not its formation, eliminating **choice (C)**. Longitudinal growth occurs in long bones and is responsible for increasing height over time, but does not play a role in fontanelle ossification, eliminating **choice (D)**.

15. C

An unprovoked fracture of the hip is not a normal finding in a young woman. Given that she has a high calcium level, it is likely that she has an increased level of bone resorption that is causing her bones to be more fragile. Parathyroid hormone causes calcium release from bones. If this woman had an overactive parathyroid gland—or even cancer in this gland—then it is likely that calcium could still be resorbed from her bones even though her blood calcium levels are already high.

Introduction

European royal families, for generations, practiced what is known as royal intermarriage. For purposes of establishing or continuing political alliances, maintaining bloodline purity, or smoothing out diplomatic relations, marriages between royal families were arranged, resulting in such an interweaving of bloodlines that eventually most European royalty was—and still is—genetically related.

Such marriage unions led to rather severe restrictions on the gene pool—all the alleles represented in the royal family lines. Offspring of parents who were also related to each other through blood lineage (consanguinity) came to have greater similarities in their genotypes, and certain alleles became so frequent that their phenotypic expression became almost a hallmark of royal descent. The House of Habsburg, which ruled a number of European kingdoms from the 11th century until the late 18th century was perhaps the most infamous for its inbreeding practices, and members of this royal family bore the unmistakable mark of their restricted genes through a jaw malformation that even came to be known as the *Habsburg lip*. Medically termed *prognathism* (Greek: "forward jaw"), the condition is a misalignment of the mandible and maxilla. The Habsburg family portraits present individuals with prominent, forward-thrusting lower jaws and chins, characteristic of mandibular prognathism. The genetic condition has more than just aesthetic implications; it can lead to serious disfigurement and disability. Charles II of Spain suffered from the worst case of the Habsburg lip on record—his lower teeth protruded so much further than his upper teeth that he was not able to chew his food.

In this chapter, we will explore the concepts of classical genetics, which were originally described in the mid-1800s. Consider this chapter in tandem with the discussions of molecular genetics in Chapters 6 and 7 of *MCAT Biochemistry Review*. Then, we will explore the changes in the gene pool that occur over time with a discussion of evolution. We'll also quantify populations that are not undergoing evolution with the Hardy–Weinberg principle.

12.1 Fundamental Concepts of Genetics

Bridge

Blood type A individuals carry the A antigen on their erythrocytes and have circulating anti-B antibodies. Blood type B individuals carry the B antigen on their erythrocytes and have circulating anti-A antibodies. Those with type AB have both antigens and neither antibody; those with type O have neither antigen and both antibodies. That makes type O individuals universal donors and type AB individuals universal recipients. Blood typing is discussed in Chapter 7 of *MCAT Biology Review*.

The physical and biochemical characteristics of every living organism are determined by **genes**, which are DNA sequences that code for heritable traits that can be passed from one generation to the next. Taken together, all genes (as well as a large supply of noncoding DNA) are organized into **chromosomes** to ensure that genetic material is passed easily to daughter cells during mitosis and meiosis. Each gene may have alternative forms called **alleles**. We've already explored the ABO blood antigens as an example of three alleles for the same gene (I^A, I^B, and i). The genetic combination possessed by an individual is known as a **genotype**, and the manifestation of a given genotype as an observable trait is known as a **phenotype**.

Each human being possesses two copies of each chromosome, called **homologues**, except for male sex chromosomes (in which there is one X chromosome and one Y chromosome). Each gene has a particular **locus**, or location on a specific chromosome. The normal locus of a particular gene is consistent among human beings, such that a gene can be described by its location. Because each chromosome is part of a homologous pair, a person will inherit two alleles for all genes (again, except for male sex chromosomes). Alleles can be categorized based on their expression. If only one copy of an allele is needed to express a given phenotype, the allele is said to be **dominant** and is usually represented with a capital letter. If two copies are needed, the allele is said to be **recessive** and is usually represented with a lowercase letter. If both alleles are the same for a given gene, the individual is said to have a **homozygous** genotype. If the alleles are different, the individual has a **heterozygous** genotype. A **hemizygous** genotype describes a situation in which only one allele is present for a given gene, as is the case for parts of the X chromosome in males.

PATTERNS OF DOMINANCE

When only one dominant and one recessive allele exist for a given gene, there is said to be **complete dominance**. In this case, the presence of one dominant allele will mask the recessive allele, if present. When more than one dominant allele exists for

a given gene, there is **codominance**. For example, a person with one allele for the A blood antigen and one allele for the B blood antigen will express both antigens simultaneously. Finally, **incomplete dominance** occurs when a heterozygote expresses a phenotype that is intermediate between the two homozygous genotypes. A classic example of incomplete dominance is the mating of certain flowers, in which a red flower crossed with a white flower results in pink flowers, as shown in Figure 12.1.

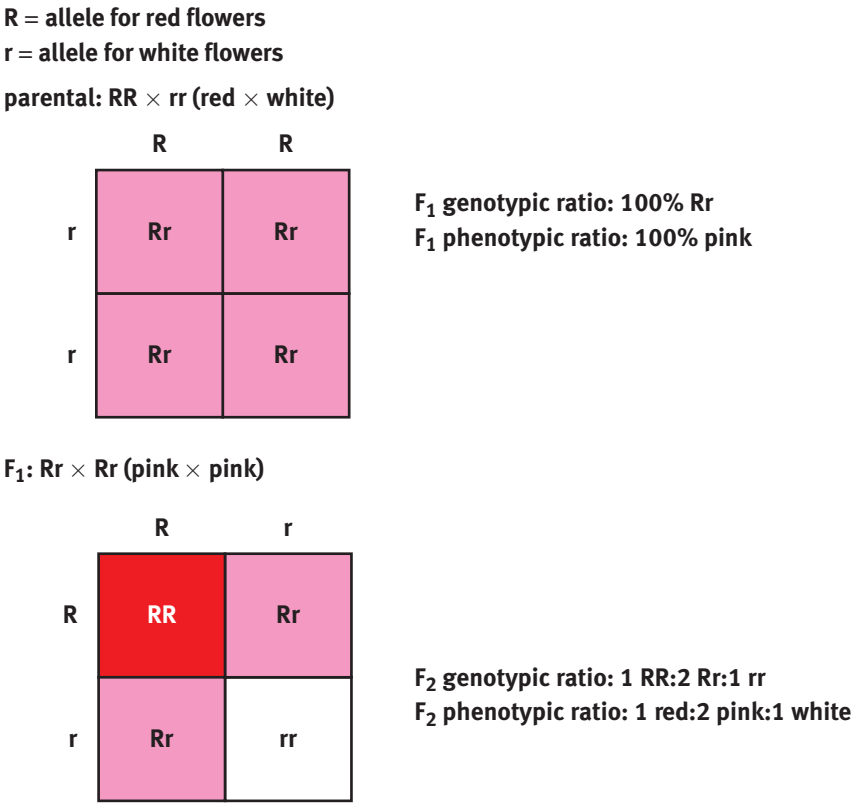

Figure 12.1. Incomplete Dominance
Snapdragons display incomplete dominance, in which neither allele is dominant and the heterozygous phenotype is a mixture of the two homozygous phenotypes.

PENETRANCE AND EXPRESSIVITY

Penetrance and expressivity both reveal the complex interplay between genes and the environment. **Penetrance** is a population measure defined as the proportion of individuals in the population carrying the allele who actually express the phenotype. In other words, it is the probability that, given a particular genotype, a person will express the phenotype. Alleles can be classified by their degree of penetrance; Huntington's disease, caused by an expansion of a repetitive sequence in the *huntingtin* gene, is a classic example. Individuals with over 40 sequence repeats

have **full penetrance**—100 percent of individuals with this allele show symptoms of Huntington's disease. Individuals with fewer sequence repeats show **high penetrance**, wherein most—but not all—of those with the allele show symptoms of the disease. With fewer sequence repeats, the gene comes to have **reduced penetrance**, **low penetrance**, or even **nonpenetrance**.

Key Concept

- **Penetrance**—the proportion of the population with a given genotype who actually express the phenotype
- **Expressivity**—the different manifestations of the same genotype across the population

A related, but distinct, concept is **expressivity**, which is defined as varying phenotypes despite identical genotypes. If expressivity is **constant**, then all individuals with a given genotype express the same phenotype. However, if expressivity is **variable**, then individuals with the same genotype may have different phenotypes. Whereas penetrance is a population parameter (what percent of individuals with a given genotype express the phenotype?), expressivity explores the grey area in expression and is more commonly considered at the individual level. For example, the disease *neurofibromatosis type II* is an autosomal dominant disease that results from a mutation of the gene *NF2* (*merlin*). Interestingly, a range of phenotypes is associated with carrying the affected allele. Many patients have debilitating tumors of the vestibulocochlear nerve, which is needed for hearing and balance. Some have cataracts. Others have tumors in the skin called neuromas. Still others have spinal lesions. A small proportion of the population is nonpenetrant. The disease shows variable expressivity because there is a range of presentations between no clinical effect and severe disability.

MENDELIAN CONCEPTS

Gregor Mendel, an Augustinian friar, developed several of the tenets of genetics in the 1860s based on his work with pea plants. While the study of genetics has come a long way, from pedigree analysis to DNA probes to whole-genome sequencing, many of Mendel's original ideas still hold.

Mendel's First Law: Law of Segregation

There are four basic tenets of the modern interpretation of **Mendel's first law (of segregation)**, some of which have already been discussed:

- Genes exist in alternative forms (alleles).
- An organism has two alleles for each gene, one inherited from each parent.
- The two alleles segregate during meiosis, resulting in gametes that carry only one allele for any inherited trait.
- If two alleles of an organism are different, only one will be fully expressed and the other will be silent. The expressed allele is said to be dominant, the silent allele recessive. (Keep in mind that codominance and incomplete dominance are exceptions to this rule.)

The key cellular correlate to draw here is the separation of homologous chromosomes during anaphase I of meiosis. By separating—segregating—these chromosomes into different cells, each gamete carries only one allele for any given trait.

Mendel's Second Law: Law of Independent Assortment

Mendel's second law (of independent assortment) states that the inheritance of one gene does not affect the inheritance of another gene. Remember from Chapter 2 of *MCAT Biology Review* that, before meiosis I, spermatogonia and oogonia undergo genome replication. The daughter DNA strand is held to the parent strand at the **centromere**. Together, these DNA strands are known as **sister chromatids**. During prophase I of meiosis, homologous chromosomes pair up to form **tetrads**, which derive their name from the four chromatids involved (two chromatids in each of two homologous chromosomes). Small segments of genetic material are swapped between chromatids in homologous chromosomes, resulting in novel combinations of alleles that were not present in the original chromosomes (**recombination**). This allows the inheritance of one gene to be independent of the inheritance of all others.

Mendel's second law has been problematized by the discovery of linked genes. We will discuss nonindependent assortment and linkage later in this chapter in the section on analytical approaches in genetics.

Both segregation of homologous chromosomes and independent assortment of alleles increase the genetic diversity of gametes and, subsequently, the genetic diversity of offspring. This has been demonstrated to improve the ability of a species to evolve to adapt to environmental stresses.

Key Concept

Segregation and independent assortment allow for greater genetic diversity in the offspring.

DNA AS GENETIC MATERIAL

While Mendel noticed that there were certain patterns of inheritance, what he did not know was that DNA was the genetic material transferred to offspring and that genes were made of DNA. In fact, the scientific community rejected Mendel's initial papers on inheritance. It wasn't until the early 1900s that his work was rediscovered. In the early to mid-1900s, it was largely believed that protein was the heritable material. In the mid-1900s, there were three experiments conducted that largely pointed to DNA's role in genetic inheritance.

In the 1920s, Frederick Griffith was a scientist working with the British government to study *Streptococcus pneumoniae*, a bacteria that causes pneumonia. Two strains of *S. pneumoniae* were identified: a virulent (disease-causing) strain and a nonvirulent strain. In successive trials, Griffith exposed mice to these strains of bacteria under different conditions and observed whether the mouse lived or died, as shown in Figure 12.2. The virulent *S. pneumonia* has a smooth capsule that helps the bacterium

Bridge

The transforming principle described in Griffith's experiment is the same as bacterial transformation discussed in Chapter 1 of *MCAT Biology Review*. Remember that transformation is one of three main ways bacteria increase genetic variability; the other two are conjugation and transduction.

eschew the immune system and cause disease. He injected this strain into mice, which resulted in death of the mice. However, if the virulent bacteria were killed prior to injection, no disease resulted. Likewise, exposure of the mice to the non-virulent strain, which has a rough capsule, did not cause disease. However, when both dead virulent bacteria and live nonvirulent bacteria were injected into the mouse, the mouse died, and live bacteria with smooth capsules could be found in the mice. He theorized that the live, nonvirulent bacteria must have acquired the ability to form smooth capsules from the dead virulent bacteria. This was known as the *transforming principle*.

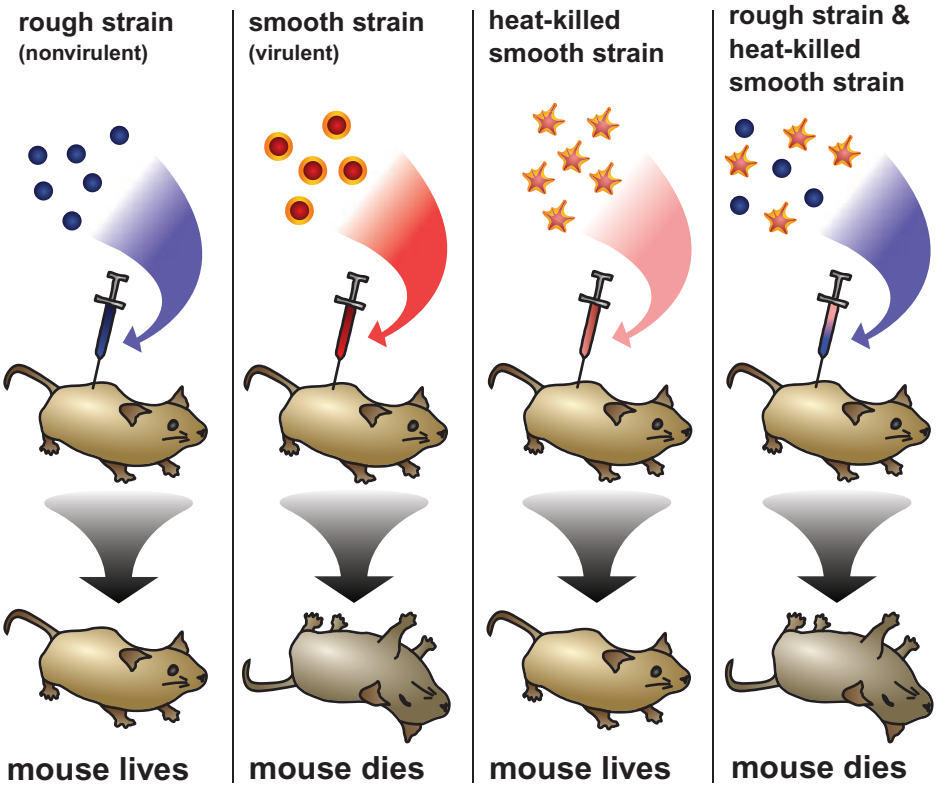

Figure 12.2. The Griffith Experiment

Researchers at the Rockefeller Institute confirmed the transformation principle. Three American scientists—Oswald Avery, Colin MacLeod, and Maclyn McCarty—were attempting to determine the exact material underlying the transformation principle. These scientists purified a very large quantity of heat-killed virulent *S. pneumoniae* bacteria and separated the subcellular components of the bacteria into different extracts. It was noted that the addition of one particular extract to non-virulent *S. pneumoniae* transformed the bacteria and enabled them to kill the mouse when injected. When this substance was treated with enzymes known to degrade DNA, the bacteria were not transformed and the mice lived. However, when the substance was treated with enzymes known to degrade proteins, the bacteria were still transformed and the mice died. Thus, the group concluded that the transforming substance must be DNA.

In 1952 (one year before the description of the Watson–Crick model), Alfred Hershey and Martha Chase worked to confirm the idea that DNA could independently carry genetic information. These scientists created bacteriophages with radiolabeled DNA and protein. One group of bacteriophages contained radiolabeled sulfur, which is found in protein but not in DNA. Another group contained radiolabeled phosphorus, which is found in DNA but not in protein. Each of these bacteriophages was permitted to infect a group of nonlabeled bacteria. Recall from Chapter 1 of *MCAT Biology Review* that when bacteriophages infect a bacterium, they inject their genetic material into the cell and leave their capsid outside. After the phages and bacteria were incubated, the sample was centrifuged to separate the material that remained outside the cell from the bacterial cells themselves. It was determined that no radiolabeled protein entered the cells, but that radiolabeled DNA had. It was known that viruses must enter a cell to cause disease and replicate, so this experiment once again confirmed that DNA was the heritable genetic material.

Bridge

Radiolabeling sulfur was an appropriate choice to tag proteins in the Hershey–Chase experiment. Recall from Chapter 1 of *MCAT Biochemistry Review* that two amino acids—cysteine and methionine—contain sulfur in their R group, while no nucleotides contain any sulfur.

MCAT Concept Check 12.1:

Before you move on, assess your understanding of the material with these questions.

1. What does it mean for an allele to be dominant? Recessive?
   - Dominant: _____
   - Recessive: _____
2. What does it mean for a genotype to be homozygous? Heterozygous? Hemizygous?
   - Homozygous: _____
   - Heterozygous: _____
   - Hemizygous: _____
3. What is the difference between complete dominance, codominance, and incomplete dominance?
   - Complete dominance: _____
   - Codominance: _____
   - Incomplete dominance: _____
4. What is the difference between penetrance and expressivity?
   - Penetrance: _____
   - Expressivity: _____

5. With which phase of meiosis does each of Mendel's laws most closely correlate?
   - Mendel's first law: _____
   - Mendel's second law: _____

12.2 Changes in the Gene Pool ★★★

All of the alleles that exist within a species are known as the **gene pool**. When mutations or genetic leakage occur, new genes are introduced into the gene pool. Genetic variability is essential for the survival of a species because it allows it to evolve to adapt to changing environmental stresses. Certain traits may be more desirable than others and confer a selective advantage—an advantage that allows for the individual to produce more viable, fertile offspring. In this section, we will consider genetic diversity and mutations, leakage, and genetic drift, which cause changes to the alleles present in the gene pool.

MUTATIONS

A **mutation** is a change in DNA sequence, and it results in a mutant allele. Mutant alleles can be contrasted with their **wild-type** counterparts, which are alleles that are considered "normal" or "natural" and are ubiquitous in the study population. New mutations may be introduced in a variety of ways. Ionizing radiation, such as ultraviolet rays from the sun, and chemical exposures can damage DNA; substances that can cause mutations are called **mutagens**. *DNA polymerase* is subject to making mistakes during DNA replication, albeit at a very low rate; proofreading mechanisms also help prevent mutations from occurring through this mechanism. Elements known as **transposons** can insert and remove themselves from the genome. If a transposon inserts in the middle of a coding sequence, the mutation will disrupt the gene.

Flawed proteins can arise in other ways without an underlying change in DNA sequence, as well. Incorrect pairing of nucleotides during transcription or translation, or a tRNA molecule charged with the incorrect amino acid for its anticodon, can result in derangements of the normal amino acid sequence.

The major types of nucleotide-level mutations are discussed in great detail in Chapter 7 of *MCAT Biochemistry Review*, so we offer just a brief overview here of each type.

Nucleotide-Level Mutations

Many mutations occur at the level of a single nucleotide (or a very small number of nucleotides). These mutations are shown in Figure 12.3 and are summarized below.

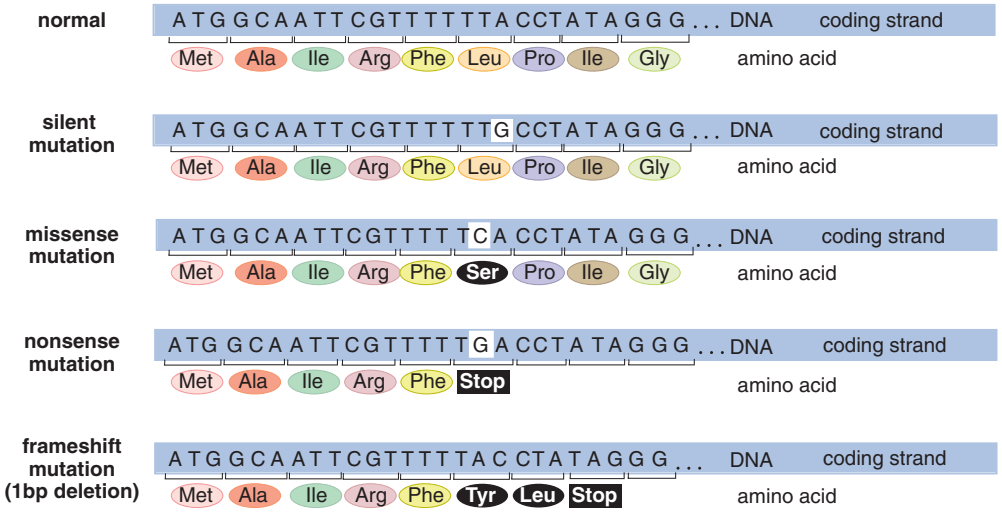

Figure 12.3. Common Nucleotide-Level Mutations

Point mutations occur when one nucleotide in DNA (A, C, T, or G) is swapped for another. These can be subcategorized as silent, missense, or nonsense mutations:

- **Silent mutations** occur when the change in nucleotide has no effect on the final protein synthesized from the gene. This most commonly occurs when the changed nucleotide is transcribed to be the third nucleotide in a codon because there is **degeneracy** (**wobble**) in the genetic code.
- **Missense mutations** occur when the change in nucleotide results in substituting one amino acid for another in the final protein.
- **Nonsense mutations** occur when the change in nucleotide results in substituting a **stop codon** for an amino acid in the final protein.

Frameshift mutations occur when nucleotides are inserted into or deleted from the genome. Because mRNA transcribed from DNA is always read in three-letter sequences called **codons**, insertion or deletion of nucleotides can shift the **reading frame**, usually resulting in either changes in the amino acid sequence or premature truncation of the protein (due to the generation of a nonsense mutation). These can be subcategorized as **insertion** or **deletion mutations**.

Chromosomal Mutations

Chromosomal mutations are larger-scale mutations in which large segments of DNA are affected, as demonstrated in Figure 12.4 and summarized below.

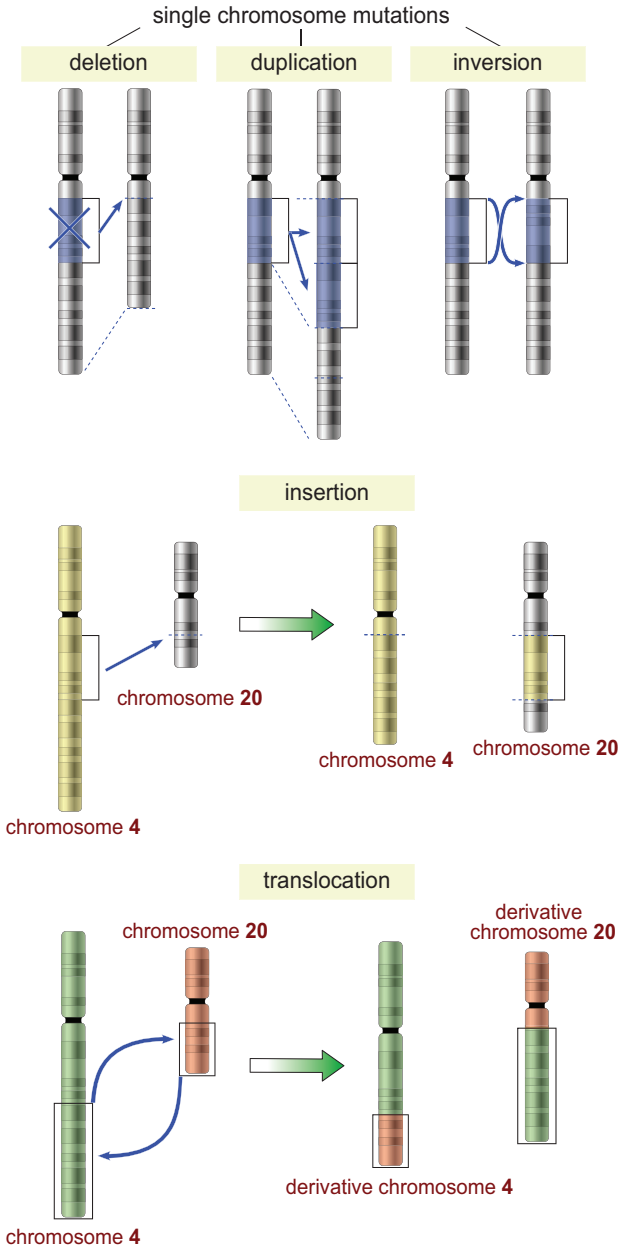

Figure 12.4. Common Chromosomal Mutations

- **Deletion mutations** occur when a large segment of DNA is lost from a chromosome. Small deletion mutations are considered frameshift mutations, as described previously.
- **Duplication mutations** occur when a segment of DNA is copied multiple times in the genome.

- **Inversion mutations** occur when a segment of DNA is reversed within the chromosome.
- **Insertion mutations** occur when a segment of DNA is moved from one chromosome to another. Small insertion mutations (including those where the inserted DNA is not from another chromosome) are considered frameshift mutations, as described previously.
- **Translocation mutations** occur when a segment of DNA from one chromosome is swapped with a segment of DNA from another chromosome.

Consequences of Mutations

Mutations can have many different consequences. Some mutations can be **advantageous**, conferring a positive selective advantage that may allow the organism to produce more offspring. For example, sickle cell disease is a single nucleotide mutation that causes sickled hemoglobin. While the disease itself is detrimental to life, heterozygotes for sickle cell disease usually have minor symptoms, if any, and have natural resistance to malaria because their red blood cells have a slightly shorter lifespan—just short enough that the parasitic *Plasmodium* species that cause malaria cannot reproduce. Thus, heterozygotes for sickle cell disease actually have a selective advantage because they are less likely to die from malaria.

On the other hand, some mutations can be detrimental or **deleterious**. For example, *xeroderma pigmentosum* (XP) is an inherited defect in the nucleotide excision repair mechanism. In patients with XP, DNA that has been damaged by ultraviolet radiation cannot be repaired appropriately. Ultraviolet radiation can introduce cancer-causing mutations; without a repair mechanism, patients with XP are frequently diagnosed with malignancies, especially of the skin.

One important class of deleterious mutations is known as **inborn errors of metabolism**. These are defects in genes required for metabolism. Children born with these defects often require very early intervention in order to prevent permanent damage from the buildup of metabolites in various pathways. For example, in *phenylketonuria* (PKU), the enzyme *phenylalanine hydrolase*, which completes the metabolism of the amino acid phenylalanine, is defective. In the absence of this enzyme, toxic metabolites of phenylalanine accumulate, causing seizures, impairment of cerebral function, and learning disabilities, as well as a musty odor to bodily secretions. However, if the disease is discovered shortly after birth, then dietary phenylalanine can be eliminated and treatments can be administered to aid in metabolizing any additional phenylalanine.

LEAKAGE

Genetic **leakage** is a flow of genes between species. In some cases, individuals from different (but closely related) species can mate to produce **hybrid** offspring. Many hybrid offspring, such as the mule (hybrid of a male horse and a female donkey), are not able to reproduce because they have odd numbers of chromosomes—horses have 64 chromosomes and donkeys have 62, so mules, with 63 chromosomes, cannot undergo normal homologous pairing in meiosis and cannot form gametes. In some cases, however, a hybrid can reproduce with members of one species or the other, such as the *beefalo* (a cross between cattle and American bison). The hybrid carries genes from both parent species, so this can result in a net flow of genes from one species to the other.

GENETIC DRIFT

Genetic drift refers to changes in the composition of the gene pool due to chance. Genetic drift tends to be more pronounced in small populations. The **founder effect** is a more extreme case of genetic drift in which a small population of a species finds itself in reproductive isolation from other populations as a result of natural barriers, catastrophic events, or other **bottlenecks** that drastically and suddenly reduce the size of the population available for breeding. Because the breeding group is small, **inbreeding**, or mating between two genetically related individuals, may occur in later generations. Inbreeding encourages homozygosity, which increases the prevalence of both homozygous dominant and recessive genotypes. Ultimately, genetic drift, the founder effect, and inbreeding cause a reduction in genetic diversity, which is often the reason why a small population may have increased prevalence of certain traits and diseases. For example, *branched-chain ketoacid dehydrogenase deficiency* (also called *maple syrup urine disease*) is especially common in Mennonite communities; this implies a common origin of the mutation, which may have been a very small original population.

This loss of genetic variation may cause reduced fitness of the population, a condition known as **inbreeding depression**. On the opposite end of the spectrum, **outbreeding** or **outcrossing**, is the introduction of unrelated individuals into a breeding group. Theoretically, this could result in increased variation within a gene pool and increased fitness of the population.

MCAT Concept Check 12.2:
Before you move on, assess your understanding of the material with these questions.

1. What are the three main types of point mutations? What change occurs in each?
   - _____
   - _____
   - _____
2. What are the two main types of frameshift mutations?
   - _____
   - _____
3. What are the three main types of chromosomal mutations that do NOT share their name with a type of frameshift mutation? What change occurs in each?
   - _____
   - _____
   - _____
4. Why would genetic leakage in animals be rare prior to the last century?

   _____

   _____
5. Why is genetic drift more common in small populations? What relationship does this have to the founder effect?

   _____

   _____

   _____

12.3 Analytical Approaches in Genetics

Genetics is a field in which a number of **biometric techniques**, the statistical analysis of biological data, have been developed. These range from the Punnett square to mapping of chromosomes with recombinant frequencies to Hardy–Weinberg equilibrium.

MCAT Expertise

Pedigree (or family tree) analysis was once a mainstay of MCAT passages and questions. While this topic no longer appears on the exam, it will be a major focus of your medical school genetics class. The symbology of pedigree analysis is complex and intricate, but a great deal of information can be gleaned from a well-drawn pedigree.

PUNNETT SQUARES

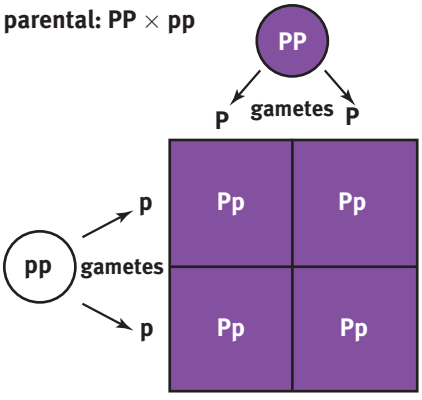
Punnett squares are diagrams that predict the relative genotypic and phenotypic frequencies that will result from the crossing of two individuals. The alleles of the two parents are arranged on the top and side of the square, with the genotypes of the progeny represented at the intersections of these alleles. The genotypes of the progeny will be the sum of the two parental alleles.

Monohybrid Cross

In genetics problems, including those on the MCAT, dominant alleles are assigned capital letters and recessive alleles are assigned lowercase letters. If both copies of the allele are the same, that individual is said to be homozygous. If they are different, the individual is heterozygous.

A cross in which only one trait is being studied is said to be **monohybrid**. The **parent** or **P generation** refers to the individuals being crossed; the offspring are the **filial** or **F generation**. Multiple generations can be denoted F generations by using numeric subscripts. If you think of your grandparents as the P generation, then your parents are in the F_1 generation, and you are in the F_2 generation.

Mendel worked with pea plants that had either purple or white flowers. Before crossing the different plants, each group contained homozygotes; subsequent experimentation revealed that the allele for purple color was dominant (P) and the allele for white color was recessive (p). Thus, crossing a homozygous purple flower with a white flower would be crossing PP with pp, resulting in an F_1 generation that contained 100 percent Pp or heterozygotes, as shown in Figure 12.5. All of the flowers in this generation would be purple because P is a dominant allele.

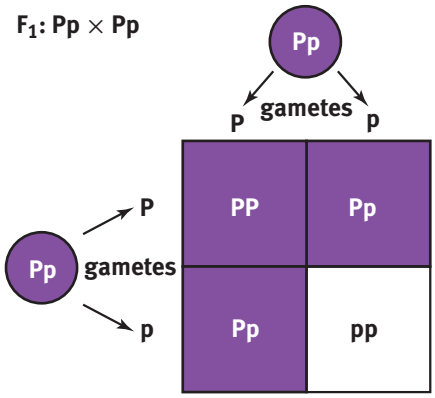


F_1 genotypic ratio: 100% Pp (heterozygous)

F_1 phenotypic ratio: 100% purple

Figure 12.5. Punnett Square of Homozygous Parents

If two members of the F_1 generation were crossed, the resulting offspring in the F_2 generation would be more genotypically and phenotypically diverse than their parents. Crossing two plants with the genotype Pp would result in 25 percent PP, 50 percent Pp, and 25 percent pp offspring, as shown in Figure 12.6. Phenotypically, this would be a 3:1 distribution because both the homozygous dominant and heterozygous dominant offspring would be purple-flowering plants. Thus, crossing two heterozygotes in a case of complete dominance will result in a 1:2:1 distribution of genotypes (homozygous dominant:heterozygous dominant:homozygous recessive) and a 3:1 distribution of phenotypes (dominant:recessive). These ratios are, of course, theoretical probabilities and will not always hold true—especially in a small population of offspring. Usually, the more offspring that parents have, the closer their phenotypic ratios will be to the expected ratios.



F_2 genotypic ratio: 1:2:1; 1 PP: 2 Pp:1 pp

F_2 phenotypic ratio: 3:1; 3 purple:1 white

Figure 12.6. Punnett Square of Heterozygous Parents

Test Cross

A **test cross** is used to determine an unknown genotype, as shown in Figure 12.7. In a test cross, the organism with an unknown genotype is crossed with an organism known to be homozygous recessive. If all of the offspring (100 percent) are of the dominant phenotype, then the unknown genotype is likely to be homozygous dominant. If there is a 1:1 distribution of dominant to recessive phenotypes, then the unknown genotype is likely to be heterozygous. Because a test cross is used to determine the genotype of the parent based on the phenotypes of its offspring, test crosses are sometimes called **back crosses**.

Key Concept

Crossing two heterozygotes for a trait with complete dominance results in a 1:2:1 ratio of genotypes and a 3:1 ratio of phenotypes. Know these ratios cold for Test Day!

MCAT Expertise

The ability to create and read a Punnett square quickly on Test Day is one of the most useful skills for questions involving Mendelian inheritance. Often, an entire passage in the *Biological and Biochemical Foundations of Living Systems* section will be devoted to classical and molecular genetics and will require the use of at least one Punnett square.

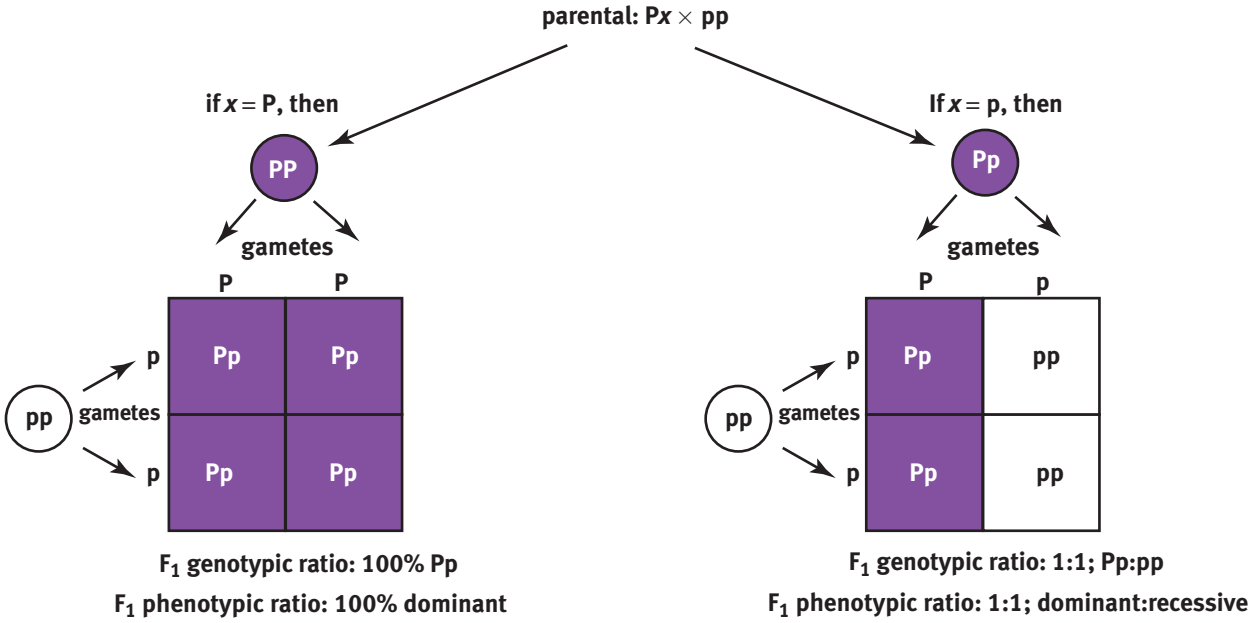


Figure 12.7. Test Cross
An organism with an unknown genotype is crossed with a homozygous recessive organism to identify the unknown genotype using the phenotypes of the resulting offspring.

Dihybrid Cross

We can extend a Punnett square to account for the inheritance of two different genes using a **dihybrid cross**. Remember that, according to Mendel's second law (of independent assortment), the inheritance of one gene is independent of the inheritance of the other. This will hold true for **unlinked genes**, although it will be more complicated for linked genes, as described later in this chapter.

If we expand the previous crosses to consider not only flower color, but also plant height, then we can create a 4 × 4 Punnett square, as shown in Figure 12.8. Remember that purple is dominant (P) and white is recessive (p); similarly, tall is dominant (T) and short or dwarf is recessive (t). If we cross two plants that are heterozygous for both traits, then the offspring have a phenotypic ratio of 9:3:3:1 (9 tall and purple:3 tall and white:3 dwarf and purple:1 dwarf and white). Note that the 3:1 phenotypic ratio still holds for each trait (12 tall:4 dwarf and 12 purple:4 white), reflecting Mendel's second law.

MCAT Expertise

Just as with the 3:1 phenotypic ratio of a monohybrid cross, it is worth memorizing the 9:3:3:1 distribution for dihybrid crosses between two heterozygotes with complete dominance.

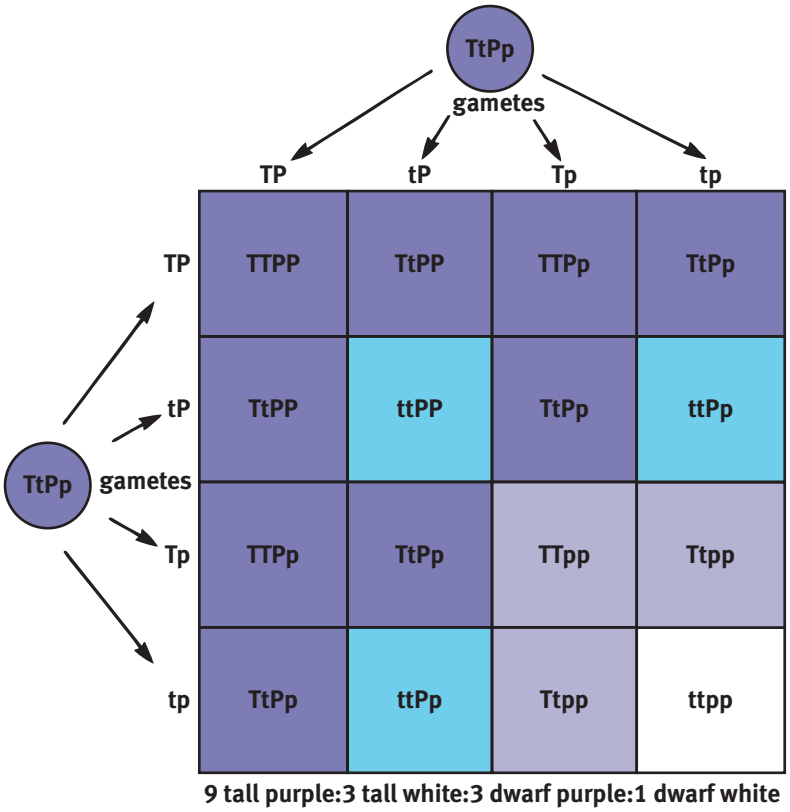

Figure 12.8. Dihybrid Cross

Sex-Linked Crosses

When considering **sex-linked** (**X-linked**) **traits**, a slightly different system is used to symbolize the various alleles. This is because females have two X chromosomes and thus may be homozygous or heterozygous for a condition carried on the X chromosome. Males, on the other hand, have only one X chromosome (and one Y chromosome) and are hemizygous for many genes carried on the X chromosome. This is why sex-linked traits are much more common in males; having only one recessive allele is sufficient for expression of the recessive phenotype.

When writing genotypes for sex-linked traits, we use X and Y to symbolize normal X and Y chromosomes. An X chromosome carrying an affected allele is commonly given a subscript, such as X_h, to indicate the presence of the disease-carrying allele. Hemophilia is a particularly common example of a sex-linked

Mnemonic

On the MCAT, se**x**-linked is **X**-linked. Y-linked diseases exist, but are exceedingly rare. Further, unless told otherwise, assume that sex-linked traits are recessive.

Key Concept

Because an egg necessarily carries an X chromosome, it is the sperm that determines the sex of a child. It follows that men with a sex-linked trait will have daughters who are all either carriers of the trait or who express the trait (if his partner also has an affected allele), and that a man can never pass down a sex-linked trait to his son.

trait; a Punnett square for a heterozygous (**carrier**) female and both a normal male and affected (hemophiliac) male are shown in Figure 12.9.

cross between a carrier female (X_hX) and a normal male (XY)

	X_h	X
X	X_hX	XX
Y	X_hY	XY

offspring
25% X_hX = 25% carrier female
25% XX = 25% normal female
25% X_hY = 25% hemophiliac male
25% XY = 25% normal male

cross between a carrier female (X_hX) and a hemophiliac male (X_hY)

	X_h	X
X_h	X_hX_h	X_hX
Y	X_hY	XY

offspring
25% X_hX_h = 25% hemophiliac female
25% X_hX = 25% carrier female
25% X_hY = 25% hemophiliac male
25% XY = 25% normal male

Figure 12.9. Sex-Linked Cross
Unless stated otherwise, assume that all sex-linked traits on the MCAT are X-linked recessive.

GENE MAPPING

Genes are organized in a linear fashion on chromosomes. As discussed earlier, crossing over during prophase I of meiosis causes alleles to be swapped between homologous chromosomes, supporting Mendel's second law (of independent assortment). However, genes that are located very close together on a chromosome are less likely to be separated from each other during crossing over. In other words, the further apart two genes are, the more likely it is that there will be a point of crossing over, called a **chiasma**, between them. The likelihood that two alleles are separated from each other during crossing over, called the **recombination frequency** (θ), is roughly proportional to the distance between the genes on the chromosome. We can also describe the strength of linkage between genes based on the recombination frequency: tightly linked genes have recombination frequencies close to 0 percent; weakly linked genes have recombination frequencies approaching 50 percent, as expected from independent assortment.

By analyzing recombination frequencies, a **genetic map** that represents the relative distance between genes on a chromosome can be constructed. By convention, one **map unit** or **centimorgan** corresponds to a 1 percent chance of recombination occurring

between two genes. Thus, if two genes were 25 map units apart, we would expect 25 percent of the total gametes examined to show recombination somewhere between these two genes. Recombination frequencies can be added in a crude approximation to determine the order of genes in the chromosome, as shown in Figure 12.10.

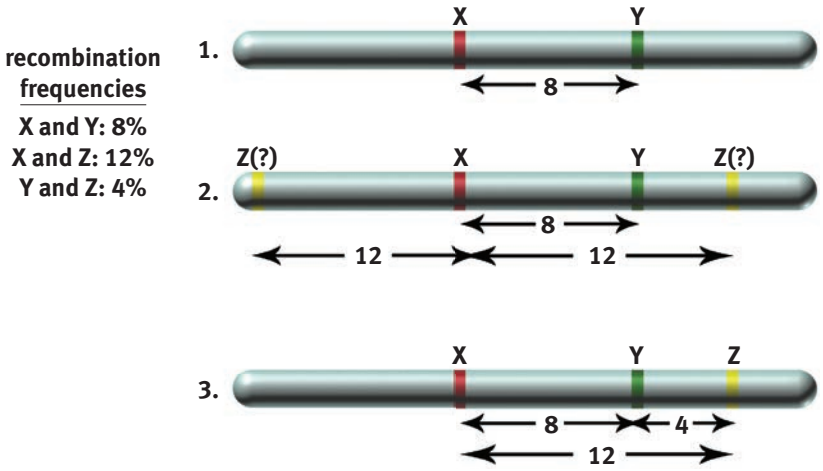

Figure 12.10. Genetic Maps from Recombination Frequencies
If the recombination frequencies are known, one can deduce the order of genes on the chromosome because map units are roughly additive.

HARDY–WEINBERG PRINCIPLE

How often an allele appears in a population is known as its **allele frequency**. For example, if we took a one-cell sample from 50 of Mendel's plants, we could collect 100 copies of alleles for flower color (two from each cell). If 75 of these alleles were the dominant allele, we could say that the allele frequency of P is $75 \div 100 = 0.75$. Note that this does not indicate which flowers contain the allele, or if those flowers are homozygous or heterozygous; it only tells us the representation of the allele across all chromosomes in the population. Evolution results from changes in these gene frequencies in reproducing populations over time. However, when the gene frequencies of a population are not changing, the gene pool is stable, and evolution is ostensibly *not* occurring. Five criteria must be met for this to be possible:

- The population is very large (no genetic drift).
- There are no mutations that affect the gene pool.
- Mating between individuals in the population is random (no sexual selection).
- There is no migration of individuals into or out of the population.
- The genes in the population are all equally successful at reproducing.

Provided that all of these conditions are met, the population is said to be in **Hardy–Weinberg equilibrium**, and a pair of equations can be used to predict the allelic and phenotypic frequencies.

Let us define a particular gene as having only two possible alleles, T and t. We will define p to be the frequency of the dominant allele T and q to be the frequency of the recessive allele t. Because there are only these two choices at the same gene locus, $p + q = 1$. That is, the combined allele frequencies of T and t must equal 100 percent. If we square both sides of the equation, we get:

$$(p + q)^2 = 1^2$$
$$p^2 + 2pq + q^2 = 1$$

where p^2 is the frequency of the TT (homozygous dominant) genotype, $2pq$ is the frequency of the Tt (heterozygous dominant) genotype, and q^2 is the frequency of the tt (homozygous recessive) genotype. Note that the sum $p^2 + 2pq$ would represent the frequency of the dominant *phenotype* (both homozygous and heterozygous dominant genotypes).

Key Concept

All you need to know to solve any MCAT Hardy–Weinberg problem is the value of p (or p^2) or q (or q^2). From there, you can calculate everything else using $p + q = 1$ and $p^2 + 2pq + q^2 = 1$.

For Test Day, you should be aware of the two key Hardy–Weinberg equations demonstrated above:

$$p + q = 1$$
$$p^2 + 2pq + q^2 = 1$$

Equation 12.1

Key Concept

The Hardy–Weinberg equations allow you to find two pieces of information: first, the relative frequency of alleles in a population and, second, the frequency of a given genotype or phenotype in the population. Remember that there will be twice as many alleles as individuals in a population—because each individual has two autosomal copies of each gene.

We should be aware that each equation provides us with different information. The first tells us about the frequency of *alleles* in the population, whereas the second provides information about the frequency of *genotypes* and *phenotypes* in the population.

These equations can also be used to demonstrate that evolution is *not* occurring in a population. Assuming that the conditions listed earlier are met, the allele frequencies will remain constant from generation to generation. For example, imagine that we have a population of Mendel's pea plants in which the frequency of the tall allele, T, is 0.80. This value is represented by p. This means that q (the short allele, t) is 0.20 by subtraction. Setting up our F_1 cross for two heterozygotes, we can see the results of such a mating:

	$p = 0.80$ (T = 80%)	$q = 0.20$ (t = 20%)
$p = 0.80$ (T = 80%)	$p^2 = 0.64$ (TT = 64%)	$pq = 0.16$ (Tt = 16%)
$q = 0.20$ (t = 20%)	$pq = 0.16$ (Tt = 16%)	$q^2 = 0.04$ (tt = 4%)

We see that the filial generation contains 64 percent homozygous tall, 32 percent heterozygous tall, and 4 percent homozygous short plants. These are the genotypic frequencies. We can determine the allele frequencies in this generation as follows:

64% TT = 64% T	and	0% t
32% Tt = 16% T	and	16% t
4% tt = 0% T	and	4% t
allele frequencies = 80% T	and	20% t

Notice that the allele frequencies are unchanged compared to the parent generation. T is still 0.80 and t is still 0.20. Populations in Hardy–Weinberg equilibrium will exhibit this property.

MCAT Concept Check 12.3:

Before you move on, assess your understanding of the material with these questions.

1. For each of the crosses below, what is the phenotypic ratio seen in the offspring?

Cross	Phenotypic Ratio
Bb × Bb	
Aa × aa	
DdEe × ddEE	
$X_qX \times XY$	
$X_rX \times X_rY$	

2. If genes Q and R have a recombination frequency of 2%, genes R and S have a recombination frequency of 6%, genes S and T have a recombination frequency of 23%, and genes Q and T have a recombination frequency of 19%, then what is the order of these four genes in the chromosome?

_____

_____

3. All five criteria of the Hardy–Weinberg principle are required to imply what characteristic of the study population?

_____

4. Assume that a population is in Hardy–Weinberg equilibrium. If 9% of the population is homozygous dominant, then solve for the following:
   - The frequency of the dominant allele:

     _____
   - The frequency of the recessive allele:

     _____

- The portion of the population that is heterozygous:

_____

- The portion of the population with a homozygous recessive genotype:

_____

- The portion of the population with a dominant phenotype:

_____

12.4 Evolution ★★★

The development of evolutionary thought has a relatively short history; the first theories suggesting that new species may arise from older ones were proposed in the 19th century. Significant alterations to these initial theories have been made since then.

NATURAL SELECTION

Natural selection, sometimes phrased as *survival of the fittest*, is the theory that certain characteristics or traits possessed by individuals within a species may help those individuals to have greater reproductive success, thus passing on those traits to offspring. This theory was originally proposed by Charles Darwin in his 1859 publication *On the Origin of Species*. His theory was built on several basic tenets including:

- Organisms produce offspring, few of which survive to reproductive maturity.
- Chance variations within individuals in a population may be heritable. If these variations give an organism a slight survival advantage, the variation is termed **favorable**.
- Individuals with a greater preponderance of these favorable variations are more likely to survive to reproductive age and produce offspring; the overall result will be in an increase in these traits in future generations. This level of reproductive success is termed **fitness**, and an organism's fitness is directly related to the relative genetic contribution of this individual to the next generation.

Darwin's theory was ultimately proven to be correct in many ways, although not completely. In the 20th century, the field of modern genetics led to the development of the currently accepted theory.

Key Concept

Evolution is not equivalent to natural selection. The MCAT likes to test your ability to understand that natural selection is simply a mechanism for evolution. Natural selection is, however, equivalent to *survival of the fittest*.

Modern Theories

The **modern synthesis model**, sometimes called **neo-Darwinism**, adds knowledge of genetic inheritance and changes in the gene pool to Darwin's original theory. Once scientists showed that inheritance occurs through the passing of genes from parent to child, and that genes ultimately change due to mutation or recombination, Darwin's theory was updated to its current form: when mutation or recombination results in a change that is favorable to the organism's reproductive success, that change is more likely to pass on to the next generation; the opposite is also true. This process is termed **differential reproduction**. Over time, those traits passed on by the more successful organisms will become ubiquitous in the gene pool. Because it is the gene pool that changes over time, it is important to note that it is populations that evolve, not individuals.

Also germane to the modernization of Darwin's theory is a shift in scope to focus on inclusive fitness over the fitness of an individual organism. **Inclusive fitness** is a measure of an organism's success in the population. This is based on the number of offspring, success in supporting offspring, and the ability of the offspring to then support others. Early descriptions of evolutionary success, like those of Darwin, were based solely on the number of viable offspring of an organism. However, contemporary theories take into account the benefits of certain behaviors on the population at large. For example, the existence of altruism could be supported by the observation that close relatives of an individual will share many of the same genes; thus, promoting the reproduction and survival of related or similar individuals can also lead to genetic success. Other species show examples of inclusive fitness by protecting the offspring of the group at large. By sacrificing themselves to protect the young, these organisms ensure the passing of genes to future generations. Inclusive fitness therefore promotes the idea that altruistic behavior can improve the fitness and success of a species as a whole.

One final theory to consider was proposed as a result of research into the fossil record. Upon examination, it was discovered that little evolution would occur within a lineage of related lifeforms for long periods of time, followed by a massive explosion of evolutionary change. Niles Eldridge and Stephen Jay Gould proposed the theory of **punctuated equilibrium** to explain this in 1972. In contrast to Darwin's theory, punctuated equilibrium suggests that changes in some species occur in rapid bursts rather than evenly over time.

Modes of Natural Selection

Natural selection may occur as stabilizing selection, directional selection, or disruptive selection, as shown in Figure 12.11.

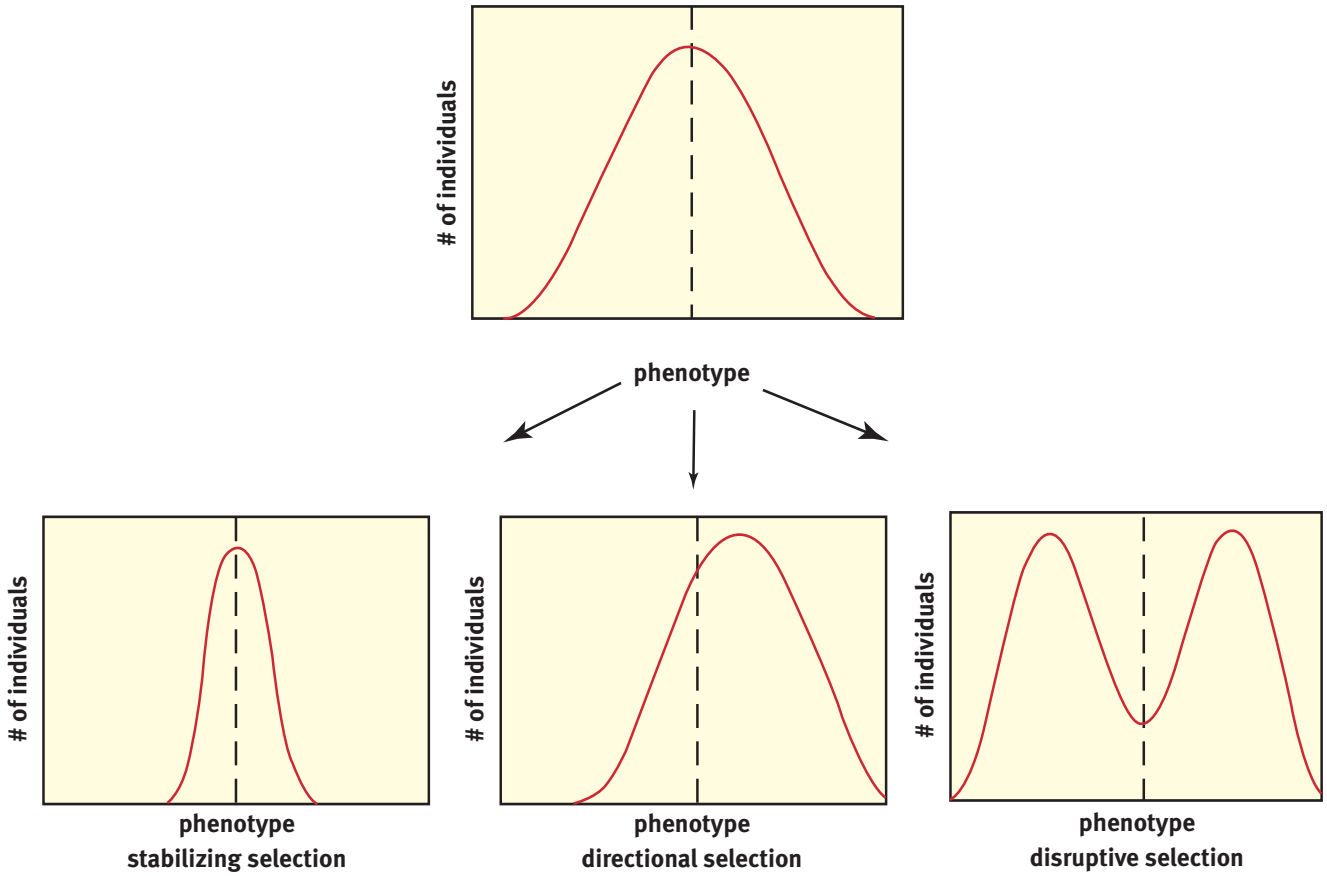

Figure 12.11. Modes of Natural Selection

Stabilizing selection keeps phenotypes within a specific range by selecting against extremes. For instance, human birth weight is maintained within a narrow band by stabilizing selection. Fetuses that weigh too little may not be healthy enough to survive, and fetuses that weigh too much can experience trauma during delivery through the relatively narrow birth canal. In addition, the larger the fetus, the more resources it requires from the mother. For all of these reasons, it is advantageous to keep birth weights within a narrow range.

Adaptive pressure can lead to the emergence and dominance of an initially extreme phenotype through **directional selection**. For example, if we have a heterogeneous plate of bacteria, very few may have resistance to antibiotics. If the plate is then treated with *ampicillin* (an antibiotic), only those colonies that exhibit resistance to this antibiotic will survive. A new standard phenotype emerges as a result of differential survivorship. Natural selection is the history of differential survivorship over time. The emergence of mosquitoes resistant to *dichlorodiphenyltrichloroethane* (DDT), a type of pesticide, is attributed to directional selection.

In **disruptive selection**, two extreme phenotypes are selected over the norm. When Darwin studied finches on the Galapagos Islands, he noted that although there were many species, all the species arguably had a common ancestor, given their similar appearances. However, when he compared beak sizes, they were all either large or small, as shown in Figure 12.12. No animals exhibited the intermediate phenotype of medium-size beaks. Darwin hypothesized that the sizes of seeds on the island (the finches' food) led to this effect. Seeds were either quite large or fairly small, requiring a large or small beak, respectively. Thus, if the original ancestor had a medium-size beak, over time, the animals with slightly larger or smaller beaks would be selected. Disruptive selection is facilitated by the existence of **polymorphisms**; that is, naturally occurring differences in form between members of the same population, such as light and dark coloration in the same species of butterfly. **Adaptive radiation** is a related concept that describes the rapid rise of a number of different species from a common ancestor. The benefit of adaptive radiation is that it allows the various species to occupy different **niches** (specific ways of life, including habitat location and utilization of resources), decreasing competition for limited resources.

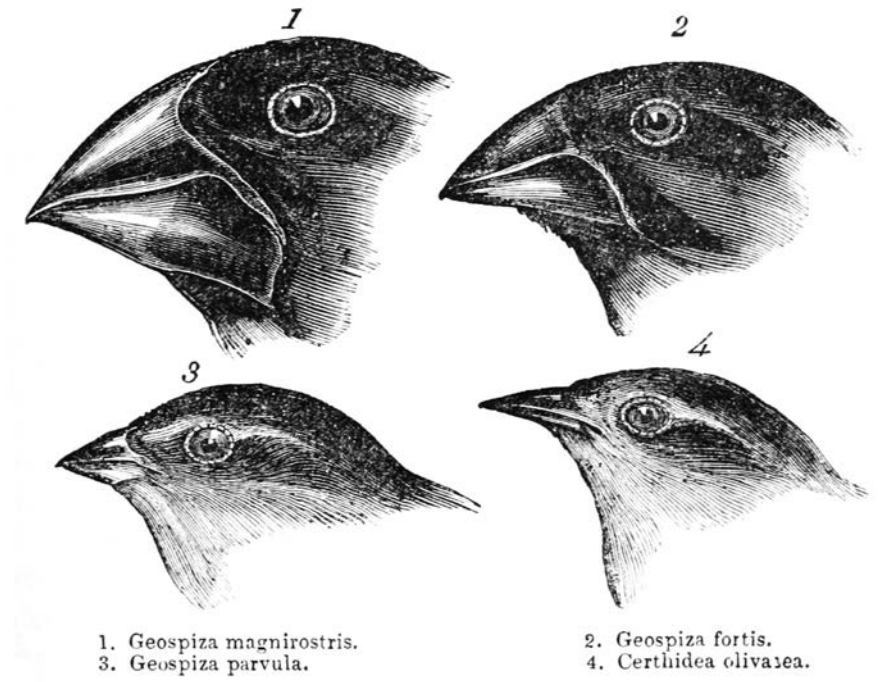

Figure 12.12. Darwin's Finches
Image drawn by Darwin in 1845.

SPECIATION

A **species** is defined as the largest group of organisms capable of breeding to form fertile offspring; the formation of a new species through evolution is called **speciation**. If we took two populations from the same species and separated them geographically for a long period of time, different evolutionary pressures would lead to different adaptive changes. If enough time passed, the changes would be sufficient to lead to **isolation**, in which the progeny of these populations could no longer freely interbreed. We would now consider the two groups separate species. Reproductive isolation may occur either prezygotically or postzygotically. **Prezygotic mechanisms** prevent formation of the zygote completely; **postzygotic mechanisms** allow for gamete fusion but yield either nonviable or sterile offspring. Examples of prezygotic mechanisms include temporal isolation (breeding at different times), ecological isolation (living in different niches within the same territory), behavioral isolation (a lack of attraction between members of the two species due to differences in pheromones, courtship displays, and so on), reproductive isolation (incompatibility of reproductive anatomy), or gametic isolation (intercourse can occur, but fertilization cannot). Postzygotic mechanisms include hybrid inviability (formation of a zygote that cannot develop to term), hybrid sterility (forming hybrid offspring that cannot reproduce), and hybrid breakdown (forming first-generation hybrid offspring that are viable and fertile, but second-generation hybrid offspring that are inviable or infertile). As described earlier in this chapter, mules are an example of postzygotic hybrid sterility. Although a horse and donkey can produce a viable mule, the mule will be sterile and thus unable to contribute to a self-perpetuating mule lineage.

Patterns of Evolution

When we look at similarities between two species, we must be careful to determine whether those similarities are due to sharing a common ancestor or sharing a common environment with the same evolutionary pressures. When analyzing species this way, three patterns of evolution emerge: divergent evolution, parallel evolution, and convergent evolution, as shown in Figure 12.13.

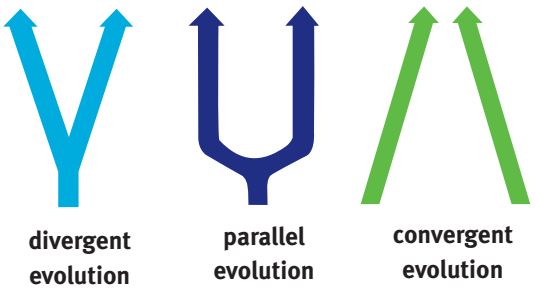

Figure 12.13. Patterns of Evolution

Divergent evolution refers to the independent development of dissimilar characteristics in two or more lineages sharing a common ancestor. For example, seals and cats are both mammals in the order Carnivora, yet they differ markedly in general appearance. These two species live in very different environments and adapted to different selection pressures while evolving.

Parallel evolution refers to the process whereby related species evolve in similar ways for a long period of time in response to analogous environmental selection pressures.

Convergent evolution refers to the independent development of similar characteristics in two or more lineages not sharing a recent common ancestor. For example, fish and dolphins have come to resemble one another physically, although they belong to different classes of vertebrates. They evolved certain similar features in adapting to the conditions of aquatic life.

MEASURING EVOLUTIONARY TIME

Evolution is a slow process, featuring changes in the environment and subsequent changes in genotypes and phenotypes of a population over time. The rate of evolution is measured by the rate of change of a genotype over a period of time and is related to the severity of the evolutionary pressures put on the species. In other words, if a species is already perfectly suited to its habitat and there are no changes to the conditions in which it lives, the rate of evolution will be exceedingly slow—although there will still be some small base rate of genetic mutation. On the other hand, if an organism lives in a rapidly changing environment, the rate of evolution will be greater, as selection for and against certain traits will be actively occurring within that population.

By comparing DNA sequences between different species, scientists can quantify the degree of similarity between two organisms. For example, chimpanzees share over 95 percent of their genome with humans, whereas mice share only about 70 percent. As species become more taxonomically distant, the proportion of shared genome will decrease. Molecular evolutionists correlate the degree of genomic similarity with the amount of time since two species split off from the same common ancestor; the more similar the genomes, the more recently the two species separated from each other. This is sometimes called the **molecular clock model**.

MCAT Concept Check 12.4:
Before you move on, assess your understanding of the material with these questions.

1. What are the key tenets of each of the following theories of evolution?
   - Natural selection:

     _____
   - Modern synthesis model:

     _____
   - Inclusive fitness:

     _____
   - Punctuated equilibrium:

     _____
2. What are the three patterns of selection? What changes would each create to the population phenotype?

Pattern of Selection	Change to Population Phenotype

3. What are the three patterns of evolution between species? What is the outcome of each one?

Pattern of Evolution	Outcome

4. What is the biological definition of a species?

_____

_____

Conclusion

Genetics and the mechanisms of evolution are becoming increasingly important in medicine, as we unintentionally breed strains of highly resistant bacteria. Antibiotic stewardship, or the use of the appropriate antibiotics only as necessary, is very important as the medical community seeks to preserve the effectiveness of antibiotics.

In order to understand and apply the concepts of antibiotic stewardship, one must be aware of how creating environmental pressures leads to directional selection in microorganisms and can increase the frequency of the resistant phenotype. In this chapter, we covered genetics and mutations, as well as evolution. We also gave you some tools to analyze the biometric (statistical) side of genetics through the use of Punnett squares, recombinant frequencies, and the Hardy–Weinberg equations.

It seems fitting to complete this book with a discussion of evolution. You've spent hundreds of pages (and hours!) preparing for the MCAT, learning the basics of cell biology, embryogenesis and development, anatomy and physiology, genetics, and evolution. Our understanding of these topics relies on generations and generations of scientists who came before us, and who passed down their knowledge through books, letters, articles, lectures, and—more recently—television, film, and popular media. But science is a field that is constantly evolving, itself. At the beginning of medical school, students are often told that no more than 25 percent of what they learn during the first year will remain true by the time they enter practice. We're not sure if this statistic actually holds, but it does bespeak the importance of staying on top of the latest research—not only as a medical student, but also once in practice. Every day, new discoveries about the human body and the practice of medicine are being made—and soon, you'll be one of those making these very discoveries and bringing them to patients, improving their lives. And at the end of it all, as a provider, an attending physician, a researcher, you too will pass your knowledge to future generations of physicians, who will also help medical science to evolve and improve. The human body is astoundingly complex. Take a moment to genuinely think about that—*the human body is astoundingly complex*. There's so much more to learn; medical school and your future awaits!

CONCEPT SUMMARY

Fundamental Concepts of Genetics

- **Chromosomes** contain **genes** in a linear sequence.
- **Alleles** are alternative forms of a gene.
  - A **dominant** allele requires only one copy to be expressed.
  - A **recessive** allele requires two copies to be expressed.
- A **genotype** is the combination of alleles one has at a given genetic **locus**.
  - Having two of the same allele is termed **homozygous**.
  - Having two different alleles is termed **heterozygous**.
  - Having only one allele is termed **hemizygous** (such as male sex chromosomes).
  - A **phenotype** is the observable manifestation of a genotype.
- There are different patterns of dominance.
  - **Complete dominance** has one dominant allele and one recessive allele.
  - **Codominance** has more than one dominant allele.
  - **Incomplete dominance** has no dominant alleles; heterozygotes have intermediate phenotypes.
- **Penetrance** is the proportion of a population with a given genotype who express the phenotype.
- **Expressivity** refers to the varying phenotypic manifestations of a given genotype.
- The modern interpretations of Mendel's laws help explain the inheritance of genes from parent to offspring.
  - **Mendel's first law (of segregation)** states that an organism has two alleles for each gene, which segregate during meiosis, resulting in gametes carrying only one allele for a trait.
  - **Mendel's second law (of independent assortment)** states that the inheritance of one allele does not influence the probability of inheriting a given allele for a different trait.
- Support for DNA as genetic material came through a number of experiments.
  - The Griffith experiment demonstrated the transforming principle, converting non-virulent bacteria into virulent bacteria by exposure to heat-killed virulent bacteria.
  - The Avery–MacLeod–McCarty experiment demonstrated that DNA is the genetic material because degradation of DNA led to a cessation of bacterial transformation.
  - The Hershey–Chase experiment confirmed that DNA is the genetic material because only radiolabeled DNA could be found in bacteriophage-infected bacteria.

Changes in the Gene Pool

- All of the alleles in a given population constitute the **gene pool**.
- **Mutations** are changes in DNA sequence.
- Nucleotide mutations include **point mutations** (the substituting of one nucleotide for another) and **frameshift mutations** (moving the three-letter transcriptional reading frame).
  - A **silent mutation** has no effect on the protein.
  - A **missense mutation** results in the substitution of one amino acid for another.
  - A **nonsense mutation** results in the substitution of a stop codon for an amino acid.
  - **Insertions** and **deletions** result in a shift in the **reading frame**, leading to changes for all downstream amino acids.
- Chromosomal mutations include much larger-scale mutations affecting whole segments of DNA.
  - **Deletion mutations** occur when a large segment of DNA is lost.
  - **Duplication mutations** occur when a segment of DNA is copied multiple times.
  - **Inversion mutations** occur when a segment of DNA is reversed.
  - **Insertion mutations** occur when a segment of DNA is moved from one chromosome to another.
  - **Translocation mutations** occur when a segment of DNA is swapped with a segment of DNA from another chromosome.
- Genetic **leakage** is a flow of genes between species through hybrid offspring.
- **Genetic drift** occurs when the composition of the gene pool changes as a result of chance.
- The **founder effect** results from **bottlenecks** that suddenly isolate a small population, leading to **inbreeding** and increased prevalence of certain homozygous genotypes.

Analytical Approaches in Genetics

- **Punnett squares** visually represent the crossing of gametes from parents to show relative genotypic and phenotypic frequencies.
  - The **parent generation** is represented by P; **filial** (offspring) **generations** are represented by F_1, F_2, and so on in sequence.
  - A **monohybrid cross** accounts for one gene; a **dihybrid cross** accounts for two genes.

- In **sex-linked crosses**, sex chromosomes are usually used to indicate sex as well as genotype.
  - The **recombination frequency** (***θ***) is the likelihood of two alleles being separated during crossing over in meiosis. **Genetic maps** can be made using recombination frequency as the scale, in **centimorgans**.
  - The **Hardy–Weinberg principle** states that if a population meets certain criteria (aimed at a lack of evolution), then the **allele frequencies** will remain constant (**Hardy–Weinberg equilibrium**).

Evolution

- **Natural selection** states that chance variations exist between individuals, and that advantageous variations—those that increase an individual's **fitness** for the environment—afford the most opportunity for reproductive success.
- The **modern synthesis model** (**neo-Darwinism**) accounts for mutation and recombination as mechanisms of variation and considers **differential reproduction** to be the mechanism of reproductive success.
- **Inclusive fitness** considers an organism's success to be based on the number of offspring, success in supporting offspring, and the ability of the offspring to then support others; survival of offspring or relatives ensures continuation of genes in subsequent generations.
- **Punctuated equilibrium** considers evolution to be a very slow process with intermittent rapid bursts of evolutionary activity.
- Different types of selection lead to changes in phenotypes.
  - **Stabilizing selection** keeps phenotypes in a narrow range, excluding extremes.
  - **Directional selection** moves the average phenotype toward one extreme.
  - **Disruptive selection** moves toward two different phenotypes at the extremes and can lead to **speciation**.
  - **Adaptive radiation** is the rapid emergence of multiple species from a common ancestor, each of which occupies its own ecological **niche**.
- A **species** is the largest group of organisms capable of breeding to form fertile offspring. Species are **reproductively isolated** from each other by **pre-** or **postzygotic mechanisms**.
- Two species can evolve with different relationship patterns.
  - **Divergent evolution** occurs when two species sharing a common ancestor become more different.

- **Parallel evolution** occurs when two species sharing a common ancestor evolve in similar ways due to analogous selection pressures.
- **Convergent evolution** occurs when two species not sharing a recent ancestor evolve to become more similar due to analogous selection pressures.

- According to the **molecular clock model**, the degree of difference in the genome between two species is related to the amount of time since the two species broke off from a common ancestor.

ANSWERS TO CONCEPT CHECKS

12.1

1. A dominant allele is one that requires only one copy for expression. A recessive allele requires two copies for expression.
2. A homozygous genotype is one in which the two alleles are the same. A heterozygous genotype is one in which the two alleles are different. A hemizygous genotype is one in which only one allele is present for a given gene (such as parts of the X chromosome in males).
3. Complete dominance occurs when a gene has only one dominant and one recessive allele. Codominance occurs when a gene has more than one dominant allele, and two different dominant alleles can be expressed simultaneously. Incomplete dominance occurs when a gene has no dominant alleles, and heterozygotes have phenotypes that are intermediate between homozygotes.
4. Penetrance describes the proportion of the population that expresses a phenotype, given a particular genotype. Expressivity describes the differences in expression (severity, location, and so on) of a phenotype across affected members of a population.
5. Mendel's first law (of segregation) most aligns with anaphase I of meiosis. Mendel's second law (of independent assortment) most aligns with prophase I of meiosis.

12.2

1. Silent point mutations occur when one nucleotide is changed for another, but there is no change in the protein coded for by this DNA sequence (due to redundancy in the genetic code). Missense mutations occur when one nucleotide is changed for another, and one amino acid is substituted for another in the final protein. Nonsense mutations occur when one nucleotide is changed for another, and a stop codon substitutes for an amino acid in the final protein.
2. The two types of frameshift mutations are insertion and deletion mutations.
3. Duplication mutations occur when a segment of DNA is copied multiple times in the genome. Inversion mutations occur when a segment of DNA is reversed in the genome. Translocation mutations occur when a segment of DNA from one chromosome is swapped with a segment of DNA from another chromosome.
4. Genetic leakage requires the formation of a hybrid organism that can then mate with members of one or the other parent species. While hybrids existed historically (especially mules), fertile hybrids were certainly rare before a more modern understanding of genetics (and a commercial, financial, or academic impetus to create these organisms).

5. Genetic drift occurs due to chance, so its effects will be more pronounced with a smaller sample size (in smaller populations). The founder effect occurs when a small group is reproductively isolated from the larger population, allowing certain alleles to take on a higher prevalence in the group than the rest of the population.

12.3

1.

Cross	Phenotypic Ratio
Bb × Bb	3 dominant:1 recessive
Aa × aa	1 dominant:1 recessive
DdEe × ddEE	1 dominant (for D)/dominant (for E): 1 recessive (for D)/dominant (for E)
$X_qX \times XY$	Female: all unaffected; male: 1 unaffected:1 affected
$X_rX \times X_rY$	Both male and female: 1 unaffected:1 affected

2. The genes must be in the order SQRT: S $\overset{4\%}{\longleftrightarrow}$ Q $\overset{2\%}{\longleftrightarrow}$ R $\overset{17\%}{\longleftrightarrow}$ T.
3. The criteria for the Hardy–Weinberg principle all imply that the study population is *not* undergoing evolution; thus, the allele frequencies will remain stable over time.
4. The frequency of the dominant allele (p) is 0.3. The frequency of the recessive allele (q) is 0.7. The fraction of the population with a heterozygous genotype ($2pq$) is $2 \times 0.3 \times 0.7 = 0.42$ (42%). The fraction of the population with a homozygous recessive genotype (q^2) is $(0.7)^2 = 0.49$ (49%). The fraction of the population with a dominant phenotype ($p^2 + 2pq$) is $0.09 + 0.42 = 0.51 = 51\%$.

12.4

1. Natural selection states that certain traits that arise from chance are more favorable for reproductive success in a given environment, and that those traits will be passed on to future generations. The modern synthesis model takes natural selection and explains that selection is for specific alleles, which are passed to future generations through formation of gametes, and that these favorable traits arise from mutations. Inclusive fitness explains that the reproductive success of an organism is not only due to the number of offspring it creates, but also the ability to care for young (that can then care for others); it explains changes not only at the individual level, but based on the survival of the species (and that individual's alleles within the species, including in other related individuals). Punctuated equilibrium states that for some species, little evolution occurs for a long period, which is interrupted by rapid bursts of evolutionary change.

2.

Pattern of Selection	Change to Population Phenotype
Stabilizing	Loss of extremes, maintenance of phenotype in a small window
Directional	Movement toward one extreme or the other
Disruptive	Movement toward both extremes with loss of the norm; speciation may occur

3.

Pattern of Evolution	Outcome
Divergent	Two species with a common ancestor become less similar because of different evolutionary pressures
Parallel	Two species with a common ancestor remain similar because of similar evolutionary pressures
Convergent	Two species with no recent common ancestor become more similar because of similar evolutionary pressures

4. A species is defined as the largest group of organisms capable of breeding to form fertile offspring.

EQUATIONS TO REMEMBER

(12.1) **Hardy–Weinberg equations:** $p + q = 1$

$$p^2 + 2pq + q^2 = 1$$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. What is the gene order of linked genes M, N, O, and P, given the following recombination frequencies?

MN: 6% NO: 18%
MO: 12% NP: 1%
MP: 5% OP: 17%

A. MOPN
B. NPMO
C. ONPM
D. PNMO

2. Suppose that in a mammalian species, the allele for black hair (B) is dominant to the allele for brown hair (b), and the allele for curly hair (C) is dominant to the allele for straight hair (c). When an organism of unknown genotype is crossed against one with straight, brown hair, the phenotypic ratio is as follows:

25% curly black hair
25% straight black hair
25% curly brown hair
25% straight brown hair

What is the genotype of the unknown parent?

A. BbCC
B. bbCc
C. Bbcc
D. BbCc

3. If a male with hemophilia (X_hY) is crossed with a female carrier of both color blindness and hemophilia (X_cX_h), what is the probability that a female child will be phenotypically normal?

A. 0%
B. 25%
C. 50%
D. 100%

4. If a test cross on a species of plant reveals the appearance of a recessive phenotype in the offspring, what must be true of the phenotypically dominant parent?

A. It must be genotypically heterozygous.
B. It must be genotypically homozygous.
C. It could be either genotypically heterozygous or homozygous.
D. It must have the same genotype as the test cross control parent.

5. Which of the following definitions is FALSE?

A. Penetrance—the percentage of individuals in the population carrying the allele who actually express the phenotype associated with it
B. Expressivity—the percentage of individuals in the population carrying the allele who do not express the phenotype associated with it
C. Incomplete dominance—occurs when the phenotype of the heterozygote is an intermediate of the phenotypes of the homozygotes
D. Codominance—occurs when multiple alleles exist for a given gene and more than one of them is dominant

6. In a species of plant, a homozygous red flower (RR) is crossed with a homozygous yellow flower (rr). If the F_1 generation is self-crossed and the F_2 generation has a phenotypic ratio of red:orange:yellow of 1:2:1, which characteristic accounts for these results?

A. Codominance
B. Incomplete dominance
C. Penetrance
D. Expressivity

7. Which of the following statements is INCORRECT regarding inheritance of traits according to the modern synthesis model?

A. A mutation due to excessive amounts of ultraviolet light occurs in an unfertilized egg; this will affect the child who is born from that egg.
B. The muscular strength gained by a weight lifter during his lifetime is inherited by his children.
C. A green-feathered bird that survived all of the predators in the forest will pass on the green feather genes to its offspring.
D. A flower with a tasty nectar eaten by a butterfly is more likely to pass on its genes through the pollen spread by the butterfly then a flower with less desirable nectar.

8. Which of the following statements is FALSE based on Darwin's theory of evolution?

A. Natural selection is the driving force for evolution.
B. Favorable genetic variations become more and more common in individuals throughout their lives.
C. Natural selection can drive organisms living in groups to ultimately become distinct species.
D. Fitness is measured by reproductive success.

9. Which of the following is NOT a necessary condition for Hardy–Weinberg equilibrium?

A. Large population size
B. No mutations
C. Monogamous mating partners
D. No migration into or out of the population

10. As the climate became colder during the Ice Age, a particular species of mammal evolved a thicker layer of fur. What kind of selection occurred in this population?

A. Stabilizing selection
B. Directional selection
C. Disruptive selection
D. Speciation selection

11. At what point are two populations descended from the same ancestral stock considered to be separate species?

A. When they can no longer produce viable, fertile offspring.
B. When they look significantly different from each other.
C. When they can interbreed successfully and produce offspring.
D. When their habitats are separated by a significantly large distance so that they cannot meet.

12. In a nonevolving population, there are two alleles, R and r, which code for the same trait. The frequency of R is 30 percent. What are the frequencies of all the possible genotypes?

A. 49% RR, 42% Rr, 9% rr
B. 30% RR, 21% Rr, 49% rr
C. 0.09% RR, 0.42% Rr, 0.49% rr
D. 9% RR, 42% Rr, 49% rr

13. In a particular Hardy–Weinberg population, there are only two eye colors: brown and blue. Of the population, 36% have blue eyes, the recessive trait. What percentage of the population is heterozygous?

A. 24%
B. 48%
C. 60%
D. 64%

14. Which of the following was NOT a belief of Darwin's?

A. Evolution of species occurs gradually and evenly over time.
B. There is a struggle for survival among organisms.
C. Genetic recombination and mutation are the driving forces of evolution.
D. Those individuals with fitter variations will survive and reproduce.

15. A child is born with a number of unusual phenotypic features and genetic testing is performed. The child is determined to have partial trisomy 21, with three copies of some segments of DNA from chromosome 21, and partial monosomy 4, with only one copy of some segments of DNA from chromosome 4. Which of the following mutations could have occurred in one of the parental gametes during development to explain both findings?

A. Deletion
B. Insertion
C. Translocation
D. Inversion

Explanations to Discrete Practice Questions

1. B

This is a gene-mapping problem. Because there is a correlation between the frequency of recombination and the distance between genes on a chromosome, if we are given the frequencies, we can determine gene order. Remember that one map unit equals 1 percent recombination frequency. The easiest way to begin is to determine the two genes that are farthest apart; in this case, N and O recombine with a frequency of 18%, so they are 18 map units apart on the chromosome:

$$N \xleftarrow{18\%} O$$

N and P recombine with 1% frequency, and P and O recombine with 17% frequency, so P must be between N and O:

$$N \xleftarrow{1\%} P \xleftarrow{17\%} O$$

Finally, M and P recombine with 5% frequency, and M and O recombine with 12% frequency, so M must be between P and O:

$$N \xleftarrow{1\%} P \xleftarrow{5\%} M \xleftarrow{12\%} O$$

2. D

In this dihybrid problem, a doubly recessive individual is crossed with an individual of unknown genotype; this is known as a test cross. The straight- and brown-haired organism has the genotype bbcc and can thus only produce gametes carrying bc. Looking at the F_1 offspring, there is a 1:1:1:1 phenotypic ratio. The fact that both the dominant and recessive traits are present in the offspring means that the unknown parental genotype must contain both dominant and recessive alleles for each trait. The unknown parental genotype must therefore be BbCc. If you want to double-check the answer, you can work out the Punnett square for the cross BbCc × bbcc:

	BC	Bc	bC	bc
bc	BbCc	Bbcc	bbCc	bbcc
bc	BbCc	Bbcc	bbCc	bbcc
bc	BbCc	Bbcc	bbCc	bbcc
bc	BbCc	Bbcc	bbCc	bbcc
	25% black curly	25% black straight	25% brown curly	25% brown straight

3. C

The female in this example is a carrier of two sex-linked traits; based on her genotype, the affected alleles are found on different X chromosomes. Drawing out a Punnett square, we see that 25% of the offspring will be female hemophiliacs (X_hX_h) and 25% will be female carriers of both alleles (X_cX_h). This question is asking what percentage of females will have a normal phenotype, which would be half of the females (those who are carriers for both traits).

	X_c	X_h
X_h	X_cX_h	X_hX_h
Y	X_cY	X_hY

<u>offspring</u>
25% female hemophiliac
25% female carrier of both traits (phenotypically normal)
25% male hemophiliac
25% male colorblind

4. A

The control parent in a test cross is always recessive. Therefore, if the test parent is phenotypically dominant, yet can provide a recessive allele (as evidenced by the presence of recessive children), then the parent must have both a dominant and recessive allele. Therefore, this test parent must by heterozygous.

5. B

The definition given here for expressivity is a much better match for defining penetrance (or, really, one minus the penetrance). Expressivity refers to the variable manifestations of a given genotype as different phenotypes; the degree to which various phenotypes are expressed. All of the other definitions given are accurate.

6. B

Some progeny in the second generation are apparently blends of the parental phenotypes. The orange color is the result of the combined effects of the red and yellow alleles. An allele is incompletely dominant if the phenotype of the heterozygotes is an intermediate of the phenotypes of the homozygotes.

7. B

To find the correct answer, we have to read each choice and eliminate the ones that fit with the modern-day theories of inheritance, which state that the genes that make an organism most fit for its environment will be passed to offspring. This can be seen in **choice (C)** and **(D)**, both of which demonstrate that an organism with improved fitness will pass those genes to offspring. **Choice (A)** mentions a gamete being exposed to mutagens; a zygote created from this gamete would contain any mutations in the egg and would be affected by them. Thus, **choice (B)** must be the correct answer: indeed, acquired characteristics not encoded in the genome should not be passed to offspring according to the modern synthesis model.

8. B

Darwin's theory of natural selection argues that chance variations between organisms can help certain organisms survive to reproductive age and produce many offspring, transmitting their variations to the next generation. Thus, natural selection would drive the process of evolution forward, enabling the survival of characteristics that impart an advantage in the environment, eliminating **choice (A)**. In Darwin's theory, fitness is measured in terms of reproductive success, as **choice (D)** states. Through natural selection, organisms may be separated in groups depending on environmental pressures, and these groups can eventually separate to the point of becoming distinct species, eliminating **choice (C)**. **Choice (B)** is the correct answer because the theory of natural selection applies to a population of organisms, not to a particular individual. As such, favorable genetic variations become more and more common from generation to generation, not during the lifetime of an individual.

9. C

Hardy–Weinberg equilibrium exists in certain ideal conditions that, when satisfied, allow one to calculate the gene frequencies within a population. The Hardy–Weinberg equation can be applied only under these five conditions: (1) the population is very large; (2) there are no mutations that affect the gene pool; (3) mating between individuals in the population is random; (4) there is no migration of individuals into or out of the population; (5) the genes in the population are all equally successful at reproduction. Thus, from the given choices, only **choice (C)** is false: monogamy is not a necessary condition for the Hardy–Weinberg equations to be applied.

10. B

The situation described in the question stem is an example of directional selection. In directional selection, the phenotypic norm of a particular species shifts toward an extreme to adapt to a selective pressure, such as an increasingly colder environment. Only those individuals with a thicker layer of fur were able to survive during the Ice Age, thus shifting the phenotypic norm.

11. A

A species is defined as the largest group of organisms that can interbreed to produce viable, fertile offspring. Therefore, two populations are considered separate species when they can no longer do so.

12. D

Let's use the information provided by the question stem to set up our equations. We are told that the frequency of R equals 30%, and as such, $p = 0.30$. The frequency of the recessive gene r = 100% – 30% = 70%; thus, $q = 0.70$. The frequency of the genotypes, according to the Hardy–Weinberg equilibrium, are given by p^2 = RR, $2pq$ = Rr, and q^2 = rr. Therefore, the frequency of the genotypes are $(0.3)^2 = 0.09 = 9\%$ RR, $2 \times 0.3 \times 0.7 = 0.42 = 42\%$ Rr, and $(0.7)^2 = 0.49 = 49\%$ rr.

13. B

Using the information given in the question stem, we can determine that the percentage of the population with blue eyes (genotype bb) = 36% = 0.36 = q^2; therefore, $q = 0.6$. Because this is a Hardy–Weinberg population, we can assume that $p + q = 1$, so $p = 1 - 0.6 = 0.4$. The frequency of heterozygous brown eyes is therefore $2pq = 2 \times 0.4 \times 0.6 = 0.48 = 48\%$.

14. C

Darwin's main argument was that natural selection is the driving force for evolution. Darwin did not consider the role of genetic mutation and recombination, which were unknown at the time. These aspects were added to Darwin's theory as part of the modern synthesis model, which did not occur until significantly after Darwin's time.

15. C

This scenario—a deletion of some DNA and a duplication of other DNA—would be consistent with a translocation between chromosomes 4 and 21 during development of an egg or sperm. If part of chromosome 21 was swapped with part of chromosome 4, then a gamete resulting from meiosis in this cell would result in a daughter cell with two copies of some of the DNA from 21 and no copies of some of the DNA from 4. Therefore, after fertilization, there would be partial trisomy 21 and partial monosomy 4. While a deletion or insertion could explain one of the findings, it cannot explain both, eliminating **choices (A)** and **(B)**. An inversion should not lead to partial trisomy or partial monosomy because the DNA is simply reversed, eliminating **choice (D)**.

Glossary

Abductor—A muscle that moves a limb away from the center of the body.

Absorption—The process by which substances are taken up into or across tissues.

Acetylcholine—A neurotransmitter found throughout the nervous system (somatic motor neurons, preganglionic parasympathetic and sympathetic nerves, and postganglionic parasympathetic neurons); metabolized by acetylcholinesterase.

Acrosome—The large vesicle at the head of a sperm cell containing enzymes that degrade the ovum cell membrane to allow fertilization.

Actin—A protein found in the cytoskeleton and muscle cells; it is the principal constituent of the thin filaments and microfilaments.

Action potential—An abrupt change in the membrane potential of a nerve or muscle caused by changes in membrane ionic permeability; results in conduction of an impulse in nerves or contraction in muscles.

Active immunity—An immune response (antibody production or cellular immunity) acquired in response to exposure to an antigen.

Active site—Substrate-binding region of an enzyme.

Adaptation—The development of characteristics that enable an organism to survive and reproduce in its habitat.

Adaptive immunity—Highly specific form of immunity that retains chemical memory of each invader encountered and is able to tailor the immune response to the specific pathogen.

Adaptive radiation—The evolutionary process by which one species gives rise to several species, each specialized for different niches.

Adductor—A muscle that moves a limb toward the center of the body.

Adenine—A purine base present in DNA and RNA; it forms hydrogen bonds with thymine and uracil.

Adenosine triphosphate (ATP)—A nucleotide molecule consisting of adenine, ribose, and three phosphate moieties; the outer two phosphates are bound by high-energy bonds.

Adipose—Refers to fatty tissue, fat-storing tissue, or fat within cells.

Aerobic—Refers to a biological process that occurs in the presence of molecular oxygen (O_2) or to organisms that cannot live without molecular oxygen.

Afferent (sensory) neuron—A neuron that picks up impulses from sensory receptors and transmits them toward the central nervous system.

Agranulocyte—Type of leukocyte that does not contain cytoplasmic granules, including lymphocytes and monocytes.

Albumin—Protein synthesized in the liver that maintains the oncotic pressure of the blood and serves as a carrier for many drugs and hormones.

Allantois—One of four embryonic membranes; it contains the growing embryo's waste products.

Allele—Alternative forms of the same gene coding for a particular trait; alleles segregate during meiosis.

Allergy—A type of autoimmunity in which a person's immune system becomes overactivated by common substances in the environment.

Alveolus—Basic functional unit of the lung; a tiny sac specialized for passive gas exchange between the lungs and the blood.

Amino acids—The building blocks of proteins, each containing an amino

group, a carboxylic acid group, and a side chain (or R group) attached to the α-carbon.

Amnion—The innermost fluid-filled embryonic membrane; it forms a protective sac surrounding the embryos of birds, reptiles, and mammals.

Amplification—Characteristic of a signalling cascade, in which the binding of a single peptide hormone to a membrane-bound receptor results in a signal that increases in strength through the signalling cascade.

Anaerobic—Refers to a biological process that can occur without oxygen or to organisms that can live without molecular oxygen.

Anaphase—The stage of mitosis or meiosis characterized by the migration of chromatids or homologous chromosomes to opposite poles of the dividing cell.

Androgen—Any male sex hormone, such as testosterone.

Antibiotic—Substance that kills or inhibits the growth of bacteria or fungi (usually by disrupting cell wall assembly or by binding to ribosomes, thus inhibiting protein synthesis).

Antibody—Immune or protective protein evoked by the presence of foreign substances (antigens) in the body; each antibody binds to a specific antigen in an immune response; also called immunoglobulin.

Antigen—A substance that binds to an antibody; may be foreign or a self-antigen.

Antigen-binding region—Portion of an antibody that is specific for a particular antigen; the area of the antibody to which the antigen binds.

Aortic valve—One of the semilunar valves, separating the left ventricle from the aorta.

Apoptosis—Process by which a cell undergoes programmed cell death in a highly organized manner in response to either external or internal signals.

Appendicular skeleton—Peripheral portion of the skeleton consisting of arms, legs, and pelvic and pectoral girdles.

Archenteron—The central cavity in the gastrula stage of embryological development; it is lined by endoderm and ultimately gives rise to the adult digestive tract.

Arterioles—Small arterial structures that link the arteries to the capillaries.

Artery—Thick-walled, muscular blood vessel that generally carries blood away from the heart.

Articular cartilage—Cartilaginous coating at the ends of bones that provides a smooth surface for articulation of bones within a joint.

Asexual reproduction—Any reproductive process that does not involve the fusion of gametes (such as budding).

Asters—Star-shaped structures that form around the centrosome during mitosis.

Atrium—One of two paired structures on either side of the heart, into which blood returning from either the body (right atrium) or the lungs (left atrium) flows.

Autocrine—Form of cell–cell communication in which a cell releases a substance that then binds to the membrane of the releasing cell to either inhibit or activate a cellular activity.

Autoimmunity—Inappropriate immune response that targets self-antigens.

Autonomic nervous system—Subdivision of the peripheral nervous system responsible for involuntary activities, which is further subdivided into the parasympathetic and sympathetic nervous systems.

Autosome—Any chromosome other than a sex chromosome.

Axial skeleton—Midline structures of the skeleton including the skull, vertebral column, and ribcage; provides the central framework of the body.

Axon—The long fiber of a neuron; it conducts impulses away from the cell body toward the synapse.

Axon hillock—Transition point between the cell body (soma) and the axon of a neuron; the site of action potential initiation.

Bacillus—Rod-shaped bacterium.

Bacteriophage—A virus that invades bacteria and sometimes uses bacterial RNA and ribosomes to self-replicate.

Basophil—Type of granulocytic leukocyte that largely participates in allergic reactions and local inflammation.

Bile—A solution of salts, pigments, and cholesterol produced by the liver and stored in the gallbladder; it emulsifies large fat droplets when secreted into the small intestine via the bile duct.

Bilirubin—Product of the breakdown of hemoglobin that is modified to a more soluble form in the liver.

Binary fission—A type of asexual reproduction characteristic of prokaryotes in which there is equal nuclear and cytoplasmic division.

Blastocoel—The fluid-filled central cavity of the blastula.

Blastocyst—A mammalian blastula, consisting of the trophoblastic cells and an inner cell mass.

Blastopore—Opening of the archenteron to the external environment in the gastrula stage of embryonic development.

Blastula—The early embryonic stage during which the embryo is a hollow, fluid-filled sphere of undifferentiated cells.

Blastulation—Process by which a solid mass of early embryonic cells, known as the morula, becomes the blastula, a hollow fluid-filled sphere of undifferentiated cells.

Bohr effect—Changes in the affinity of hemoglobin for oxygen caused by changes in the environment; when pH is low (increased concentration of hydrogen ions), the oxyhemoglobin dissociation curve shifts right, indicating a decreased affinity of hemoglobin for oxygen and more efficient off-loading of oxygen from hemoglobin.

Bolus—An initial dose of medication; in the digestive system, chewed food leaving the mouth, traveling through the esophagus, and entering the stomach.

Bone marrow—Central portion of bones, especially long bones, that contains fat and developing blood cells, including erythrocytes, leukocytes, and megakaryocytes.

Bone matrix—Organic and inorganic minerals that provide strength to compact bone; organic components include collagen, glycoproteins, and other peptides; inorganic components include calcium, phosphate, and hydroxide ions (in hydroxyapatite).

Bowman's capsule—The cuplike structure of the nephron; it collects the glomerular filtrate and channels it into the proximal convoluted tubule.

Bronchi—Tubelike passages for air that connect the trachea to the bronchioles.

Bronchioles—Passageways for air that start at the bronchi, dividing into continuously smaller passageways that eventually lead to the alveoli, where gas exchange occurs.

Brush-border enzymes—Group of enzymes present on the luminal surface of cells lining the duodenum that break down larger biomolecules into monomers that are able to be absorbed.

Bundle of His—Part of the conduction system of the heart; it carries impulses from the AV node to the ventricles.

Callus—Area of excessive deposition of keratin in response to repeated strain due to friction.

Canaliculi—Small canals connecting lacunae within the bone matrix with Haversian canals, allowing for the flow of nutrients and wastes.

Capillary—Small, thin-walled blood vessel where gas, nutrient, and waste exchange occurs between blood and tissues.

Capsid—Protein coat surrounding a virus.

Cardiac output—Total blood volume pumped by the left ventricle in one minute, found by multiplying the heart rate times the stroke volume.

Cartilage—A firm, elastic, translucent connective tissue produced by cells called chondrocytes.

Catabolism—The chemical breakdown of complex substances (macromolecules) to yield simpler substances and energy.

Cecum—The first part of the large intestine; accepts material flowing through the ileocecal valve and is the site of the appendix.

Cell-mediated immunity—Type of immunity that uses cytotoxic chemicals released from cells to cause death of cells that have been infected by viruses.

Cell body—Portion of a neuron where the nucleus, endoplasmic reticulum, and ribosomes are located; also known as the soma.

Cell theory—A foundational belief in modern biology that all living things are composed of cells, that the cell is the basic functional unit of life, that all cells arise from preexisting cells, and that DNA is genetic material.

Central nervous system (CNS)—The brain and spinal cord.

Centriole—A small organelle in the cytoplasm of animal cells; it organizes the spindle apparatus during mitosis or meiosis.

Centromere—The area of a chromosome where sister chromatids are joined; it is also the point of attachment to the spindle fiber during mitosis and meiosis.

Centrosomes—Paired cylindrical organelles, located in the cytoplasm, that contain the centrioles.

Cerebellum—The section of the mammalian hindbrain that controls muscle coordination and equilibrium.

Cerebral cortex—The outer layer of the forebrain, consisting of grey matter; it is the site of higher cognitive functions in humans.

Cervix—Lower end of the uterus that marks the transition between the vagina and the uterus.

Chemical digestion—Enzymatic cleavage of chemical bonds within foodstuffs, resulting in smaller molecules.

Chemotaxis—Movement of cells toward or away from a chemical within the environment.

Chiasmata—Sites where crossing over occurs between homologous chromosomes during meiosis.

Chief cells—Cells within the stomach that secrete pepsinogen, a zymogen that is converted to its active form, pepsin, by the acidic environment of the stomach.

Chondrin—Elastic cartilage matrix substance secreted by chondrocytes.

Chondrocyte—A differentiated cartilage cell that synthesizes the cartilaginous matrix.

Chromatid—Each of the two chromosomal strands formed by DNA replication in the S phase of the cell cycle; held together by the centromere.

Chromosome—A filamentous body found within the nucleus of a eukaryotic cell or nucleoid region of a prokaryotic cell, composed of DNA.

Chylomicron—Soluble lipid molecule that consists of triglycerides and esterified cholesterol molecules; absorbed into lacteals from the digestive tract.

Chyme—Aqueous mixture of food and secretions that leaves the stomach to enter the duodenum.

Cilia—Projection from a cell involved in movement of materials on the outside of the cell.

Circadian rhythm—A behavioral pattern based on a 24-hour cycle, related to a consistent cycling of hormones such as cortisol and melatonin.

Cleavage—A series of mitotic divisions of the zygote immediately following fertilization, resulting in progressively smaller cells with increased nucleus-to-cytoplasm ratios.

Clonal selection—Phenomenon in which only B- or T-cells specific to a particular pathogen are activated.

Coccus—Spherically shaped bacterium.

Codominance—A genetic effect in which the phenotype of a heterozygote is a reflection of both alleles at a particular locus.

Competent—Describes a cell capable of responding to induction signals.

Conjugation—The temporary joining of two organisms via a tube called a pilus, through which genetic material is exchanged; a form of sexual reproduction used by bacteria.

Connective tissue—Animal tissue composed of cells lying in an extracellular proteinaceous network that supports, connects, and surrounds the organs and structures of the body.

Constant region—Portion of an antibody molecule that is not variable and participates in the binding of other immune modulators.

Convergent evolution—The process by which unrelated organisms living in a similar environment develop analogous structures.

Corona radiata—Layer of cells surrounding an oocyte that aid in the development of the ovum.

Corpus luteum—The remnant of the ovarian follicle, which after ovulation continues to secrete progesterone. Its degeneration leads to menstruation; maintains uterine lining during pregnancy.

Cortex—The external layer found in many organs of the body, including the brain, adrenal glands, and kidney.

Cortical reaction—Release of calcium ions by an ovum after fertilization, resulting in the creation of a fertilization membrane, a structure that prevents fertilization of an ovum by multiple sperm cells.

Corticosteroids—Steroid hormones produced in the adrenal cortex, including glucocorticoids (cortisol), mineralocorticoids (aldosterone), and cortical sex hormones.

Crossing over—The exchange of genetic material between homologous chromosomes during meiosis.

Cyclic adenosine monophosphate (cAMP)—An intracellular second messenger in the signaling cascade initiated by a peptide hormone; synthesized from ATP by adenylate cyclase.

Cytokine—Chemical substance that stimulates inflammation and recruits additional immune cells to a specific area.

Cytokinesis—The division and distribution of parent cell cytoplasm to the two daughter cells during mitotic and meiotic cell division.

Cytoplasm—The fluid and solutes within a cell membrane, external to the nucleus and cellular organelles.

Cytotoxic T-cell—T-cell that seeks out infected cells and induces apoptosis in these cells to prevent spread of the pathogen.

Deletion—A type of genetic mutation in which some variable amount of DNA is removed.

Dendrite—The portion of a neuron that receives stimuli and conveys them toward the cell body.

Dermis—The layer of skin cells under the epidermis. Contains sweat glands, hair follicles, fat, and blood vessels.

Determinate cleavage—Rapid mitotic divisions occurring in an embryo that result in cells with predetermined fates; these cells are only capable of differentiating into certain groups of tissues within an organism.

Determination—Designation of a cell within an embryo as having a particular future function.

Diaphragm—Thin, muscular structure that divides the thorax from the abdomen and provides the driving force for inhalation.

Diaphysis—Cylindrical shaft of a long bone.

Diastole—The period of relaxation of cardiac muscle during which the atrioventricular valves open and the ventricles fill with blood.

Differentiation—The process by which unspecialized cells become specialized. Involves selective transcription of the genome.

Digestion—The breakdown of macromolecular nutrient material via mechanical and chemical means to simple molecular building blocks; this facilitates absorption.

Diploid—Having two chromosomes of each type per cell; symbolized by $2n$.

Direct hormone—Substance secreted into the bloodstream that causes a change in the physiological activity of cells without requiring an intermediary.

Directional selection—Selective pressures favor the development of an extreme phenotype that provides

a selective advantage; this phenotype emerges as the primary phenotype over time.

Disruptive selection—Selective pressures favoring extreme phenotypes over the norm.

Divergent evolution—A process of change whereby organisms with a common ancestor evolve dissimilar structures (such as dolphin flippers and human arms).

Dominant—Refers to an allele that requires only one copy for expression.

Ductus arteriosus—Fetal structure that shunts blood from the pulmonary artery to the aorta to bypass the developing lungs.

Ductus venosus—Shunt from the umbilical vein to the inferior vena cava, allowing oxygenated blood returning from the placenta to bypass the liver and enter the systemic circulation.

Duodenum—First segment of the small intestine; the contents of the stomach and the pancreatic and bile ducts empty into it; site of digestion and some absorption.

Ectoderm—Outermost embryonic germ layer; it gives rise to the skin, nervous system, inner ear, lens of the eye, and other structures.

Effector—An organ, muscle, or gland used by an organism to respond to a stimulus.

Efferent (motor) neuron—A neuron that transmits nervous impulses from the central nervous system to an effector.

Embryo—The early developmental stage of an organism; in humans, the term refers to the first eight weeks after fertilization.

Endocrine—A form of cell–cell communication that involves the secretion of hormones into the bloodstream by ductless glands; these hormones then travel to distant locations within the organism to cause a change in cellular expression.

Endoderm—Innermost embryonic germ layer; it later gives rise to the linings of the alimentary canal and of the digestive and respiratory organs.

Endometrium—Uterine lining that is regenerated each month in preparation for implantation of an embryo; absence of an embryo results in sloughing off of the endometrium in a process known as menstruation.

Endoplasmic reticulum—Membrane-bound channels in the cytoplasm that transport proteins and lipids to various parts of the cell.

Endothelium—Lining of blood vessels consisting of endothelial cells.

Enteric nervous system—Collection of neurons within the gastrointestinal tract that govern peristalsis.

Eosinophil—Type of granulocytic leukocyte that largely participates in the immune response against parasites; also involved in the pathogenesis of allergies.

Epidermis—The outermost layer of the skin.

Epididymis—The coiled tube in which sperm gains motility and is stored after its production in the testes.

Epiglottis—The small flap of cartilage that covers the glottis during swallowing, preventing food from entering the larynx.

Epinephrine—A hormone synthesized by the adrenal medulla; it stimulates the fight-or-flight response; also a neurotransmitter in the sympathetic nervous system.

Epiphyseal plate—Cartilaginous structure in the epiphysis where growth occurs.

Epiphysis—Dilated end of a long bone.

Episomes—A specialized subset of plasmids capable of integrating into the genome of bacteria under specific circumstances.

Epithelium—The cellular layer that covers internal and external surfaces of body structures and cavities.

Erythrocyte—Red blood cell; a biconcave, disk-shaped cell that contains hemoglobin and has no nucleus.

Esophagus—Portion of the alimentary canal connecting the pharynx and the stomach.

Eukaryote—A unicellular or multicellular organism composed of cells that contain a membrane-bound nucleus and other membrane-bound organelles.

Evolution—The changes in the gene pool from one generation to the next caused by mutation, nonrandom mating, natural selection, and genetic drift.

Exocrine glands—Glands that release their secretions into ducts (such as the liver and sweat glands).

Expressivity—Varying expression of disease symptoms despite identical genotypes.

Extensor—A muscle used in the straightening of a limb.

Facultative anaerobes—Prokaryotes that can exist with or without oxygen.

Fertilization—Fusion of two gametes.

Fertilization membrane—Structure created by the cortical reaction after fertilization of an ovum by a sperm cell; prevents fertilization of an ovum by multiple sperm cells.

Fetus—A developing organism that has passed the early developmental stages. In humans, the term refers to an embryo from the ninth week after fertilization until birth.

Fibrin—The insoluble protein that forms the bulk of a blood clot.

Filial generation—Offspring in a genetic cross; may be supplemented with a subscript to show how many generations out from the parents.

Filtration—In the nephron, the process by which blood plasma is forced (under high pressure) out of the glomerulus into Bowman's capsule.

Fitness—Reproductive success of an individual, measured in increased number and survival of offspring.

Flagellum—A microscopic, whip-like filament that functions in the locomotion of sperm cells and some unicellular organisms; composed of microtubules.

Flexor—A muscle used in the bending of a limb.

Follicle—The set of cells surrounding a developing or mature ovum. Secretes nutrients and estrogen and atrophies into the corpus luteum after ovulation.

Foramen ovale—Shunt within the fetal heart between the right and left atria that allows the circulation to largely bypass the developing lungs.

Gallbladder—Organ below the liver that stores bile; contracts in response to stimulation by cholecystokinin, resulting in release of bile into the biliary system and eventually into the duodenum.

Gamete—Sperm or ovum; a cell that has half the number of chromosomes of a somatic cell (haploid) and can fuse with another gamete to form a zygote.

Ganglion—A mass of neuron cell bodies outside the central nervous system.

Gastrula—The embryonic stage characterized by the presence of ectoderm, mesoderm, and endoderm.

Gene—The basic unit of heredity; a region on a chromosome that codes for a specific product.

Gene pool—All of the alleles for every gene in every individual in a given population.

Genetic drift—Variations in the gene pool caused by chance.

Genetic map—A diagrammatic representation of a chromosome indicating distance between two genes on a chromosome as determined by recombination frequencies.

Genome—An organism's complete set of chromosomes.

Genotype—The genetic composition of an entire organism or in reference to a particular trait.

Glomerulus—The network of capillaries encapsulated by Bowman's capsule. Acts as a filter for blood entering the nephron.

Glottis—The opening to the trachea.

Golgi apparatus—Organelle that plays a role in the packaging and secretion of proteins and other molecules produced intracellularly.

Gonad—Ovary or testis; the reproductive organ in which gametes are produced.

Gram staining—A process of staining bacterial cells such that cells containing large amounts of peptidoglycan within the cell wall are stained purple, while cells with less peptidoglycan within their cell walls appear pink-red after counter-staining.

Granulocyte—Type of leukocyte with cytoplasmic granules that are visible under a microscope, such as neutrophils, basophils, or eosinophils.

Grey matter—Any region in the central nervous system that consists largely of neuron cell bodies, dendrites, and synapses.

Growth factors—Substances that cause induction during embryonic development and ensure the development of the correct structure in the right location.

Haploid—Having only one of each type of chromosome per cell; symbolized by *n*.

Hardy–Weinberg principle—States that gene ratios and allelic frequencies remain constant through the generations in a nonevolving population.

Haversian canal—Central channel within the osteon (Haversian system) containing blood vessels, nerve fibers, and lymph vessels.

Heavy chain—One of two types of chains, made of peptides, that create an antibody; each antibody consists of two heavy chains and two light chains.

Helper T-cells—Type of T-cell that secretes lymphokines; the specific combination of lymphokines secreted will determine the nature of the immune response; activation of T_h1 cells will result in a cytotoxic response, while a T_h2 response will rely on B-cells.

Hematocrit—Measurement of how much of a blood sample consists of red blood cells, expressed as a percentage.

Hemoglobin—Iron-containing protein found in red blood cells that binds O_2 and transports it throughout the body.

Heterozygous—Having two different alleles for a particular trait.

Hilum—Area of an organ where large vessels or other structures enter or exit; the renal hilum is where the renal artery enters the kidney, the renal vein leaves the kidney, and the ureter exits the kidney to transport urine to the bladder.

Histamine—An inflammatory mediator that causes vasodilation and results in increased movement of fluid and cells out of the blood vessels and into the tissues.

Homeostasis—Maintenance of a stable internal physiological environment in an organism.

Homologous chromosomes—Chromosomes in a diploid cell that carry corresponding genes for the same traits at corresponding loci.

Homozygous—Having two identical alleles for a given trait.

Hormones—Chemical messengers secreted by cells of one part of the body and carried by the bloodstream to cells elsewhere in the body, where they regulate biochemical activity.

Humoral immunity—Form of adaptive immunity driven by B-cells and antibodies.

Hybrid—The resultant offspring of a cross (mating) either between two different gene types or between two different species.

Hypodermis—Subcutaneous layer beneath the dermis in the skin.

Hypothalamus—The region of the vertebrate forebrain that controls the autonomic nervous system and is the control center for hunger, thirst, body temperature, and other visceral functions; also secretes factors that stimulate or inhibit pituitary secretions.

Ileum—The terminal portion of the small intestine.

Impulse propagation—Movement of an action potential down an axon, resulting in neurotransmitter release at the synaptic bouton and transmission of the impulse to the target neuron or organ.

Inborn error of metabolism—Genetic mutation that causes a change in an enzyme required for metabolism; early intervention is necessary to prevent the

development of life-threatening conditions; some inborn errors of metabolism are ultimately incompatible with life.

Incomplete dominance—A genetic effect in which the phenotype of a heterozygote is a mixture of the two parental phenotypes.

Indeterminate cleavage—Rapid mitotic divisions resulting in cells that are individually capable of becoming complete organisms.

Independent assortment—Unlinked genes within a primary germ cell separate randomly during gametogenesis.

Inducer—A chemical substance passed from an organizing cell to a responsive cell, resulting in differentiation of the responsive cell.

Induction—The initiation of cell differentiation in a developing embryo due to the influence of other cells.

Innate immunity—Form of immunity that is nonspecific and does not require activation.

Integument—The outer layer of the body (skin); provides function for thermoregulation and innate immunity.

Intermediate filament—Collection of fibers that help to maintain the overall integrity of the cytoskeleton.

Interneuron—A neuron that has its cell body and nerve terminals confined to one specific area; often involved in spinal reflexes.

Interphase—The stage between successive nuclear divisions; it is divided into the G_1, S, and G_2 stages; cell growth and DNA replication occur during interphase.

Intracellular digestion—Oxidation of fatty acids and glucose for energy within cells.

Intrapleural space—Fluid-filled potential space between the parietal and visceral pleura that lubricates the two pleural surfaces and allows for a pressure differential between the intrapleural space and the lungs.

Inversion—A chromosomal mutation in which a section of a chromosome breaks off, flips over, and then reattaches in its original spot.

Isolation—Mechanism that prevents genetic exchange between individuals of different species or populations.

Jejunum—The middle portion of the small intestine.

Joint cavity—Space between two bones in a joint; enclosed and maintained by fibrous tissues.

Juxtacrine—A form of cell–cell communication in which a cell releases a substance that binds to receptors on cells directly adjacent to the releasing cell.

Keratin—Protein present in the outermost layer of the skin that is largely responsible for preventing the loss of fluids and salts as well as the entry of foreign substances into the body; also present as an intermediate filament within cells.

Keratinocytes—Cells within the epidermis that produce keratin.

Kidney—Vertebrate organ that regulates water and salt concentration in the blood and is responsible for urine formation.

Kinetochore—A protein structure, located at the centromere, that provides a place for spindle fibers to attach to the chromosome.

Lacteal—Small lymphatic vessel that runs in the center of the villi in the small intestine; site of lipid absorption into the lymphatic system.

Lacunae—Small spaces within the bone matrix where osteocytes reside.

Lamellae—Concentric circles of bony matrix within the Haversian systems of bone.

Langerhans cells—Specialized macrophages that reside within the skin.

Large intestine—Tubelike structure, shorter but wider than the small intestine, largely responsible for resorption of water and the formation of semisolid feces; consists of the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum.

Larynx—Pathway for air between the pharynx and the trachea. The epiglottis closes to prevent food from entering the larynx.

Latent period—The short interval between the application of a stimulus to a muscle and the contraction of the muscle.

Leakage—Flow of genes between closely related species.

Leukocytes—White blood cells; can be subdivided into granulocytes and agranulocytes.

Ligament—Connective tissue that joins two bones.

Light chain—One of two types of chains, made of peptides, that create antibodies; each antibody consists of two heavy chains and two light chains.

Linkage—Tendency for certain alleles to be inherited together due to proximity on the same chromosome.

Lipase—Enzyme that specifically cleaves the bonds of lipids.

Locus—In genetics, an area or region of a chromosome.

Loop of Henle—The U-shaped section of a mammalian nephron.

Lower esophageal sphincter—Ring-shaped muscular structure that separates the esophagus from the stomach; also known as the cardiac sphincter.

Lumen—The space within a tube or a sac.

Lymph—Clear fluid derived from blood plasma and transported through lymph vessels to the lymphatic ducts, which empty into the circulatory system.

Lymph node—Small, bean-shaped structure that provides a location for antigen presentation and mounting of an attack of the adaptive immune system.

Lymphocyte—A type of white blood cell involved in an organism's specific immune response.

Lysogenic cycle—Bacteriophage infection involving the integration of viral DNA into the bacterial genome without disrupting or destroying the host. The virus may subsequently reemerge and enter a lytic cycle.

Lysosome—A membrane-bound organelle that stores hydrolytic enzymes.

Lytic cycle—Bacteriophage infection involving the destruction (lysis) of the host bacterium.

Macrophage—A phagocytic white blood cell.

Map unit—A unit used to denote a 1 percent recombination frequency between two genes when creating a genetic map; also measured as one centimorgan.

Mast cel—A granulocyte that releases histamine and causes inflammation.

Mastication—Breaking up of large food particles using the teeth, tongue, and lips; chewing.

Mechanical digestion—Physical breakdown of large food particles into smaller food particles.

Medulla—The internal section of an organ (such as the adrenal glands and the kidney); may generally refer to the medulla oblongata of the mammalian hindbrain.

Medulla oblongata—The part of the brainstem closest to the spinal cord. It controls vital functions, such as breathing and heartbeat.

Megakaryocyte—Precursor cell that gives off platelets.

Meiosis—A process of cell division in which two successive nuclear divisions produce up to four haploid gametes from one diploid germ cell.

Melanocytes—Melanin-producing cells of the skin.

Melanin—Skin pigment produced by melanocytes that protects the skin from UV radiation and provides color to skin.

Memory cell—Lymphocyte of B- or T-cell lineage that remains after an infection is gone in order to recognize the previous invader and rapidly induce a humoral immune response.

Menstruation—The shedding of the uterine lining that occurs every four weeks in a nonpregnant, sexually mature human female.

Mesoderm—The middle embryonic germ layer; it gives rise to the muscular, skeletal, urogenital, and circulatory systems.

Metabolism—The sum of all biochemical reactions that occur in an organism.

Metaphase—The stage of mitosis or meiosis during which single chromosomes or tetrads line up on the central axis of the dividing cell and become attached to spindle fibers.

Microfilaments—Small polymerized rods of actin that participate in muscle contraction, movement of material within the cellular membrane, and amoeboid movement.

Microglia—Phagocytic white blood cells that reside in the central nervous system.

Microtubule—A small, hollow tube composed of two types of protein subunits; serves numerous functions in the cell, such as comprising the internal structures of cilia and flagella and allowing vesicle movement in the cell.

Missense mutation—Type of mutation that results in the substitution of one amino acid for another.

Mitochondria—Membrane-bound cellular organelles in which the reactions of aerobic respiration and ATP synthesis occur.

Mitosis—Cellular division that results in the formation of two daughter cells that are genetically identical to each other and to the parent cell.

Mitral valve—One of the atrioventricular valves separating the left atrium from the left ventricle.

Mixed nerve—Nerve carrying both afferent (sensory) and efferent (motor) fibers.

Monocyte—A white blood cell that transforms into a macrophage once it enters tissues.

Monohybrid cross—A cross between two members of a species that seeks to study only one trait.

Monosaccharide—A sugar consisting of one monomer (glucose, fructose, or galactose).

Morula—The solid ball of cells that results from the early stages of cleavage in an embryo.

Morphogen—Molecule that causes nearby cells to proceed in a specific developmental pathway during embryonic development.

Mucosa—The type of epithelial tissue that lines moist body cavities; a mucous membrane.

Mucous cells—Type of cell within the gastric glands of the stomach; secretes a mucus that protects the mucosa of the stomach from the harshly acidic conditions.

Multipotent—Stem cell that is able to differentiate into various cells within a particular lineage.

Mutagen—An agent, either chemical or physical, that can cause mutations.

Mutation—A change in DNA sequence.

Myelin—The white, lipid-containing material surrounding the axons of many neurons in the central and peripheral nervous systems.

Myogenic activity—Ability of a muscle cell to contract without input from the nervous system; found in smooth and cardiac muscle types.

Myoglobin—Heme-containing protein that binds molecular oxygen in muscle cells.

Myosin—A protein found in muscle cells that functions in muscle contraction; myosin fibers are also called thick filaments.

Natural selection—An ongoing evolutionary process resulting in changes in gene frequencies, leading to the differential development of phenotypes in a population.

Negative sense—Describes the genome of an RNA virus that contains an RNA genome that is complementary to the actual transcript for viral protein synthesis.

Nephron—The functional unit of the vertebrate kidney.

Nerve—A bundle of neurons.

Nerve impulse—The self-propagating change in electrical potential across the axon membrane.

Nerve terminal—End of the axon from which neurotransmitter molecules are released; also called a synaptic bouton.

Neural crest cells—Cells that originate at the tip of the neural fold and then migrate outward to form the peripheral nervous system, melanocytes, C-cells of the thyroid, and others.

Neural fold—Group of ectodermal cells that slide together to create a fold, which later becomes the neural tube.

Neural tube—Embryonic hollow tube that subsequently gives rise to the central nervous system.

Neuroglia—Support cells for neurons; responsible for functions such as holding neurons in place, supplying neurons with oxygen and nutrients, insulating neurons from other neurons, destroying pathogens, and removing dead neurons.

Neuron—A cell that conducts electrical impulses; the functional unit of the nervous system.

Neurotransmitter—A chemical agent released into the synaptic cleft by the synaptic bouton of a neuron; binds to receptor sites on postsynaptic neurons or effector membranes to alter activity.

Neutrophil—Type of granulocytic leukocyte that largely participates in the nonspecific immune response against bacteria.

Niche—The specific way of life occupied by a given organism within the environment, including its interactions with other organisms and with the physical environment.

Nodes of Ranvier—Points on a myelinated axon that are not covered by myelin.

Nondisjunction—Failure of homologous chromosomes to separate during meiosis.

Nonsense mutation—A change in nucleotide sequence of DNA that results in a premature stop codon in the mRNA sequence.

Norepinephrine—A hormone synthesized by the adrenal medulla; it stimulates the fight-or-flight response; also, a neurotransmitter in the sympathetic nervous system.

Notochord—A supportive rod running just ventral to the neural tube in lower chordates and in vertebrate embryos that induces neurulation.

Nuclear membrane—Double membrane enveloping the nucleus, interrupted periodically by pores; found in eukaryotic cells only; also known as the nuclear envelope.

Nuclear pore—Small hole in the nuclear membrane that allows for two-way exchange of material between the cytoplasm and nucleus.

Nucleoid region—Location in prokaryotic cells where the chromosome is found.

Nucleolus—Dense body visible in a nondividing nucleus; site of ribosomal RNA synthesis.

Nucleus—The eukaryotic membrane-bound organelle that contains the cell's chromosomes; in neuroscience, a collection of cell bodies in the central nervous system.

Oligodendrocyte—Myelin-producing cells in the central nervous system.

Oocyte—An undifferentiated cell that undergoes meiosis to produce an egg cell (ovum).

Oogenesis—Gametogenesis in the ovary leading to the formation of mature ova.

Osmotic pressure—A "sucking" pressure generated by the presence of solutes drawing in water.

Osteoblast—Bone cell responsible for the generation of new bone due to bone remodeling or storage of minerals within the bone matrix.

Osteoclast—Bone cell responsible for the resorption of bone due to bone remodeling or mobilization of minerals from the bone matrix.

Osteocytes—Mature bone cells housed within the bone matrix.

Ovary—The female egg-producing gonad.

Oviduct—The tube leading from the ovary to the uterus; generally, the site of fertilization; also called the fallopian tube.

Ovulation—The release of the mature ovum from the ovarian follicle.

Ovum—The female gamete; egg cell.

Oxygen debt—The amount of oxygen needed to reconvert lactic acid to pyruvate following strenuous exercise of muscle tissue; the difference between the amount of oxygen needed by the tissue and the amount of oxygen available.

Pancreas—A gland that secretes digestive enzymes into the duodenum via a duct and synthesizes and secretes the hormones insulin, glucagon, and somatostatin; located between the stomach and the duodenum.

Papillary layer—Upper layer of the dermis, right below the epidermis, that consists of loose connective tissue.

Paracrine—A form of cell–cell communication in which a cell releases a substance into the extracellular fluid and the substance binds to receptors on nearby cells to cause a change in cellular activities.

Parasympathetic nervous system—The subdivision of the autonomic nervous system involved in rest and homeostasis; it is generally antagonistic to the sympathetic nervous system.

Parathyroid glands—Two pairs of glands located on the thyroid that secrete hormones that regulate calcium and phosphorous metabolism.

Parietal cells—Cells within the stomach that are responsible for the secretion of acid into the lumen of the stomach.

Passive immunity—Immunity conferred by the transfer or injection of previously formed antibodies.

Pathogen—An infectious disease-causing agent; includes bacteria, viruses, fungi, parasites, and prions.

Pattern recognition receptor—Type of receptor on macrophages and dendritic cells that is able to recognize the nature of the invader (bacteria, virus, or fungi) and release the appropriate cytokines to attract the right immune cells to the area.

Penetrance—Percent of individuals with a particular genotype that actually express the associated phenotype.

Peptidase—Enzyme that cleaves peptide bonds.

Periosteum—Fibrous sheath surrounding long bones.

Peripheral nervous system—Includes all neurons outside the central nervous system, including sensory and motor neurons; it is subdivided into the somatic and autonomic nervous systems.

Peristalsis—Rhythmic waves of muscular contraction that move a substance through a tube (most commonly, food through the digestive tract).

Peroxisome—Organelle that contains hydrogen peroxide and participates in the breakdown of very long chain fatty acids.

Pharynx—Pathway for food from the mouth to the esophagus, and for air from the nose and mouth to the larynx.

Phenotype—The physical manifestation of an organism's genotype.

Pineal gland—Structure within the brain that secretes melatonin, a hormone that aids in the regulation of sleep–wake cycles.

Pituitary—The bilobed endocrine gland that lies just below the hypothalamus; because many of its hormones regulate other endocrine glands, it is known as the "master gland."

Placenta—The structure formed by the wall of the uterus and the chorion of the embryo; contains a network of capillaries through which exchange between maternal and fetal circulation occurs.

Plasma—The fluid component of blood containing dissolved solutes, minus the cells.

Plasma cells—Derived from B-lymphocytes; have the ability to produce and secrete antibodies.

Plasmid—Small circular ring of extrachromosomal DNA found in bacteria.

Platelets—Small, enucleated, disk-shaped shards of blood cells that play an important role in clotting.

Pleura—Connective tissue that surrounds each lung and aids in providing attachment of the lungs to the chest

wall; the parietal pleura lies along the chest wall, while the visceral pleura is adherent to the lungs.

Pluripotent—Stem cell that has undergone gastrulation and is able to differentiate into any cell type within the same primary germ layer.

Polar body—A small, nonfunctional haploid cell created during oogenesis.

Population—A group of organisms of the same species living together in a given location.

Portal system—A circuit of blood in which there are two capillary beds in tandem connected by an artery or vein; examples include the hypophyseal, hepatic, and renal portal systems.

Positive sense—Describes the genome of an RNA virus containing RNA that serves directly as the transcript for viral protein production.

Potency—Term used to describe the ability or inability of a stem cell to differentiate into different cell types.

Primary response—Humoral immune response against an invader during the first encounter; takes seven to ten days to become effective.

Prion—Infectious protein that causes disease by causing changes in the three-dimensional structure of other proteins from α-helices to β-pleated sheets.

Prokaryote—Cell lacking a nuclear membrane and membrane-bound organelles, such as a bacterium.

Prophase—The stage of mitosis or meiosis during which the DNA strands condense to form visible chromosomes; during prophase I of meiosis, homologous chromosomes align.

Prostate—A gland in the mammalian male that secretes alkaline seminal fluid.

Pulmonary valve—One of the semilunar valves, separating the right ventricle from the pulmonary arteries.

Purkinje fibers—The terminal fibers of the heart's conduction system; located in the walls of ventricles.

Pyloric sphincter—The valve that regulates the flow of chyme from the stomach into the small intestine.

Recessive—An allele that requires two copies to be expressed.

Recombination—New gene combinations achieved by sexual reproduction or crossing over in eukaryotes and by transformation, transduction, or conjugation in prokaryotes.

Recombination frequency—Measurement of how often genes recombine in different combinations; genes that are closer together have lower recombination frequencies.

Rectum—Terminal portion of the large intestine, where feces is stored until defecation.

Reflex—An involuntary nervous pathway consisting of sensory neurons, interneurons, motor neurons, and effectors; it occurs in response to a specific stimulus.

Refractory period—The period of time following an action potential during which the neuron is incapable of depolarization.

Releasing hormones—Proteins synthesized and secreted by the hypothalamus that stimulate the pituitary to synthesize and release its hormones. Also known as tropic hormones.

Renal pelvis—The widest part of the ureter, located within the kidney; location into which all collecting ducts eventually empty.

Renin–angiotensin–aldosterone system—Hormonal pathway that, among other functions, raises blood pressure.

Repolarization—Restoration of the resting membrane potential in neurons from being depolarized by both active and passive processes.

Respiration—In biochemistry, the series of oxygen-requiring biochemical reactions that lead to ATP synthesis; in physiology, the inhalation and exhalation of gases and their exchange in the lungs.

Responder—Embryonic cell that is undergoing induction.

Resting potential—The electrical potential of a cell at rest, approximately –70 mV in most excitable cells.

Restriction point—A point in the cell cycle that prevents the cell from

entering the next portion of the cell cycle unless certain criteria are met.

Reticular layer—Lower layer of the dermis, consisting of dense connective tissue.

Retrovirus—An RNA virus that contains the enzyme reverse transcriptase, which transcribes RNA into DNA.

Rh factor—An antigen on a red blood cell, the presence or absence of which is indicated by + or –, respectively, in blood type notation; may also be called the D allele.

Ribosome—Organelle composed of RNA and protein; it translates mRNA during protein synthesis.

Rough endoplasmic reticulum—Portion of the endoplasmic reticulum that appears rough microscopically due to the presence of ribosomes attached to the outer surface; site of protein synthesis for proteins destined to be membrane-bound or secreted.

Saltatory conduction—Process by which an electrical signal jumps across the nodes of Ranvier to travel down the axon.

Sarcolemma—Muscle cell membrane capable of propagating action potentials.

Sarcomere—The functional contractile unit of striated muscle.

Sarcoplasmic reticulum—The endoplasmic reticulum of a muscle cell; it envelops myofibrils.

Schwann cell—Myelin-producing cell in the peripheral nervous system.

Second messenger—Substance that is mobilized within a cell after the binding of a hormone to its receptor.

Secondary response—Humoral immune response against a previously encountered invader; results in activation of memory cells and an immediate response.

Semen—Fluid released during ejaculation consisting of sperm cells suspended in seminal fluid.

Seminal vesicle—A gland found in mammalian males that produces seminal fluid.

Sex factor—Plasmid containing genetic material for the formation of a sex pili, required for conjugation.

Sex-linked gene—A gene located only on a sex chromosome (almost always the X chromosome); such genes exhibit different inheritance patterns in males and females.

Sex pilus—Appendage made from the donor male (+) bacterial cell to the recipient female (–), allowing for the formation of the cytoplasmic bridge and transfer of genetic material.

Sexual reproduction—Any reproductive process that involves the fusion of gametes, resulting in the passage of combined genetic information to offspring.

Silent mutation—Change of one nucleotide for another that does not result in a change in the protein due to the degenerative nature of the genetic code (multiple codons code for the same amino acid).

Small intestine—Long tubelike structure, longer, but narrower than the large intestine, largely responsible for chemical digestion of foodstuffs and absorption of nutrients; consists of the duodenum, jejunum, and ileum.

Smooth endoplasmic reticulum—Portion of the endoplasmic reticulum that lacks ribosomes on its surface; location of lipid synthesis and detoxification of drugs and poisons.

Somatic cells—All cells in the body except germ cells and gametes.

Somatic nervous system—Subdivision of the peripheral nervous system that governs all voluntary actions.

Species—The largest group of organisms capable of mating to produce viable, fertile offspring.

Specific immune response—An organism's targeted fight against a specific pathogen using both antibodies and cytotoxic immunity.

Sperm—The mature male gamete or sex cell.

Spermatids—Immature haploid sperm cells.

Spermatogenesis—Gametogenesis in the testes leading to sperm formation.

Spermatogonia—Diploid stem cells in males that eventually give rise to sperm cells.

Spermatozoa—Mature haploid sperm cells.

Sphincter—A ring-shaped muscle that closes and opens a tube (such as the pyloric sphincter).

Sphygmomanometer—Device used to measure blood pressure, consisting of an inflatable cuff and a gauge that measures pressure.

Spindle—A structure within dividing cells composed of microtubules; it is involved in the separation of chromosomes during mitosis and meiosis.

Spirilli—Spiral-shaped bacteria.

Spleen—Highly vascular organ in the left upper quadrant of the abdomen; serves as a location for disposal of aged red blood cells and the presentation of antigens to B-cells.

Stabilizing selection—Selective pressure resulting in the elimination of extremes.

Starling forces—A sum of the forces generated by hydrostatic and osmotic pressures; results in a greater attraction of fluid to one side of a membrane.

Stroke volume—Amount of blood ejected from a ventricle with each heartbeat.

Summation—Process that occurs when the postsynaptic neuron or target organ requires stimulation from multiple presynaptic neurons in order to respond to the stimulus; may be spatial or temporal.

Suppressor T-cells—Also known as regulatory T-cells (T_{reg}), these T-cells limit the immune response to prevent detrimental immune reactions, such as autoimmunity.

Surfactant—A detergent that lowers surface tension and prevents collapse of the alveoli.

Symbiote—Organism living closely with a host and engaging in a mutually beneficial relationship.

Sympathetic nervous system—The subdivision of the autonomic nervous system that produces the "fight-or-flight" response.

Synapse—The junction between two neurons into which neurotransmitters are released.

Synapsis—The pairing of homologous chromosomes during prophase I of meiosis.

Synovial capsule—Fluid-filled space between bones in a joint; enclosed by fibrous tissue; synovial fluid lubricates the joint.

Systole—The period of the cardiac cycle during which the ventricles contract and pump blood into the aorta and pulmonary arteries.

T-cells—Type of leukocyte that matures in the thymus and participates in adaptive immunity.

Telophase—The final stage of mitosis or meiosis during which the chromosomes uncoil, nuclear membranes reform, and cytokinesis occurs.

Tendon—A fibrous connective tissue that connects a bone to a muscle.

Test cross—A cross between an organism showing a dominant trait and an organism showing a recessive trait to determine whether the former organism is homozygous or heterozygous for that trait.

Testis—The male sperm-producing organ; also secretes testosterone.

Tetanus—Sustained muscle contraction that results from continuous stimulation.

Tetrad—A pair of homologous chromosomes synapsing during prophase I of meiosis. Each chromosome consists of two sister chromatids; thus, each tetrad consists of four chromatids.

Thermoregulation—Process by which an organism regulates its internal temperature by using the respiratory, integumentary, and circulatory systems.

Thoracic duct—The main lymphatic vessel that empties lymph into the bloodstream.

Threshold—The lowest magnitude of stimulus strength that will induce a response.

Thrombin—An enzyme that participates in blood clotting; it converts fibrinogen into fibrin.

Thymus—A ductless gland in the upper chest region of vertebrates; it functions in the development of the immune system.

Thyroid—A vertebrate endocrine gland located in the neck that synthesizes triiodothyronine, thyroxine, and calcitonin.

Tissue—A mass of similar cells and support structures organized into a functional unit.

Tonus—A continuous state of low-level muscle contraction.

Totipotent—Type of stem-cell potency describing cells that are able to differentiate into all cell types within an organism.

Trachea—The tube that connects the pharynx to the bronchi.

Transduction—The transposition of genetic material from one organism to another by a virus.

Transformation—Uptake and incorporation of DNA from the environment by a recipient bacterial cell.

Transposon—Genetic element capable of inserting and removing itself from the genome.

Tricuspid valve—One of the atrioventricular valves, separating the right atrium from the right ventricle.

Trophoblast—Embryonic cells that line the blastocoel and give rise to the chorion and the placenta.

Tropic hormone—Hormone that is secreted and travels to a target cell or organ, where it triggers release of another hormone, which causes changes in the physiological activity of target cells.

Tubulin—Protein constituent of microtubules.

Universal donor—A person (O^- blood) whose blood is able to be given to all types without inducing an immune response.

Universal recipient—A person (AB^+ blood) receiving a blood transfusion who is able to receive all blood types without causing an immune response.

Urea—A nitrogenous waste product produced in the liver from ammonia.

Ureter—The tube that carries urine from the kidneys to the bladder.

Urethra—The tube that carries urine from the bladder to the exterior.

Urine—Liquid waste resulting from the filtration, reabsorption, and secretion of filtrate in the nephron.

Uterus—Organ in the mammalian female reproductive system that is the site of embryonic development.

Vaccine—A solution of fractionated, dead, or attenuated live pathogenic material that is introduced into an individual for the purpose of stimulating a primary immune response or "boosting" a previously produced anamnestic state.

Vagina—Passageway through which childbirth occurs; location into which sperm is deposited during sexual intercourse.

Vagus nerve—The tenth cranial nerve; it innervates the palate, pharynx, larynx, heart, lungs, and abdominal viscera; responsible for maintaining homeostatic activity through the parasympathetic response.

Vas deferens—The tube carrying sperm from the testis to the urethra in mammalian males.

Vasa recta—Second capillary bed within the kidney that removes substances from the interstitium of the kidney to be returned to the systemic circulation.

Vein—Thin-walled blood vessel that carries blood toward the heart.

Venae cavae—Two large veins (superior and inferior) that return deoxygenated blood from the periphery to the right atrium of the heart.

Ventricles—The chambers of the heart that pump blood into pulmonary and systemic circulation.

Vestigial—Referring to an organ or limb that has no apparent function now, but was functional at some time in the organism's evolutionary past.

Ventilation center—Groups of neurons in the medulla oblongata that regulate respiration.

Venule—Small venous structure that links the capillaries to the veins.

Villus—A small projection from the wall of the small intestine that increases the surface area for digestion and absorption.

Viroid—A small plant pathogen consisting of a very short, circular, single strand of RNA.

Virus—A tiny, organism-like particle composed of protein-encased nucleic acid; viruses are obligate parasites.

Vitamin—An organic nutrient that an organism cannot produce itself and that is required by the organism in small amounts to aid in proper metabolic functioning; vitamins often function as cofactors for enzymes.

White matter—The portion of the central nervous system consisting primarily of myelinated axons.

Zona pellucida—One of two layers of cells surrounding an oocyte.

Zygote—The diploid ($2n$) cell that results from the fusion of two haploid (n) gametes.

Zymogen—An inactive enzyme precursor that is converted into an active enzyme.

Preface

And now it starts: your long, yet fruitful journey toward wearing a white coat. Proudly wearing that white coat, though, is hopefully only part of your motivation. You are reading this book because you want to be a healer.

If you're serious about going to medical school, then you are likely already familiar with the importance of the MCAT in medical school admissions. While the holistic review process puts additional weight on your experiences, extracurricular activities, and personal attributes, the fact remains: along with your GPA, your MCAT score remains one of the two most important components of your application portfolio—at least early in the admissions process. Each additional point you score on the MCAT pushes you in front of thousands of other students and makes you an even more attractive applicant. But the MCAT is not simply an obstacle to overcome; it is an opportunity to show schools that you will be a strong student and a future leader in medicine.

We at Kaplan take our jobs very seriously and aim to help students see success not only on the MCAT, but as future physicians. We work with our Learning Science experts to ensure that we're using the most up-to-date teaching techniques in our resources. Multiple members of our team hold advanced degrees in medicine or associated biomedical sciences, and are committed to the highest level of medical education. Kaplan has been working with the MCAT for over 50 years and our commitment to premed students is unflagging; in fact, Stanley Kaplan created this company when he had difficulty being accepted to medical school due to unfair quota systems that existed at the time.

We stand now at the beginning of a new era in medical education. As citizens of this 21st-century world of healthcare, we are charged with creating a patient-oriented, culturally competent, cost-conscious, universally available, technically advanced and research-focused healthcare system, run by compassionate providers. Suffice it to say, this is no easy task. Problem-based learning, integrated curricula, and classes in interpersonal skills are some of the responses to this demand for an excellent workforce—a workforce of which you'll soon be a part.

We're thrilled that you've chosen us to help you on this journey. Please reach out to us to share your challenges, concerns, and successes. Together, we will shape the future of medicine in the United States and abroad; we look forward to helping you become the doctor you deserve to be.

Good luck!

Alexander Stone Macnow, MD

Preface . . . iii

The *Kaplan MCAT Review* Team . . . vi

About *Scientific American* . . . vii

About the MCAT . . . viii

How This Book Was Created . . . xix

Using This Book . . . xx

Chapter 1: Atomic Structure ★★ 1

1.1 Subatomic Particles . . . 4

1.2 Atomic Mass *vs.* Atomic Weight . . . 7

1.3 Rutherford, Planck, and Bohr . . . 10

1.4 Quantum Mechanical Model of Atoms . . . 15

Chapter 2: The Periodic Table ★★ 39

2.1 The Periodic Table . . . 42

2.2 Types of Elements . . . 43

2.3 Periodic Properties of the Elements . . . 47

2.4 The Chemistry of Groups . . . 54

Chapter 3: Bonding and Chemical Interactions ★★★ 71

3.1 Bonding . . . 74

3.2 Ionic Bonds . . . 77

3.3 Covalent Bonds . . . 78

3.4 Intermolecular Forces . . . 93

Chapter 4: Compounds and Stoichiometry ★★ 109

4.1 Molecules and Moles . . . 112

4.2 Representation of Compounds . . . 117

4.3 Types of Chemical Reactions . . . 120

4.4 Balancing Chemical Equations . . . 125

4.5 Applications of Stoichiometry . . . 126

4.6 Ions . . . 130

Chapter 5: Chemical Kinetics ★★★ 147

5.1 Chemical Kinetics . . . 149

5.2 Reaction Rates . . . 157

About *Scientific American*

Founded in 1845, *Scientific American* is the award-winning authoritative source for the science discoveries and technology innovations that matter. The longest continuously published magazine in the United States, it is translated into 14 languages and reaches a global audience of more than 6 million. Other titles include *Scientific American Mind* and *Spektrum der Wissenschaft* in Germany. In its history, 152 Nobel Prize scientists have contributed 246 articles to *Scientific American*, including Albert Einstein, Francis Crick, Stanley Prusiner, and Richard Axel.

Scientific American is at the heart of Nature Publishing Group's consumer media division, meeting the needs of the general public. For more information, please visit www.scientificamerican.com.

About the MCAT

ANATOMY OF THE MCAT

Here is a general overview of the structure of Test Day:

Section	Number of Questions	Time Allotted
Examinee Agreement		8 minutes
Tutorial (optional)		10 minutes
Chemical and Physical Foundations of Biological Systems	59	95 minutes
Break (optional)		10 minutes
Critical Analysis and Reasoning Skills (CARS)	53	90 minutes
Lunch Break (optional)		30 minutes
Biological and Biochemical Foundations of Living Systems	59	95 minutes
Break (optional)		10 minutes
Psychological, Social, and Biological Foundations of Behavior	59	95 minutes
Void Question		5 minutes
Satisfaction Survey (optional)		5 minutes

The structure of the four sections of the MCAT is further detailed below.

Chemical and Physical Foundations of Biological Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 5% • General Chemistry: 30% • Organic Chemistry: 15% • Physics: 25%
Critical Analysis and Reasoning Skills (CARS)	
Time	90 minutes
Format	• 53 questions • 9 passages • All questions are passage-based. There are no discrete (stand-alone) questions. • Score between 118 and 132

What It Tests	Disciplines: • Humanities: 50% • Social Sciences: 50% Skills: • *Foundations of Comprehension*: 30% • *Reasoning Within the Text*: 30% • *Reasoning Beyond the Text*: 40%
Biological and Biochemical Foundations of Living Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 65% • General Chemistry: 5% • Organic Chemistry: 5%
Psychological, Social, and Biological Foundations of Behavior	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biology: 5% • Psychology: 65% • Sociology: 30%
Total	
Testing Time	375 minutes (6 hours, 15 minutes)
Total Seat Time	453 minutes (7 hours, 33 minutes)
Questions	230
Score	472 to 528

SCIENTIFIC INQUIRY AND REASONING SKILLS (SIRS)

The AAMC has defined four *Scientific Inquiry and Reasoning Skills* (SIRS) that will be tested in the three science sections of the MCAT:

1. *Knowledge of Scientific Concepts and Principles* (35% of questions)
2. *Scientific Reasoning and Problem-Solving* (45% of questions)
3. *Reasoning About the Design and Execution of Research* (10% of questions)
4. *Data-Based and Statistical Reasoning* (10% of questions)

Let's see how each one breaks down into more specific Test Day behaviors. Note that the bullet points of specific objectives for each of the SIRS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Skill 1: *Knowledge of Scientific Concepts and Principles*

This is probably the least surprising of the four SIRS; the testing of science knowledge is, after all, one of the signature qualities of the MCAT. Skill 1 questions will require you to do the following:

- Recognize correct scientific principles
- Identify the relationships among closely-related concepts
- Identify the relationships between different representations of concepts (verbal, symbolic, graphic)
- Identify examples of observations that illustrate scientific principles
- Use mathematical equations to solve problems

At Kaplan, we simply call these Science Knowledge or Skill 1 questions. Another way to think of Skill 1 questions is as "one-step" problems. The single step is either to realize which scientific concept the question stem is suggesting or to take the concept stated in the question stem and identify which answer choice is an accurate application of it. Skill 1 questions are particularly prominent among discrete questions (those not associated with a passage). These questions are an opportunity to gain quick points on Test Day—if you know the science concept attached to the question, then that's it! On Test Day, 35% of the questions in each science section will be Skill 1 questions.

Here are some sample Skill 1 question stems:

- How would a proponent of the James–Lange theory of emotion interpret the findings of the study cited the passage?
- Which of the following most accurately describes the function of FSH in the human female menstrual cycle?
- If the products of Reaction 1 and Reaction 2 were combined in solution, the resulting reaction would form:
- Ionic bonds are maintained by which of the following forces?

Skill 2: *Scientific Reasoning and Problem-Solving*

The MCAT science sections do, of course, move beyond testing straightforward science knowledge; Skill 2 questions are the most common way in which it does so. At Kaplan, we also call these Critical Thinking questions. Skill 2 questions will require you to do the following:

- Reason about scientific principles, theories, and models
- Analyze and evaluate scientific explanations and predictions
- Evaluate arguments about causes and consequences
- Bring together theory, observations, and evidence to draw conclusions
- Recognize scientific findings that challenge or invalidate a scientific theory or model
- Determine and use scientific formulas to solve problems

Just as Skill 1 questions can be thought of as "one-step" problems, many Skill 2 questions are "two-step" problems, and more difficult Skill 2 questions may require three or more steps. These questions can require a wide spectrum of reasoning skills, including integration of multiple facts from a passage, combination of multiple science content areas, and prediction of an experiment's results. Skill 2 questions also tend to ask about science content without actually mentioning it by name. For example, a question might describe the results of one experiment and ask you to predict the results of a second experiment without actually telling you what underlying scientific principles are at work—part of the question's difficulty will be figuring out which principles to apply in order to get the correct answer. On Test Day, 45% of the questions in each science section will be Skill 2 questions.

Here are some sample Skill 2 question stems:

- Which of the following experimental conditions would most likely yield results similar to those in Figure 2?
- All of the following conclusions are supported by the information in the passage EXCEPT:
- The most likely cause of the anomalous results found by the experimenter is:
- An impact to a man's chest quickly reduces the volume of one of his lungs to 70% of its initial value while not allowing any air to escape from the man's mouth. By what percentage is the force of outward air pressure increased on a 2 cm^2 portion of the inner surface of the compressed lung?

Skill 3: *Reasoning About the Design and Execution of Research*

The MCAT is interested in your ability to critically appraise and analyze research, as this is an important day-to-day task of a physician. We call these questions Skill 3 or Experimental and Research Design questions for short. Skill 3 questions will require you to do the following:

- Identify the role of theory, past findings, and observations in scientific questioning
- Identify testable research questions and hypotheses
- Distinguish between samples and populations and distinguish results that support generalizations about populations
- Identify independent and dependent variables
- Reason about the features of research studies that suggest associations between variables or causal relationships between them (such as temporality and random assignment)
- Identify conclusions that are supported by research results
- Determine the implications of results for real-world situations
- Reason about ethical issues in scientific research

Over the years, the AAMC has received input from medical schools to require more practical research skills of MCAT test-takers, and Skill 3 questions are the response to these demands. This skill is unique in that the outside knowledge you need to answer Skill 3 questions is not taught in any one undergraduate course; instead, the research design principles needed to answer these questions are learned gradually throughout your science classes and especially through any laboratory work you have completed. It should be noted that Skill 3 comprises 10% of the questions in each science section on Test Day.

Here are some sample Skill 3 question stems:

- What is the dependent variable in the study described in the passage?
- The major flaw in the method used to measure disease susceptibility in Experiment 1 is:
- Which of the following procedures is most important for the experimenters to follow in order for their study to maintain a proper, randomized sample of research subjects?
- A researcher would like to test the hypothesis that individuals who move to an urban area during adulthood are more likely to own a car than are those who have lived in an urban area since birth. Which of the following studies would best test this hypothesis?

Skill 4: *Data-Based and Statistical Reasoning*

Lastly, the science sections of the MCAT test your ability to analyze the visual and numerical results of experiments and studies. We call these Data and Statistical Analysis questions. Skill 4 questions will require you to do the following:

- Use, analyze, and interpret data in figures, graphs, and tables
- Evaluate whether representations make sense for particular scientific observations and data

- Use measures of central tendency (mean, median, and mode) and measures of dispersion (range, interquartile range, and standard deviation) to describe data
- Reason about random and systematic error
- Reason about statistical significance and uncertainty (interpreting statistical significance levels and interpreting a confidence interval)
- Use data to explain relationships between variables or make predictions
- Use data to answer research questions and draw conclusions

Skill 4 is included in the MCAT because physicians and researchers spend much of their time examining the results of their own studies and the studies of others, and it's very important for them to make legitimate conclusions and sound judgments based on that data. The MCAT tests Skill 4 on all three science sections with graphical representations of data (charts and bar graphs) as well as numerical ones (tables, lists, and results summarized in sentence or paragraph form). On Test Day, 10% of the questions in each science section will be Skill 4 questions.

Here are some sample Skill 4 question stems:

- According to the information in the passage, there is an inverse correlation between:
- What conclusion is best supported by the findings displayed in Figure 2?
- A medical test for a rare type of heavy metal poisoning returns a positive result for 98% of affected individuals and 13% of unaffected individuals. Which of the following types of error is most prevalent in this test?
- If a fourth trial of Experiment 1 was run and yielded a result of 54% compliance, which of the following would be true?

SIRS Summary

Discussing the SIRS tested on the MCAT is a daunting prospect given that the very nature of the skills tends to make the conversation rather abstract. Nevertheless, with enough practice, you'll be able to identify each of the four skills quickly, and you'll also be able to apply the proper strategies to solve those problems on Test Day. If you need a quick reference to remind you of the four SIRS, these guidelines may help:

Skill 1 (**Science Knowledge**) questions ask:

- Do you remember this science content?

Skill 2 (**Critical Thinking**) questions ask:

- Do you remember this science content? And if you do, could you please apply it to this novel situation?
- Could you answer this question that cleverly combines multiple content areas at the same time?

Skill 3 (**Experimental and Research Design**) questions ask:

- Let's forget about the science content for a while. Could you give some insight into the experimental or research methods involved in this situation?

Skill 4 (**Data and Statistical Analysis**) questions ask:

- Let's forget about the science content for a while. Could you accurately read some graphs and tables for a moment? Could you make some conclusions or extrapolations based on the information presented?

CRITICAL ANALYSIS AND REASONING SKILLS (CARS)

The *Critical Analysis and Reasoning Skills* (CARS) section of the MCAT tests three discrete families of textual reasoning skills; each of these families requires a higher level of reasoning than the last. Those three skills are as follows:

1. *Foundations of Comprehension* (30% of questions)
2. *Reasoning Within the Text* (30% of questions)
3. *Reasoning Beyond the Text* (40% of questions)

These three skills are tested through nine humanities- and social sciences-themed passages, with approximately 5 to 7 questions per passage. Let's take a more in-depth look into these three skills. Again, the bullet points of specific objectives for each of the CARS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Foundations of Comprehension

Questions in this skill will ask for basic facts and simple inferences about the passage; the questions themselves will be similar to those seen on reading comprehension sections of other standardized exams like the SAT® and ACT®. *Foundations of Comprehension* questions will require you to do the following:

- Understand the basic components of the text
- Infer meaning from rhetorical devices, word choice, and text structure

This admittedly covers a wide range of potential question types including Main Idea, Detail, Function, and Definition-in-Context questions, but finding the correct answer to all *Foundations of Comprehension* questions will follow from a basic understanding of the passage and the point of view of its author (and occasionally that of other voices in the passage).

Here are some sample *Foundations of Comprehension* question stems:

- **Main Idea**—The author's primary purpose in this passage is:
- **Detail**—Based on the information in the second paragraph, which of the following is the most accurate summary of the opinion held by Schubert's critics?
- **(Scattered) Detail**—According to the passage, which of the following is FALSE about literary reviews in the 1920s?
- **Function**—The author's discussion of the effect of socioeconomic status on social mobility primarily serves which of the following functions?
- **Definition-in-Context**—The word "obscure" (paragraph 3), when used in reference to the historian's actions, most nearly means:

Reasoning Within the Text

While *Foundations of Comprehension* questions will usually depend on interpreting a single piece of information in the passage or understanding the passage as a whole, *Reasoning Within the Text* questions will typically require you to infer unstated parts of arguments or bring together two disparate pieces of the passage. *Reasoning Within the Text* questions will require you to:

- Integrate different components of the text to increase comprehension

In other words, questions in this skill often ask either *How do these two details relate to one another?* or *What else must be true that the author didn't say?* The CARS section will also ask you to judge certain parts of the passage or even judge the author. These questions, which fall under the *Reasoning Within the Text* skill, can ask you to identify authorial bias, evaluate the credibility of cited sources, determine the logical soundness of an argument, or search for relevant evidence in the passage to support a given conclusion. In all, this category includes Inference and Strengthen–Weaken (Within the Passage) questions, as well as a smattering of related—but rare—question types.

Here are some sample *Reasoning Within the Text* question stems:

- **Inference (Implication)**—Which of the following phrases, as used in the passage, is most suggestive that the author has a personal bias toward narrative records of history?
- **Inference (Assumption)**—In putting together her argument in the passage, the author most likely assumes:
- **Strengthen–Weaken (Within the Passage)**—Which of the following facts is used in the passage as the most prominent piece of evidence in favor of the author's conclusions?
- **Strengthen–Weaken (Within the Passage)**—Based on the role it plays in the author's argument, *The Possessed* can be considered:

Reasoning Beyond the Text

The distinguishing factor of *Reasoning Beyond the Text* questions is in the title of the skill: the word *Beyond*. Questions that test this skill, which make up a larger share of the CARS section than questions from either of the other two skills, will always introduce a completely new situation that was not present in the passage itself; these questions will ask you to determine how one influences the other. *Reasoning Beyond the Text* questions will require you to:

- Apply or extrapolate ideas from the passage to new contexts
- Assess the impact of introducing new factors, information, or conditions to ideas from the passage

The *Reasoning Beyond the Text* skill is further divided into Apply and Strengthen–Weaken (Beyond the Passage) questions, and a few other rarely appearing question types.

Here are some sample *Reasoning Beyond the Text* question stems:

- **Apply**—If a document were located that demonstrated Berlioz intended to include a chorus of at least 700 in his *Grande Messe des Mortes*, how would the author likely respond?
- **Apply**—Which of the following is the best example of a "virtuous rebellion," as it is defined in the passage?
- **Strengthen–Weaken (Beyond the Text)**—Suppose Jane Austen had written in a letter to her sister, "My strongest characters were those forced by circumstance to confront basic questions about the society in which they lived." What relevance would this have to the passage?
- **Strengthen–Weaken (Beyond the Text)**—Which of the following sentences, if added to the end of the passage, would most WEAKEN the author's conclusions in the last paragraph?

CARS Summary

Through the *Foundations of Comprehension* skill, the CARS section tests many of the reading skills you have been building on since grade school, albeit in the context of very challenging doctorate-level passages. But through the two other skills (*Reasoning Within the Text* and *Reasoning Beyond the Text*), the MCAT demands that you understand the deep structure of passages and the arguments within them at a very advanced level. And, of course, all of this is tested under very tight timing restrictions: only 102 seconds per question—and that doesn't even include the time spent reading the passages.

Here's a quick reference guide to the three CARS skills:

Foundations of Comprehension questions ask:

- Did you understand the passage and its main ideas?
- What does the passage have to say about this particular detail?

Reasoning Within the Text questions ask:

- What must be true that the author did not say?
- What's the logical relationship between these two ideas from the passage?
- How well argued is the author's thesis?

Reasoning Beyond the Text questions ask:

- How does this principle from the passage apply to this new situation?
- How does this new piece of information influence the arguments in the passage?

SCORING

Each of the four sections of the MCAT is scored between 118 and 132, with the median at 125. This means the total score ranges from 472 to 528, with the median at 500. Why such peculiar numbers? The AAMC stresses that this scale emphasizes the importance of the central portion of the score distribution, where most students score (around 125 per section, or 500 total), rather than putting undue focus on the high end of the scale.

Note that there is no wrong answer penalty on the MCAT, so you should select an answer for every question—even if it is only a guess.

The AAMC has released the official correlation between scaled score and percentile, as shown here. It should be noted that the percentile scale is adjusted and renormalized over time and thus should not be overinterpreted.

Total Score	Percentile	Total Score	Percentile
528	100	499	47
527	100	498	43
526	100	497	40
525	100	496	37
524	100	495	34
523	100	494	31
522	99	493	28
521	99	492	25
520	98	491	22
519	98	490	20
518	97	489	18
517	96	488	15
516	95	487	13

Total Score	Percentile	Total Score	Percentile
515	93	486	11
514	91	485	10
513	89	484	8
512	87	483	7
511	85	482	6
510	83	481	5
509	80	480	4
508	77	479	3
507	74	478	2
506	71	477	1
505	68	476	1
504	64	475	1
503	61	474	0
502	57	473	0
501	54	472	0
500	51		

Source: AAMC. 2015. *Summary of Total and Section Scores from the MCAT Exam Based on Results for Tests Administered in April and May 2015.* Accessed February 2016. https://students-residents.aamc.org/search/?q=percentilenewmcat.pdf.

Further information on score reporting is included at the end of the next section (see *After Your Test*).

MCAT POLICIES AND PROCEDURES

We strongly encourage you to download the latest copy of *MCAT® Essentials*, available on the AAMC's website, to ensure that you have the latest information about registration and Test Day policies and procedures; this document is updated annually. A brief summary of some of the most important rules is provided here.

MCAT Registration

The only way to register for the MCAT is online. You can access AAMC's registration system at: www.aamc.org/mcat.

You will be able to access the site approximately six months before Test Day. The AAMC designates three registration "Zones"—Gold, Silver, and Bronze. Registering during the Gold Zone (from the opening of registration until approximately one month before Test Day) provides the most flexibility and lowest test fees. The Silver Zone runs until approximately two to three weeks before Test Day and has less flexibility and higher fees; the Bronze Zone runs until approximately one to two weeks before Test Day and has the least flexibility and highest fees.

Fees and the Fee Assistance Program (FAP)

Payment for test registration must be made by MasterCard or VISA. As described earlier, the fees for registering for the MCAT—as well as rescheduling the exam or changing your testing center—increase as one approaches Test Day. In addition, it is not uncommon for test centers to fill up well in advance of the registration deadline. For these reasons, we recommend identifying your preferred Test Day as soon as possible and registering. There are ancillary benefits to having a set Test Day, as well: when you know the date you're working toward, you'll study harder and are less likely to keep pushing back the exam. The AAMC offers a Fee Assistance Program (FAP) for students with financial hardship to help reduce the cost of taking the MCAT, as well as for the American Medical College Application Service (AMCAS®) application. Further information on the FAP can be found at: www.aamc.org/students/applying/fap.

Testing Security

On Test Day, you will be required to present a government-issued ID. When registering, take care to spell your name precisely the same as it appears on this ID; failure to provide this ID at the test center or differences in spelling between your registration and ID will be considered a "no-show," and you will not receive a refund for the exam.

You will also be required to provide an electronic thumbprint and electronic signature verification to take the exam. Some testing centers may use a metal detection wand to ensure that no prohibited items are brought into the testing room. Prohibited items include all electronic devices, including watches and timers, calculators, cell phones, and any and all forms of recording equipment; food, drinks (including water), and cigarettes or other smoking paraphernalia; hats and scarves (except for religious purposes); and books, notes, or other study materials. If you require a medical device, such as an insulin pump or pacemaker, you must apply for accommodated testing. During breaks, you are allowed to access food and drink, but not electronic devices, including cell phones.

Testing centers are under video surveillance and the AAMC does not take potential violations of testing security lightly. The bottom line: *know the rules and don't break them*.

Accommodations

Students with disabilities or medical conditions can apply for accommodated testing. Documentation of the disability or condition is required, and requests may take two months—or more—to be approved. For this reason, it is recommended that you begin the process of applying for accommodated testing as early as possible. More information on applying for accommodated testing can be found at: www.aamc.org/students/applying/mcat/accommodations

After Your Test

When your MCAT is all over, no matter how you feel you did, be good to yourself when you leave the test center. Celebrate! Take a nap. Watch a movie. Ride your bike. Plan a trip. Call up all of your neglected friends or stalk them on Facebook. Totally consume a cheesesteak and drink dirty martinis at night (assuming you're over 21). Whatever you do, make sure that it has absolutely nothing to do with thinking too hard—you deserve some rest and relaxation.

Perhaps most importantly, do not discuss specific details about the test with anyone. For one, it is important to let go of the stress of Test Day, and reliving your exam only inhibits you from being able to do so. But more significantly, the Examinee Agreement you sign at the beginning of your exam specifically prohibits you from discussing or disclosing exam content. The AAMC is known to seek out individuals who violate this agreement and retains the right to prosecute these individuals at their discretion. This means that you should not, under any circumstances, discuss the exam in person or over the phone with other individuals—including us at Kaplan—or post information or questions about exam content to Facebook, Student Doctor Network, or other online social media. You are permitted to comment on your "general exam experience," including how you felt about the exam overall or an individual section, but this is a fine line. In summary: *if you're not certain whether you can discuss an aspect of the test or not, just don't do it!* Do not let a silly Facebook post stop you from becoming the doctor you deserve to be.

Scores are released approximately one month after Test Day. The release is staggered during the afternoon and evening, starting at 5 p.m. Eastern. This means that not all examinees receive their scores at exactly the same time. Your score report will include a scaled score for each section between 118 and 132, as well as your total combined score between 472 and 528. These scores are given as confidence intervals. For each section, the confidence interval is approximately the given score ±1; for the total score, it is approximately the given score ±2. You will also be given the corresponding percentile rank for each of these section scores and the total score.

AAMC CONTACT INFORMATION

How This Book Was Created

The *Kaplan MCAT Review* project began shortly after the release of the *Preview Guide for the MCAT 2015 Exam*, 2nd edition. Through thorough analysis by our staff psychometricians, we were able to analyze the relative yield of the different topics on the MCAT, and we began constructing tables of contents for the books of the *Kaplan MCAT Review* series. A dedicated staff of 30 writers, 7 editors, and 32 proofreaders worked over 5,000 combined hours to produce these books. The format of the books was heavily influenced by weekly meetings with Kaplan's learning-science team.

These books were submitted for publication in February 2016. For any updates after this date, please visit www.kaplanmcat.com/pages/retail-book-corrections-and-updates.

If you have any questions about the content presented here, email KaplanMCATfeedback@kaplan.com. For other questions not related to content, email booksupport@kaplan.com.

Each book has been vetted through at least eight rounds of review. To that end, the information presented is these books is true and accurate to the best of our knowledge. Still, your feedback helps us improve our prep materials. Please notify us of any inaccuracies or errors in the books by sending an email to KaplanMCATfeedback@kaplan.com.

Using This Book

Kaplan MCAT General Chemistry Review, along with the other seven books in your student kit, is the cornerstone of your prep for the MCAT. This book offers the content review, strategies, and practice that make Kaplan the #1 choice for MCAT prep.

This book is designed to help you review the general chemistry topics covered on the MCAT. Please understand that content review—no matter how thorough—is not sufficient preparation for the MCAT! The MCAT tests not only your science knowledge but also your critical reading, reasoning, and problem-solving skills. Do not assume that simply memorizing the contents of this book will earn you high scores on Test Day; to maximize your scores, you must also improve your reading and test-taking skills through MCAT-style questions and practice tests.

MCAT CONCEPT CHECKS

At the end of each section, you'll find a few open-ended questions that you can use to assess your mastery of the material. These MCAT Concept Checks were introduced after multiple conversations with Kaplan's learning-science team. Research has demonstrated repeatedly that introspection and self-analysis improve mastery, retention, and recall of material. Complete these MCAT Concept Checks to ensure that you've got the key points from each section before moving on!

PRACTICE QUESTIONS

At the end of each chapter, you'll find 15 MCAT-style practice questions. These are designed to help you assess your understanding of the chapter you just read. Most of these questions focus on the first of the *Scientific Inquiry and Reasoning Skills* (*Knowledge of Scientific Concepts and Principles*), although there are occasional questions that fall into the second or fourth SIRS (*Scientific Reasoning and Problem-Solving*, and *Data-Based and Statistical Reasoning*, respectively).

SIDEBARS

The following is a guide to the five types of sidebars you'll find in *Kaplan MCAT General Chemistry Review*:

- **Bridge:** These sidebars create connections between science topics that appear in multiple chapters throughout the *Kaplan MCAT Review* series.
- **Key Concept:** These sidebars draw attention to the most important takeaways in a given topic, and they sometimes offer synopses or overviews of complex information. If you understand nothing else, make sure you grasp the Key Concepts for any given subject.
- **MCAT Expertise:** These sidebars point out how information may be tested on the MCAT or offer key strategy points and test-taking tips that you should apply on Test Day.
- **Mnemonic:** These sidebars present memory devices to help recall certain facts.
- **Real World:** These sidebars illustrate how a concept in the text relates to the practice of medicine or the world at large. While this is not information you need to know for Test Day, many of the topics in Real World sidebars are excellent examples of how a concept may appear in a passage or discrete (stand-alone) question on the MCAT.

WHAT THIS BOOK COVERS

The information presented in the *Kaplan MCAT Review* series covers everything listed on the official MCAT content lists. Every topic in these lists is covered in the same level of detail as is common to the undergraduate and postbaccalaureate classes that are considered prerequisites for the MCAT. Note that your premedical classes may include topics not discussed in these books, or they may go into more depth than these books do. Additional exposure to science content is never a bad thing, but recognize that all of the content knowledge you are expected to have walking in on Test Day is covered in these books.

New to the Third Edition of the *Kaplan MCAT Review* series are **Star Ratings**. You'll see these stars throughout the book, and they are meant as a guide to the number and density of test-worthy facts in each chapter and sub-chapter.

★★★★ Four-star chapters and topics are packed with testable facts. Make sure you have all of these down before Test Day. Even if you find these topics difficult to grasp, you should put in the extra effort to fully understand them.

★★★ Three-star chapters and topics contain content that is tested an above-average amount. If you plan to score above average–and you probably do!–then you should master all or nearly all of these before Test Day.

★★ Two-star sections will demand varied focus, depending on your personal studying needs. These topics have been proven to be MCAT-worthy, but if you have limited study time or already feel confident with these topics, you can move more quickly through this material.

★ One-star chapters and topics are unlikely to be directly tested, but many of these topics provide foundations for, and connections between, higher-yield material.

These Star Ratings were created based on material released by the AAMC. In other words, according to the testmaker and all our experience with their resources, more stars means more questions on Test Day.

This book also contains a thorough glossary and index for easy navigation of the text.

In the end, this is your book, so write in the margins, draw diagrams, highlight the key points—do whatever is necessary to help you get that higher score. We look forward to working with you as you achieve your dreams and become the doctor you deserve to be!

Concept Summary 27

Introduction

Chemistry is the investigation of the atoms and molecules that make up our bodies, our possessions, the world around us, and the food that we eat. There are different branches of chemistry, three of which are tested directly on the MCAT: general (inorganic) chemistry, organic chemistry, and biochemistry. Ultimately, all investigations in chemistry are seeking to answer the questions that confront us in the form—the shape, structure, mode, and essence—of the physical world that surrounds us.

Many students feel similarly about general chemistry and physics: *But I'm premed!*, they say. *Why do I need to know any of this? What good will this be when I'm a doctor? Do I only need to know this for the MCAT?* Recognize that to be an effective doctor, one must understand the physical building blocks that make up the human body. Pharmacologic treatment is based on chemistry; many diagnostic tests used every day detect changes in the chemistry of the body.

So, let's get down to the business of learning and remembering the principles of the physical world that help us understand what all this "stuff" is, how it works, and why it behaves the way it does—at both the molecular and macroscopic levels. In the process of reading through these chapters and applying your knowledge to practice questions, you'll prepare yourself for success not only on the *Chemical and Physical Foundations of Biological Systems* section of the MCAT but also in your future career as a physician.

This first chapter starts our review of General Chemistry with a consideration of the fundamental unit of matter—the atom. First, we focus on the subatomic particles

MCAT Expertise

The building blocks of the atom are also the building blocks of knowledge for the general chemistry concepts tested on the MCAT. By understanding these particles, we will be able to use that knowledge as the "nucleus" of understanding for all of general chemistry.

that make it up: protons, neutrons, and electrons. We will also review the Bohr and quantum mechanical models of the atom, with a particular focus on the similarities and differences between them.

1.1 Subatomic Particles ★★

Although you may have encountered in your university-level chemistry classes such subatomic particles as *quarks*, *leptons*, and *gluons*, the MCAT's approach to atomic structure is much simpler. There are three subatomic particles that you must understand: protons, neutrons, and electrons.

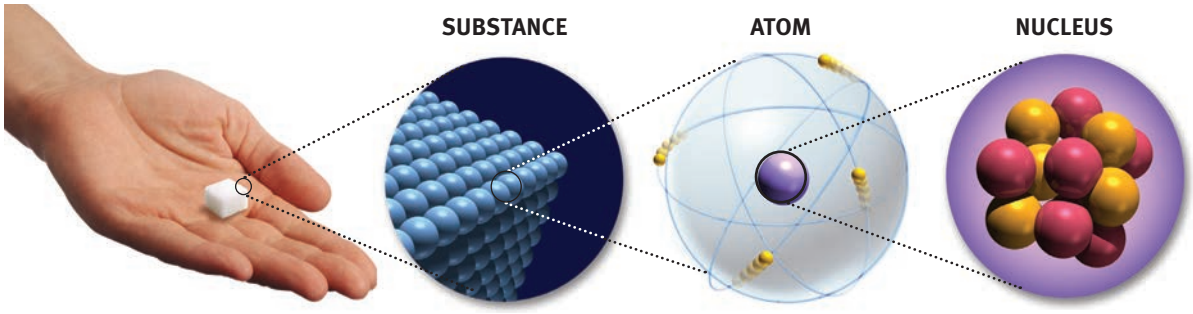

Figure 1.1. Matter: From Macroscopic to Microscopic

PROTONS

Protons are found in the **nucleus** of an atom, as shown in Figure 1.1. Each proton has an amount of charge equal to the fundamental unit of charge ($e = 1.6 \times 10^{-19}$ C), and we denote this fundamental unit of charge as "+1 e" or simply "+1" for the proton. Protons have a mass of approximately one **atomic mass unit** (**amu**). The **atomic number** (**Z**) of an element, as shown in Figure 1.2, is equal to the number of protons found in an atom of that element. As such, it acts as a unique identifier for each element because elements are defined by the number of protons they contain. For example, all atoms of oxygen contain eight protons; all atoms of gadolinium contain 64 protons. While all atoms of a given element have the same atomic number, they do not necessarily have the same mass—as we will see in our discussion of isotopes.

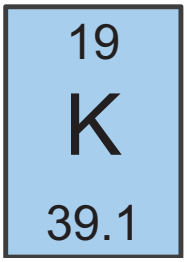

Figure 1.2. Potassium, from the Periodic Table
Potassium has the symbol K (Latin: *kalium*), atomic number 19, and atomic weight of approximately 39.1.

NEUTRONS

Neutrons, as the name implies, are neutral—they have no charge. A neutron's mass is only slightly larger than that of the proton, and together, the protons and the neutrons of the nucleus make up almost the entire mass of an atom. Every atom has a characteristic **mass number** (***A***), which is the sum of the protons and neutrons in the atom's nucleus. A given element can have a variable number of neutrons; thus, while atoms of the same element always have the same atomic number, they do not necessarily have the same mass number. Atoms that share an atomic number but have different mass numbers are known as **isotopes** of the element, as shown in Figure 1.3. For example, carbon ($Z = 6$) has three naturally occurring isotopes: ${}^{12}_{6}\mathrm{C}$, with six protons and six neutrons; ${}^{13}_{6}\mathrm{C}$, with six protons and seven neutrons; and ${}^{14}_{6}\mathrm{C}$, with six protons and eight neutrons. The convention ${}^{A}_{Z}\mathrm{X}$ is used to show both the atomic number (Z) and the mass number (A) of atom X.

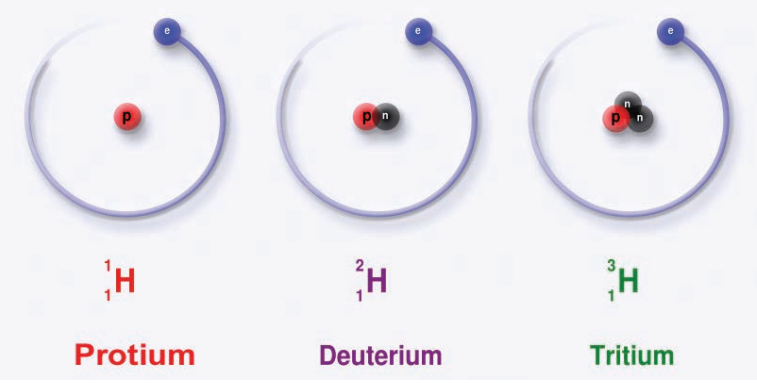

Figure 1.3. Various Isotopes of Hydrogen
Atoms of the same element have the same atomic number ($Z = 1$), but may have varying mass numbers ($A = 1, 2,$ or 3).

ELECTRONS

Electrons move through the space surrounding the nucleus and are associated with varying levels of energy. Each electron has a charge equal in magnitude to that of a proton, but with the opposite (negative) sign, denoted by "–1 *e*" or simply "–*e*." The mass of an electron is approximately $\frac{1}{2000}$ that of a proton. Because subatomic particles' masses are so small, the electrostatic force of attraction between the unlike charges of the proton and electron is far greater than the gravitational force of attraction based on their respective masses.

Electrons move around the nucleus at varying distances, which correspond to varying levels of electrical potential energy. The electrons closer to the nucleus are at lower energy levels, while those that are further out (in higher **shells**) have higher energy. The electrons that are farthest from the nucleus have the strongest interactions with the surrounding environment and the weakest interactions with the nucleus. These electrons are called **valence electrons**; they are much more likely to become involved

Bridge

Valence electrons will be very important to us in both general and organic chemistry. Knowing how tightly held those electrons are will allow us to understand many of an atom's properties and how it interacts with other atoms, especially in bonding. Bonding is so important that it is discussed in Chapter 3 of both *MCAT General Chemistry Review* and *MCAT Organic Chemistry Review*.

in bonds with other atoms because they experience the least electrostatic pull from their own nucleus. Generally speaking, the valence electrons determine the reactivity of an atom. As we will discuss in Chapter 3 of *MCAT General Chemistry Review*, the sharing or transferring of these valence electrons in bonds allows elements to fill their highest energy level to increase stability. In the neutral state, there are equal numbers of protons and electrons; losing electrons results in the atom gaining a positive charge, while gaining electrons results in the atom gaining a negative charge. A positively charged atom is called a **cation**, and a negatively charged atom is called an **anion**.

Some basic features of the three subatomic particles are shown in Table 1.1.

Subatomic Particle	Symbol	Relative Mass	Charge	Location
Proton	p, p^+, or ${}_1^1\mathrm{H}$	1	+1	Nucleus
Neutron	n^0 or ${}_0^1n$	1	0	Nucleus
Electron	e^- or ${}_{-1}^0e$	0	–1	Orbitals

Table 1.1. Subatomic Particles

Example: Determine the number of protons, neutrons, and electrons in a nickel-58 atom and in a nickel-60 +2 cation.

Solution: $^{58}\mathrm{Ni}$ has an atomic number of 28 and a mass number of 58. Therefore, $^{58}\mathrm{Ni}$ will have 28 protons, 28 electrons, and 58 – 28, or 30, neutrons.

$^{60}\mathrm{Ni}^{2+}$ has the same number of protons as the neutral $^{58}\mathrm{Ni}$ atom. However, $^{60}\mathrm{Ni}^{2+}$ has a positive charge because it has lost two electrons; thus, Ni^{2+} will have 26 electrons. Also, the mass number is two units higher than for the $^{58}\mathrm{Ni}$ atom, and this difference in mass must be due to two extra neutrons; thus, it has a total of 32 neutrons.

MCAT Concept Check 1.1:

Before you move on, assess your understanding of the material with these questions.

1. Which subatomic particle is the most important for determining each of the following properties of an atom?
   - Charge:

     _____
   - Atomic number:

     _____
   - Isotope:

     _____

2. In nuclear medicine, isotopes are created and used for various purposes; for instance, ^{18}O is created from ^{18}F. Determine the number of protons, neutrons, and electrons in each of these species.

Particle	Protons	Neutrons	Electrons
^{18}O			
^{18}F			

1.2 Atomic Mass *vs.* Atomic Weight ★★

There are a few different terms used by chemists to describe the heaviness of an element: atomic mass and mass number, which are essentially synonymous, and atomic weight. While the atomic weight is a constant for a given element and is reported in the periodic table, the atomic mass or mass number varies from one isotope to another. In this section, carefully compare and contrast the different definitions of these terms—because they are similar, they can be easy to mix up on the MCAT.

Key Concept

- Atomic number (Z) = number of protons
- Mass number (A) = number of protons + number of neutrons
- Number of protons = number of electrons (in a neutral atom)
- Electrons are not included in mass calculations because they are much smaller.

ATOMIC MASS

As we've seen, the mass of one proton is approximately one amu. The size of the atomic mass unit is defined as exactly $\frac{1}{12}$ the mass of the carbon-12 atom, approximately 1.66×10^{-24} g. Because the carbon-12 nucleus has six protons and six neutrons, an amu is approximately equal to the mass of a proton or a neutron. The difference in mass between protons and neutrons is extremely small; in fact, it is approximately equal to the mass of an electron.

The **atomic mass** of an atom (in amu) is nearly equal to its **mass number**, the sum of protons and neutrons (in reality, some mass is lost as binding energy, as discussed in Chapter 9 of *MCAT Physics and Math Review*). Atoms of the same element with varying mass numbers are called **isotopes** (from the Greek for "same place"). Isotopes differ in their number of neutrons and are referred to by the name of the element followed by the mass number; for example, carbon-12 or iodine-131. Only the three isotopes of hydrogen, shown in Figure 1.3, are given unique names: *protium* (Greek: "first") has one proton and an atomic mass of 1 amu; *deuterium* ("second") has one proton and one neutron and an atomic mass of 2 amu; *tritium* ("third") has one proton and two neutrons and an atomic mass of 3 amu. Because isotopes have the same number of protons and electrons, they generally exhibit similar chemical properties.

ATOMIC WEIGHT

In nature, almost all elements exist as two or more isotopes, and these isotopes are usually present in the same proportions in any sample of a naturally occurring element. The

Key Concept

When an element has two or more isotopes, no one isotope will have a mass exactly equal to the element's atomic weight. Bromine, for example, is listed in the periodic table as having a mass of 79.9 amu. This is an average of the two naturally occurring isotopes, bromine-79 and bromine-81, which occur in almost equal proportions. There are no bromine atoms with an actual mass of 79.9 amu.

weighted average of these different isotopes is referred to as the **atomic weight** and is the number reported on the periodic table. For example, chlorine has two main naturally occurring isotopes: chlorine-35 and chlorine-37. Chlorine-35 is about three times more abundant than chlorine-37; therefore, the atomic weight of chlorine is closer to 35 than 37. On the periodic table, it is listed as 35.5. Figure 1.4 illustrates the half-lives of the different isotopes of the elements; because half-life corresponds with stability, it also helps determine the relative proportions of these different isotopes.

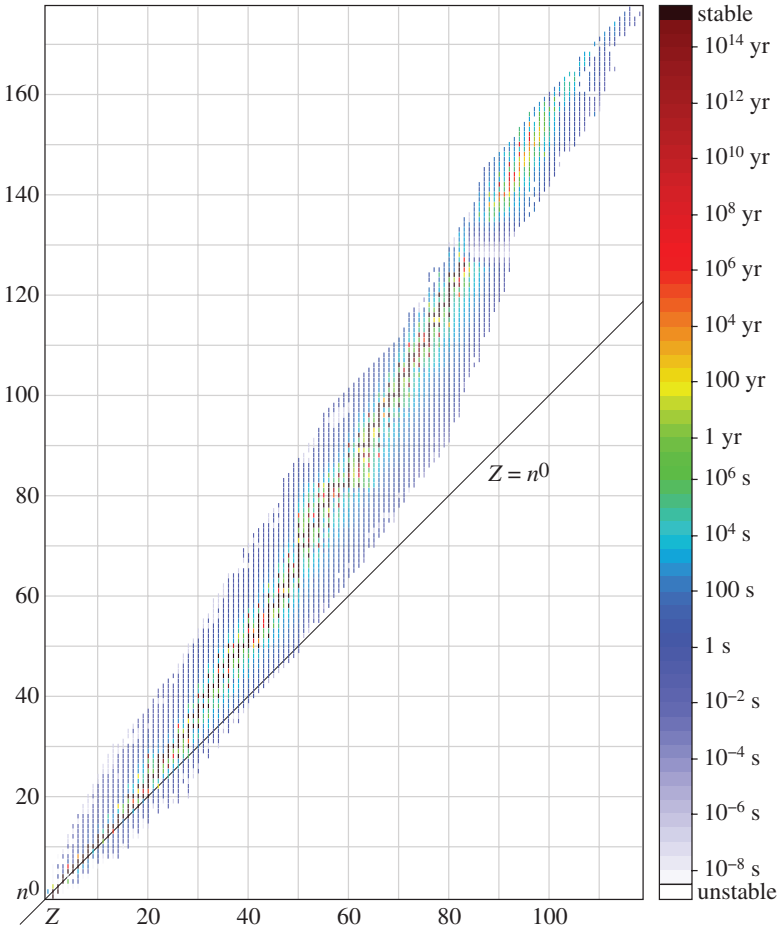

Figure 1.4. Half-Lives of the Different Isotopes of Elements
Half-life is a marker of stability; generally, longer-lasting isotopes are more abundant.

The utility of the atomic weight is that it represents both the mass of the "average" atom of that element, in amu, and the mass of one mole of the element, in grams. A mole is a number of "things" (atoms, ions, molecules) equal to **Avogadro's number**, $N_A = 6.02 \times 10^{23}$. For example, the atomic weight of carbon is 12.0 amu, which means that the average carbon atom has a mass of 12.0 amu (carbon-12 is *far* more abundant than carbon-13 or carbon-14), and 6.02×10^{23} carbon atoms have a combined mass of 12.0 grams.

Mnemonic

Atomic **mass** is nearly synonymous with **mass** number. Atomic **weight** is a **weighted** average of naturally occurring isotopes of that element.

Example: Element *Q* consists of three different isotopes: *A*, *B*, and *C*. Isotope *A* has an atomic mass of 40 amu and accounts for 60 percent of naturally occurring *Q*. Isotope *B* has an atomic mass of 44 amu and accounts for 25 percent of *Q*. Finally, isotope *C* has an atomic mass of 41 amu and accounts for 15 percent of *Q*. What is the atomic weight of element *Q*?

Solution: The atomic weight is the weighted average of the naturally occurring isotopes of that element:

0.60 (40 amu) + 0.25 (44 amu) + 0.15 (41 amu) = 24.00 amu + 11.00 amu + 6.15 amu = 41.15 amu

MCAT Concept Check 1.2:

Before you move on, assess your understanding of the material with these questions.

1. What are the definitions of atomic mass and atomic weight?
   - Atomic mass:

     _____
   - Atomic weight:

     _____
2. While molar mass is typically written in grams per mole $\left(\frac{g}{mol}\right)$, is the ratio moles per gram $\left(\frac{mol}{g}\right)$ also acceptable?

   _____

   _____
3. Calculate and compare the subatomic particles that make up the following atoms.

Isotope	Protons	Neutrons	Electrons
^{19}O			
^{16}O			
^{17}O			
^{19}F			
^{16}F			
^{238}U			
^{240}U			

1.3 Rutherford, Planck, and Bohr ★★★

In 1910, Ernest Rutherford provided experimental evidence that an atom has a dense, positively charged nucleus that accounts for only a small portion of the atom's volume. Eleven years earlier, Max Planck developed the first quantum theory, proposing that energy emitted as electromagnetic radiation from matter comes in discrete bundles called **quanta**. The **energy** of a quantum, he determined, is given by the **Planck relation**:

$$E = hf$$

Equation 1.1

where h is a proportionality constant known as **Planck's constant**, equal to 6.626×10^{-34} J · s, and f (sometimes designated by the Greek letter nu, ν) is the frequency of the radiation.

Bridge

Recall from Chapter 8 of *MCAT Physics Review* that the speed of light (or any wave) can be calculated using $v = f\lambda$. The speed of light, c, is $3 \times 10^8 \frac{\text{m}}{\text{s}}$. This equation can be incorporated into the equation for quantum energy to provide different derivations.

BOHR MODEL

In 1913, Danish physicist Niels Bohr used the work of Rutherford and Planck to develop his model of the electronic structure of the hydrogen atom. Starting from Rutherford's findings, Bohr assumed that the hydrogen atom consisted of a central proton around which an electron traveled in a circular orbit. He postulated that the centripetal force acting on the electron as it revolved around the nucleus was created by the electrostatic force between the positively charged proton and the negatively charged electron.

Bohr used Planck's quantum theory to correct certain assumptions that classical physics made about the pathways of electrons. Classical mechanics postulates that an object revolving in a circle, such as an electron, may assume an infinite number of values for its radius and velocity. The angular momentum ($L = mvr$) and kinetic energy ($K = \frac{1}{2}mv^2$) of the object could therefore take on any value. However, by incorporating Planck's quantum theory into his model, Bohr placed restrictions on the possible values of the angular momentum. Bohr predicted that the possible values for the **angular momentum** of an electron orbiting a hydrogen nucleus could be given by:

$$L = \frac{nh}{2\pi}$$

Equation 1.2

where n is the principal quantum number, which can be any positive integer, and h is Planck's constant. Because the only variable is the principal quantum number, the angular momentum of an electron changes only in discrete amounts with respect to the principal quantum number. Note the similarities between quantized angular momentum and Planck's concept of quantized energy.

MCAT Expertise

When you see a formula in your review or on Test Day, focus on ratios and relationships. This simplifies our calculations to a conceptual understanding, which is usually enough to lead us to the right answer. Further, the MCAT tends to ask how changes in one variable may affect another variable, rather than a plug-and-chug application of complex equations.

Bohr then related the permitted angular momentum values to the **energy of the electron** to obtain:

$$E = -\frac{R_H}{n^2}$$

Equation 1.3

where R_H is the experimentally determined **Rydberg unit of energy**, equal to $2.18 \times 10^{-18} \frac{J}{\text{electron}}$. Therefore, like angular momentum, the energy of the electron changes in discrete amounts with respect to the quantum number. A value of zero energy was assigned to the state in which the proton and electron are separated completely, meaning that there is no attractive force between them. Therefore, the electron in any of its quantized states in the atom will have an attractive force toward the proton; this is represented by the negative sign in Equation 1.3. Ultimately, the only thing the energy equation is saying is that the energy of an electron increases—becomes less negative—the farther out from the nucleus that it is located (increasing n). This is an important point: while the magnitude of the fraction is getting smaller, the actual value it represents is getting larger (becoming less negative).

Think of the concept of quantized energy as being similar to the change in gravitational potential energy that you experience when you ascend or descend a flight of stairs. Unlike a ramp, on which you could take an infinite number of steps associated with a continuum of potential energy changes, a staircase only allows you certain changes in height and, as a result, allows only certain discrete (quantized) changes of potential energy.

Bohr came to describe the structure of the hydrogen atom as a nucleus with one proton forming a dense core, around which a single electron revolved in a defined pathway (**orbit**) at a discrete energy value. If one could transfer an amount of energy exactly equal to the difference between one orbit and another, this could result in the electron "jumping" from one orbit to a higher-energy one. These orbits had increasing radii, and the orbit with the smallest, lowest-energy radius was defined as the ground state ($n = 1$). More generally, the **ground state** of an atom is the state of lowest energy, in which all electrons are in the lowest possible orbitals. In Bohr's model, the electron was promoted to an orbit with a larger radius (higher energy), the atom was said to be in the excited state. In general, an atom is in an **excited state** when at least one electron has moved to a subshell of higher than normal energy. Bohr likened his model of the hydrogen atom to the planets orbiting the sun, in which each planet traveled along a roughly circular pathway at set distances—and energy values—from the sun. Bohr's Nobel Prize-winning model was reconsidered over the next two decades, but remains an important conceptualization of atomic behavior. In particular, remember that we now know that electrons are *not* restricted to specific pathways, but tend to be localized in certain regions of space.

Key Concept

At first glance, it may not be clear that the energy (E) is directly proportional to the principal quantum number (n) in Equation 1.3. Take notice of the negative sign, which causes the values to approach zero from a more negative value as n increases (thereby increasing the energy). Negative signs are as important as a variable's location in a fraction when it comes to determining proportionality.

MCAT Expertise

Note that all systems tend toward minimal energy; thus on the MCAT, atoms of any element will generally exist in the ground state unless subjected to extremely high temperatures or irradiation.

Mnemonic

As electrons go from a lower energy level to a higher energy level, they get **AHED:**

- **A**bsorb light
- **H**igher potential
- **E**xcited
- **D**istant (from the nucleus)

APPLICATIONS OF THE BOHR MODEL

The Bohr model of the hydrogen atom (and other one-electron systems, such as He^+ and Li^{2+}) is useful for explaining the atomic emission and absorption spectra of atoms.

Atomic Emission Spectra

At room temperature, the majority of atoms in a sample are in the ground state. However, electrons can be excited to higher energy levels by heat or other energy forms to yield excited states. Because the lifetime of an excited state is brief, the electrons will return rapidly to the ground state, resulting in the emission of discrete amounts of energy in the form of photons, as shown in Figure 1.5.

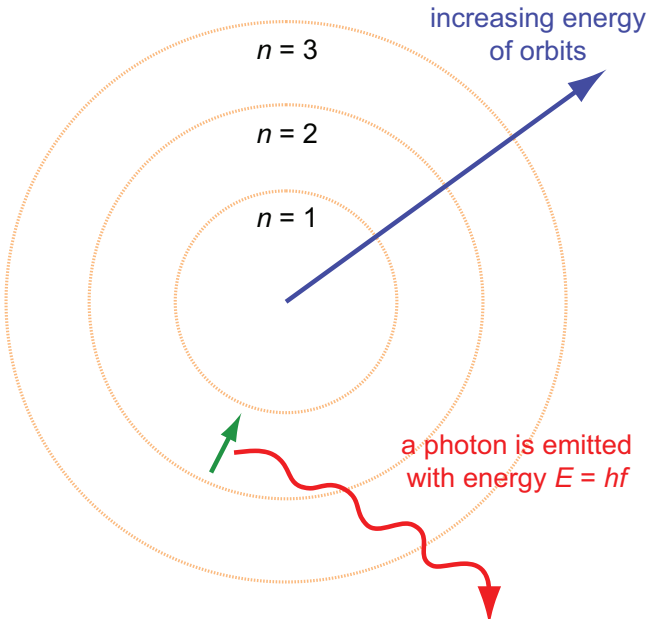

Figure 1.5. Atomic Emission of a Photon as a Result of a Ground State Transition

The electromagnetic energy of these photons can be determined using the following equation:

$$E = \frac{hc}{\lambda}$$

Equation 1.4

where h is Planck's constant, c is the speed of light in a vacuum ($3.00 \times 10^8 \frac{m}{s}$), and λ is the wavelength of the radiation. Note that Equation 1.4 is just a combination of two other equations: $E = hf$ and $c = f\lambda$.

The electrons in an atom can be excited to different energy levels. When these electrons return to their ground states, each will emit a photon with a wavelength characteristic of the specific energy transition it undergoes. As described above,

these energy transitions do not form a continuum, but rather are quantized to certain values. Thus, the spectrum is composed of light at specified frequencies. It is sometimes called a **line spectrum**, where each line on the emission spectrum corresponds to a specific electron transition. Because each element can have its electrons excited to a different set of distinct energy levels, each possesses a unique **atomic emission spectrum**, which can be used as a fingerprint for the element. One particular application of atomic emission spectroscopy is in the analysis of stars and planets: while a physical sample may be impossible to procure, the light from a star can be resolved into its component wavelengths, which are then matched to the known line spectra of the elements as shown in Figure 1.6.

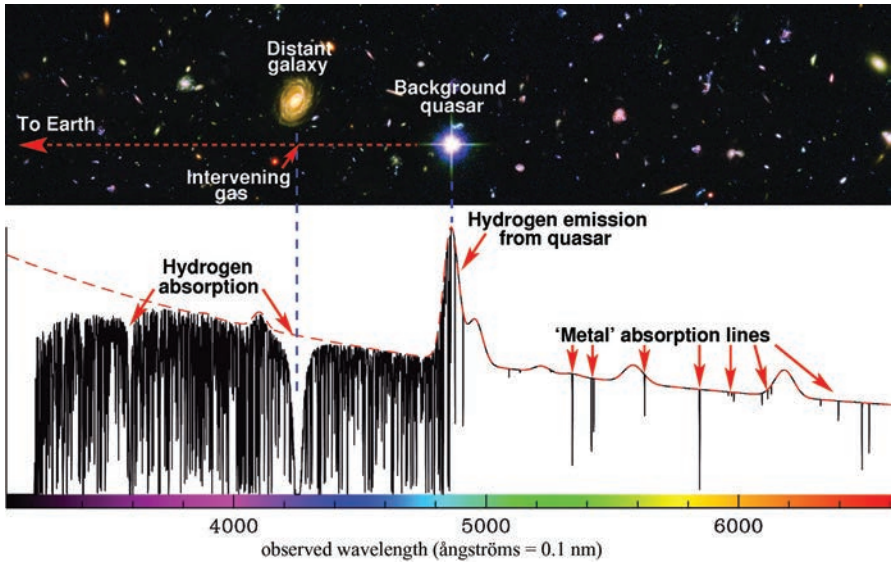

Figure 1.6. Line Spectrum with Transition Wavelengths for Various Celestial Bodies

The Bohr model of the hydrogen atom explained the atomic emission spectrum of hydrogen, which is the simplest emission spectrum among all the elements. The group of hydrogen emission lines corresponding to transitions from energy levels $n \geq 2$ to $n = 1$ is known as the **Lyman series**. The group corresponding to transitions from energy levels $n \geq 3$ to $n = 2$ is known as the **Balmer series**, and includes four wavelengths in the visible region. The Lyman series includes larger energy transitions than the Balmer series; it therefore has shorter photon wavelengths in the UV region of the electromagnetic spectrum. The **Paschen series** corresponds to transitions from $n \geq 4$ to $n = 3$. These energy transition series can be seen in Figure 1.7.

Real World

Emissions from electrons dropping from an excited state to a ground state give rise to fluorescence. What we see is the color of the emitted light.

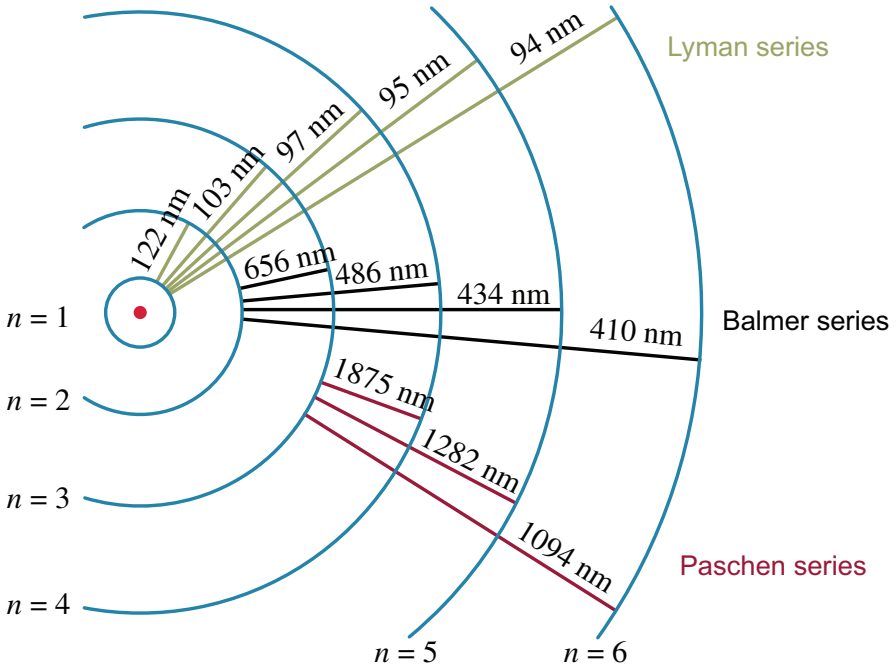

Figure 1.7. Wavelengths of Electron Orbital Transitions

Energy is inversely proportional to wavelength: $E = hf = \frac{hc}{\lambda}$.

The energy associated with a change in the principal quantum number from a higher initial value n_i to a lower final value n_f is equal to the energy of the photon predicted by Planck's quantum theory. Combining Bohr's and Planck's calculations, we can derive:

$$E = \frac{hc}{\lambda} = -R_H\left[\frac{1}{n_i^2} - \frac{1}{n_f^2}\right]$$

Equation 1.5

This complex-appearing equation essentially says: *The energy of the emitted photon corresponds to the difference in energy between the higher-energy initial state and the lower-energy final state.*

Atomic Absorption Spectra

When an electron is excited to a higher energy level, it must absorb exactly the right amount of energy to make that transition. This means that exciting the electrons of a particular element results in energy absorption at specific wavelengths. Thus, in addition to a unique emission spectrum, every element possesses a characteristic **absorption spectrum**. Not surprisingly, the wavelengths of absorption correspond exactly to the wavelengths of emission because the difference in energy between levels remains unchanged. Identification of elements in the gas phase requires absorption spectra.

Key Concept

This equation is nothing new; it is simply derived from conservation of energy by setting the energy of a photon ($E = hf = \frac{hc}{\lambda}$) equal to the energy of the electron transition (from $E = -\frac{R_H}{n^2}$). Note that unlike other equations, this is *initial* minus *final*; the negative sign in the equation accounts for absorption and emission. Thus, a positive E corresponds to emission, and a negative E corresponds to absorption.

Bridge

ΔE is the same for absorption or emission between any two energy levels according to the conservation of energy, as discussed in Chapter 2 of *MCAT Physics and Math Review*. This is also the same as the energy of the photon of light absorbed or emitted.

Atomic emission and absorption spectra are complex topics, but the takeaway is that each element has a characteristic set of energy levels. For electrons to move from a lower energy level to a higher energy level, they must absorb the right amount of energy to do so. They absorb this energy in the form of light. Similarly, when electrons move from a higher energy level to a lower energy level, they emit the same amount of energy in the form of light.

Real World

Absorption is the basis for the color of compounds. We see the color of the light that is *not* absorbed by the compound.

MCAT Concept Check 1.3:

Before you move on, assess your understanding of the material with these questions.

Note: *For these questions, try to estimate the calculations without a calculator to mimic Test Day conditions. Double-check your answers with a calculator and refer to the answers for confirmation of your results.*

1. The valence electron in a lithium atom jumps from energy level $n = 2$ to $n = 4$. What is the energy of this transition in joules? In eV? (Note: $R_H = 2.18 \times 10^{-18} \frac{J}{\text{electron}} = 13.6 \frac{eV}{\text{electron}}$)

_____

_____

2. If an electron emits 3 eV of energy, what is the corresponding wavelength of the emitted photon? (Note: 1 eV = 1.60×10^{-19} J, $h = 6.626 \times 10^{-34}$ J·s)

_____

3. Calculate the energy of a photon of wavelength 662 nm. (Note: $h = 6.626 \times 10^{-34}$ J·s)

_____

1.4 Quantum Mechanical Model of Atoms

While Bohr's model marked a significant advancement in the understanding of the structure of atoms, his model ultimately proved inadequate to explain the structure and behavior of atoms containing more than one electron. The model's failure was a result of not taking into account the repulsion between multiple electrons surrounding the nucleus. Modern quantum mechanics has led to a more rigorous and generalizable study of the electronic structure of atoms. The most important difference between Bohr's model and the modern quantum mechanical model is that Bohr postulated that electrons follow a clearly defined circular pathway or orbit at a fixed distance from the nucleus, whereas modern quantum mechanics has shown that this is not the

case. Rather, we now understand that electrons move rapidly and are localized within regions of space around the nucleus called **orbitals**. The confidence by which those in Bohr's time believed they could identify the location (or pathway) of the electron was now replaced by a more modest suggestion that the best we can do is describe the probability of finding an electron within a given region of space surrounding the nucleus. In the current quantum mechanical model, it is impossible to pinpoint exactly where an electron is at any given moment in time. This is expressed best by the **Heisenberg uncertainty principle**: *It is impossible to simultaneously determine, with perfect accuracy, the momentum and the position of an electron*. If we want to assess the position of an electron, the electron has to stop (thereby removing its momentum); if we want to assess its momentum, the electron has to be moving (thereby changing its position). This can be seen visually in Figure 1.8.

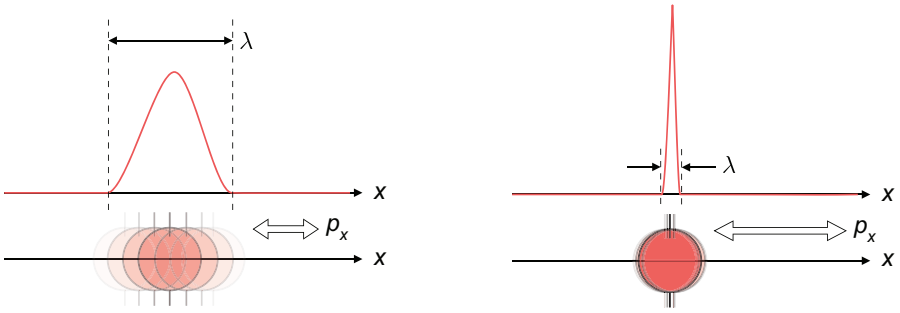

Figure 1.8. Heisenberg Uncertainty Principle
Known momentum and uncertain position (left); known position but uncertain momentum (right). λ = confidence interval of position; p_x = confidence interval of momentum.

QUANTUM NUMBERS

Modern atomic theory postulates that any electron in an atom can be completely described by four quantum numbers: n, l, m_l, and m_s. Furthermore, according to the **Pauli exclusion principle**, no two electrons in a given atom can possess the same set of four quantum numbers. The position and energy of an electron described by its quantum numbers is known as its *energy state*. The value of n limits the values of l, which in turn limit the values of m_l. In other words, for a given value of n, only particular values of l are permissible; given a value of l, only particular values of m_l are permissible. The values of the quantum numbers qualitatively give information about the size, shape, and orientation of the orbitals. As we examine the four quantum numbers more closely, pay attention especially to l and m_l because these two tend to give students the greatest difficulty.

Principal Quantum Number

The first quantum number is commonly known as the **principal quantum number** and is denoted by the letter ***n***. This is the quantum number used in

MCAT Expertise

Think of the quantum numbers as becoming more specific as one goes from n to l to m_l to m_s. This is like an address: one lives in a particular state (n), in a particular city (l), on a particular street (m_l), at a particular house number (m_s).

Bohr's model that can theoretically take on any positive integer value. The larger the integer value of n, the higher the energy level and radius of the electron's **shell**. Within each shell, there is a capacity to hold a certain number of electrons, given by:

$$\text{Maximum number of electrons within a shell} = 2n^2$$

Equation 1.6

where n is the principal quantum number. The difference in energy between two shells decreases as the distance from the nucleus increases because the energy difference is a function of $\left[\frac{1}{n_i^2} - \frac{1}{n_f^2}\right]$. For example, the energy difference between the $n = 3$ and the $n = 4$ shells $\left(\frac{1}{9} - \frac{1}{16}\right)$ is less than the energy difference between the $n = 1$ and the $n = 2$ shells $\left(\frac{1}{1} - \frac{1}{4}\right)$. This can be seen in Figure 1.7. Remember that electrons do not travel in precisely defined orbits; it just simplifies the visual representation of the electrons' motion.

Azimuthal Quantum Number

The second quantum number is called the **azimuthal** (**angular momentum**) **quantum number** and is designated by the letter ***l***. The second quantum number refers to the shape and number of **subshells** within a given principal energy level (shell). The azimuthal quantum number is very important because it has important implications for chemical bonding and bond angles. The value of n limits the value of l in the following way: for any given value of n, the range of possible values for l is 0 to $(n - 1)$. For example, within the first principal energy level, $n = 1$, the only possible value for l is 0; within the second principal energy level, $n = 2$, the possible values for l are 0 and 1. A simpler way to remember this relationship is that the n-value also tells you the number of possible subshells. Therefore, there's only one subshell ($l = 0$) in the first principal energy level; there are two subshells ($l = 0$ and 1) within the second principal energy level; there are three subshells ($l = 0$, 1, and 2) within the third principal energy level, and so on.

Spectroscopic notation refers to the shorthand representation of the principal and azimuthal quantum numbers. The principal quantum number remains a number, but the azimuthal quantum number is designated by a letter: the $l = 0$ subshell is called *s*; the $l = 1$ subshell is called *p*; the $l = 2$ subshell is called *d*; and the $l = 3$ subshell is called *f*. Thus, an electron in the shell $n = 4$ and subshell $l = 2$ is said to be in the 4*d* subshell. The spectroscopic notation for each subshell is demonstrated in Figure 1.9.

Bridge

Remember, a larger integer value for the principal quantum number indicates a larger radius and higher energy. This is similar to gravitational potential energy, as discussed in Chapter 2 of *MCAT Physics Review*, where the higher or farther the object is above the Earth, the higher its potential energy will be.

Key Concept

For any principal quantum number n, there will be n possible values for l, ranging from 0 to $(n - 1)$.

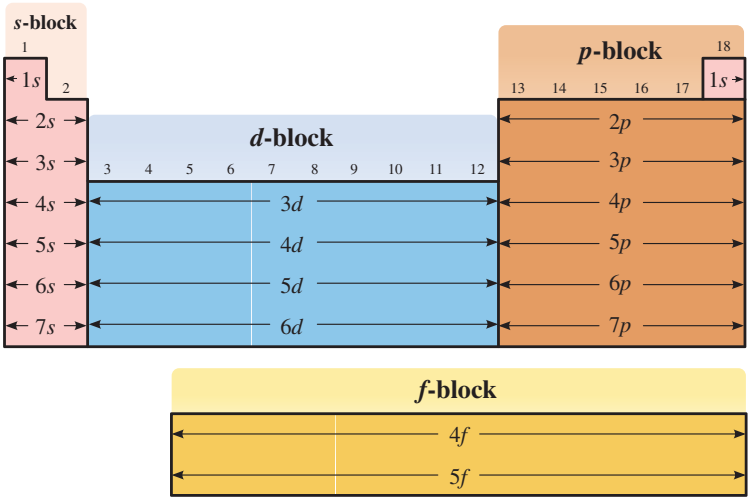

Figure 1.9. Spectroscopic Notation for Every Subshell on the Periodic Table

Within each subshell, there is a capacity to hold a certain number of electrons, given by:

$$\text{Maximum number of electrons within a subshell} = 4l + 2$$

Equation 1.7

where l is the azimuthal quantum number. The energies of the subshells increase with increasing l value; however, the energies of subshells from different principal energy levels may overlap. For example, the 4*s* subshell will have a lower energy than the 3*d* subshell.

Figure 1.10 provides an example of computer-generated probability maps of the first few electron clouds in a hydrogen atom. This provides a rough visual representation of the shapes of different subshells.

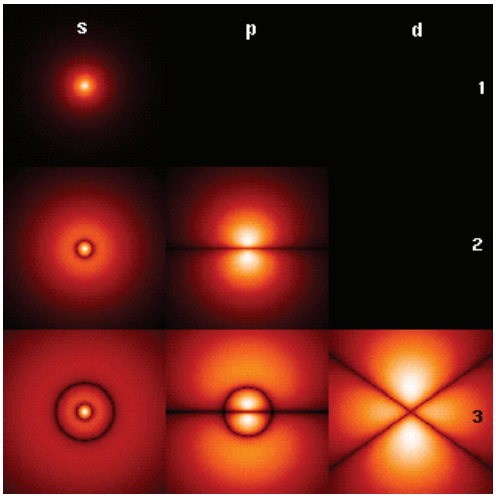

Figure 1.10. Electron Clouds of Various Subshells

Magnetic Quantum Number

The third quantum number is the **magnetic quantum number** and is designated $\boldsymbol{m_l}$. The magnetic quantum number specifies the particular **orbital** within a subshell where an electron is most likely to be found at a given moment in time. Each orbital can hold a maximum of two electrons. The possible values of m_l are the integers between $-l$ and $+l$, including 0. For example, the *s* subshell, with $l = 0$, limits the possible m_l values to 0, and because there is a single value of m_l, there is only one orbital in the *s* subshell. The *p* subshell, with $l = 1$, limits the possible m_l values to –1, 0, and +1, and because there are three values for m_l, there are three orbitals in the *p* subshell. The *d* subshell has five orbitals (–2 to +2), and the *f* subshell has seven orbitals (–3 to +3). The shape of the orbitals, like the number of orbitals, is dependent on the subshell in which they are found. The orbitals in the *s* subshell are spherical, while the three orbitals in the *p* subshell are each dumbbell-shaped and align along the *x*-, *y*-, and *z*-axes. In fact, the *p*-orbitals are often referred to as p_x, p_y, and p_z. The first five orbitals—1*s*, 2*s*, $2p_x$, $2p_y$, and $2p_z$—are demonstrated in Figure 1.11. Note the similarity to the images in Figure 1.10.

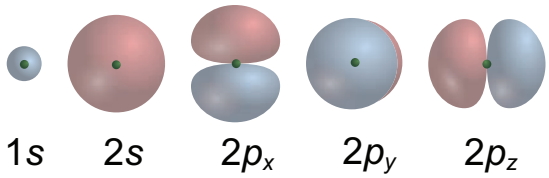

Figure 1.11. The First Five Atomic Orbitals

The shapes of the orbitals in the *d* and *f* subshells are much more complex, and the MCAT will not expect you to answer questions about their appearance. The shapes of orbitals are defined in terms of a concept called probability density, the likelihood that an electron will be found in a particular region of space.

Take a look at the 2*p* block in the periodic table. As mentioned above, 2*p* contains three orbitals. If each orbital can contain two electrons, then six electrons can be added during the course of filling the 2*p*-orbitals. As atomic number increases, so too does the number of electrons (assuming the species is neutral). Therefore, it should be no surprise that the *p* block contains six groups of elements. The *s* block contains two elements in each row of the periodic table, the *d* block contains ten elements, and the *f* block contains fourteen elements.

Spin Quantum Number

The fourth quantum number is called the **spin quantum number** and is denoted by $\boldsymbol{m_s}$. In classical mechanics, an object spinning about its axis has an infinite number of possible values for its angular momentum. However, this does not apply to the electron, which has two spin orientations designated

Key Concept

For any value of *l*, there will be $2l + 1$ possible values for m_l. For any *n*, this produces n^2 orbitals. For any value of *n*, there will be a maximum of $2n^2$ electrons (two per orbital).

$+\frac{1}{2}$ and $-\frac{1}{2}$. Whenever two electrons are in the same orbital, they must have opposite spins. In this case, they are often referred to as being **paired**. Electrons in different orbitals with the same m_s values are said to have **parallel spins**.

The quantum numbers for the orbitals in the second principal energy level, with their maximum number of electrons noted in parentheses, are shown in Table 1.2.

n	2 (8)			
l	**0 (2)**	**1 (6)**		
m_l	0 (2)	+1 (2)	0 (2)	–1 (2)
m_s	$+\frac{1}{2}, -\frac{1}{2}$	$+\frac{1}{2}, -\frac{1}{2}$	$+\frac{1}{2}, -\frac{1}{2}$	$+\frac{1}{2}, -\frac{1}{2}$

Table 1.2. Quantum Numbers for the Second Principal Energy Level

ELECTRON CONFIGURATIONS

MCAT Expertise

Remember that the shorthand used to describe the electron configuration is derived directly from the quantum numbers.

For a given atom or ion, the pattern by which subshells are filled, as well as the number of electrons within each principal energy level and subshell, are designated by its **electron configuration**. Electron configurations use spectroscopic notation, wherein the first number denotes the principal energy level, the letter designates the subshell, and the superscript gives the number of electrons in that subshell. For example, $2p^4$ indicates that there are four electrons in the second (p) subshell of the second principal energy level. This also implies that the energy levels below $2p$ (that is, $1s$ and $2s$) have already been filled, as shown in Figure 1.12.

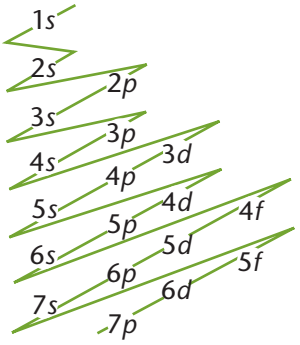

Figure 1.12. Electron Subshell Flow Diagram

To write out an atom's electron configuration, one needs to know the order in which subshells are filled. Electrons fill from lower- to higher-energy subshells, according to the ***Aufbau* principle** (also called the **building-up principle**), and each subshell will fill completely before electrons begin to enter the next one. The order need not be memorized because there are two very helpful ways of recalling this. The ***n* + *l* rule** can be used to rank subshells by increasing energy. This rule states that the lower the sum of the values of the first and second quantum numbers, $n + l$, the lower the energy

of the subshell. This is a helpful rule to remember for Test Day. If two subshells possess the same $n + l$ value, the subshell with the lower n value has a lower energy and will fill with electrons first.

> **Example:** Which will fill first, the 5*d* subshell or the 6*s* subshell?
>
> **Solution:** For 5*d*, $n = 5$ and $l = 2$, so $n + l = 7$. For 6*s*, $n = 6$ and $l = 0$, so $n + l = 6$. Therefore, the 6*s* subshell has lower energy and will fill first.

An alternative way to approach electron configurations is through simply reading the periodic table. One must remember that the lowest *s* subshell is 1*s*, the lowest *p* subshell is 2*p*, the lowest *d* subshell is 3*d*, and the lowest *f* subshell is 4*f*. This can be seen in Figure 1.9 earlier. Then, we can simply read across the periodic table to get to the element of interest, filling subshells along the way. To do this, we must know the correct position of the lanthanide and actinide series (the *f* block), as shown in Figure 1.13. In most representations of the periodic table, the *f* block is pulled out and placed below the rest of the table. This is purely an effect of graphic design—placing the *f* block in its correct location results in a lot of excess white space on a page.

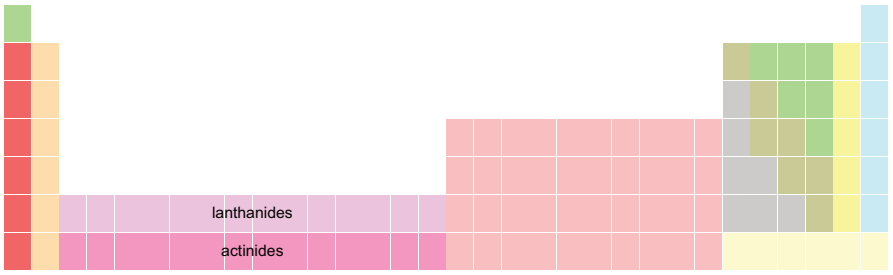

Figure 1.13. Periodic Table with Lanthanide and Actinide Series Inserted
The *f* block fits between the *s* block and *d* block in the periodic table.

Electron configurations can be abbreviated by placing the noble gas that precedes the element of interest in brackets. For example, the electron configuration of any element in period four (starting with potassium) can be abbreviated by starting with [Ar].

> **Example:** What is the electron configuration of osmium ($Z = 76$)?
>
> **Solution:** The noble gas that comes just before osmium is xenon ($Z = 54$). Therefore, the electron configuration can begin with [Xe]. Continuing across the periodic table, we pass through the 6*s* subshell (cesium and barium), the 4*f* subshell (the lanthanide series; remember its position on the periodic table!), and into the 5*d* subshell. Osmium is the sixth element in the 5*d* subshell, so the configuration is [Xe] $6s^2 4f^{14} 5d^6$.

This method works for neutral atoms, but how does one write the electron configuration of an ion? Negatively charged ions (**anions**) have additional electrons that fill

MCAT Expertise

Many general chemistry courses teach the flow diagram in Figure 1.12 as a method to determine the order of subshell filling in electron configurations. However, on Test Day, it can be both time-consuming and error-prone, resulting in incorrect electron configurations. Learning to read the periodic table, as described here, is the best method.

according to the same rules as above; for example, if fluorine's electron configuration is [He] $2s^2 2p^5$, then F^- is [He] $2s^2 2p^6$. Positively charged ions (**cations**) are a bit more complicated: start with the neutral atom, and remove electrons from the subshells with the highest value for n first. If multiple subshells are tied for the highest n value, then electrons are removed from the subshell with the highest l value among these.

Example: What is the electron configuration of Fe^{3+}?

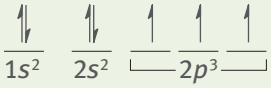
Solution: The electron configuration of iron is [Ar] $4s^2 3d^6$. Electrons are removed from the $4s$ subshell before the $3d$ subshell because it has a higher principal quantum number. Therefore, Fe^{3+} has a configuration of [Ar] $3d^5$, not [Ar] $4s^2 3d^3$.

HUND'S RULE

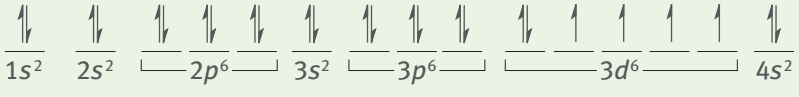
In subshells that contain more than one orbital, such as the $2p$ subshell with its three orbitals, the orbitals will fill according to **Hund's rule**, which states that, within a given subshell, orbitals are filled such that there are a maximum number of half-filled orbitals with parallel spins. Like finding a seat on a crowded bus, electrons would prefer to have their own seat (orbital) before being forced to double up with another electron. Of course, the basis for this preference is electron repulsion: electrons in the same orbital tend to be closer to each other and thus repel each other more than electrons placed in different orbitals.

Example: According to Hund's rule, what are the orbital diagrams for nitrogen and iron?

Solution: Nitrogen has an atomic number of 7. Thus, its electron configuration is $1s^2 2s^2 2p^3$. According to Hund's rule, the two s-orbitals will fill completely, while the three p-orbitals will each contain one electron, all with parallel spins.



Iron has an atomic number of 26. As determined earlier, its electron configuration is [Ar] $4s^2 3d^6$. The electrons will fill all of the subshells except for the $3d$, which will contain four orbitals with parallel (upward) spin and one orbital with electrons of both spin directions.



Subshells may be listed either in the order in which they fill ($4s$ before $3d$) or with subshells of the same principal quantum number grouped together, as shown here. Both methods are correct.

An important corollary from Hund's rule is that half-filled and fully filled orbitals have lower energies (higher stability) than other states. This creates two notable exceptions to electron configuration that are often tested on the MCAT: chromium (and other elements in its group) and copper (and other elements in its group). Chromium ($Z = 24$) should have the electron configuration [Ar] $4s^2 3d^4$ according to the rules established earlier. However, moving one electron from the 4*s* subshell to the 3*d* subshell allows the 3*d* subshell to be half-filled: [Ar] $4s^1 3d^5$ (remember that *s* subshells can hold two electrons and *d* subshells can hold ten). While moving the 4*s* electron up to the 3*d*-orbital is energetically unfavorable, the extra stability from making the 3*d* subshell half-filled outweighs that cost. Similarly, copper ($Z = 29$) has the electron configuration [Ar] $4s^1 3d^{10}$, rather than [Ar] $4s^2 3d^9$; a full *d* subshell outweighs the cost of moving an electron out of the 4*s* subshell. Other elements in the same group have similar behavior, moving one electron from the highest *s* subshell to the highest *d* subshell. Similar shifts can be seen with *f* subshells, but they are *never* observed for the *p* subshell; the extra stability doesn't outweigh the cost.

The presence of paired or unpaired electrons affects the chemical and magnetic properties of an atom or molecule. Materials composed of atoms with unpaired electrons will orient their spins in alignment with a magnetic field, and the material will thus be weakly attracted to the magnetic field. These materials are considered **paramagnetic**. An example is shown in Figure 1.14 where a ferrofluid (colloidal liquid containing a surfactant and paramagnetic particles) is influenced by the magnet beneath a glass slide. The spikes emanating from the fluid contain *magnetite* (an iron oxide) which is orienting along the magnetic field lines. This is similar to a typical iron filing and magnet demonstration.

Mnemonic

Remember that **para**magnetic means that a magnetic field will cause **para**llel spins in unpaired electrons and therefore cause an attraction.

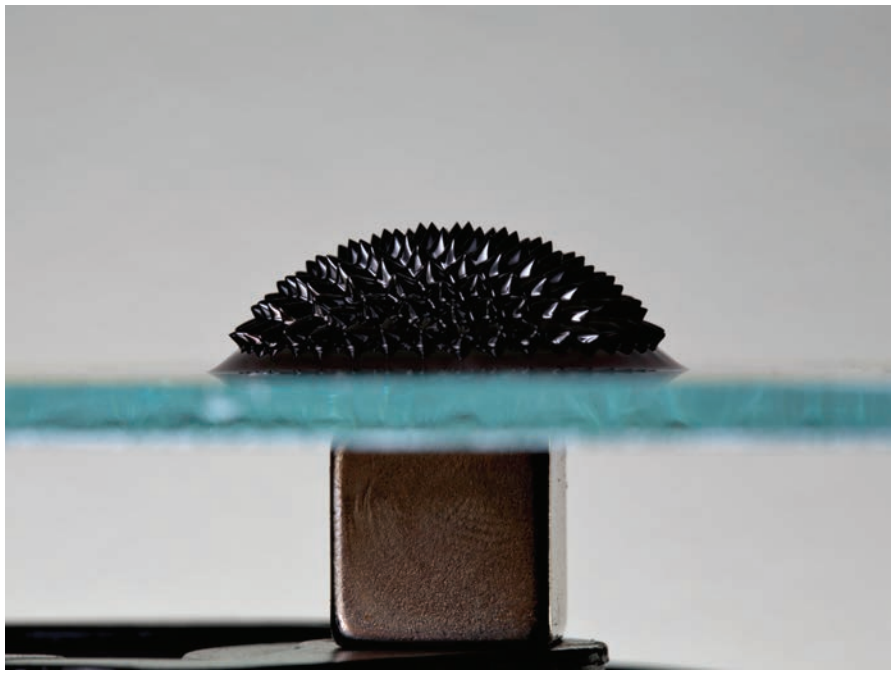


Figure 1.14. Paramagnetic Ferrofluid

Materials consisting of atoms that have only paired electrons will be slightly repelled by a magnetic field and are said to be **diamagnetic**. In Figure 1.15, a piece of pyrolytic graphite is suspended in the air over strong neodymium magnets. All the electrons in this *allotrope* (configuration) of carbon are paired because of covalent bonding between layers of the material, and are thus opposed to being reoriented. Given sufficiently strong magnetic fields beneath an object, any diamagnetic substance can be made to levitate.

Real World

The concept behind "maglev" or magnetic levitation is no longer science fiction. Using powerful magnetic fields and strongly diamagnetic materials, some transportation systems have developed frictionless, high speed rail networks such as Japan's SCMaglev.

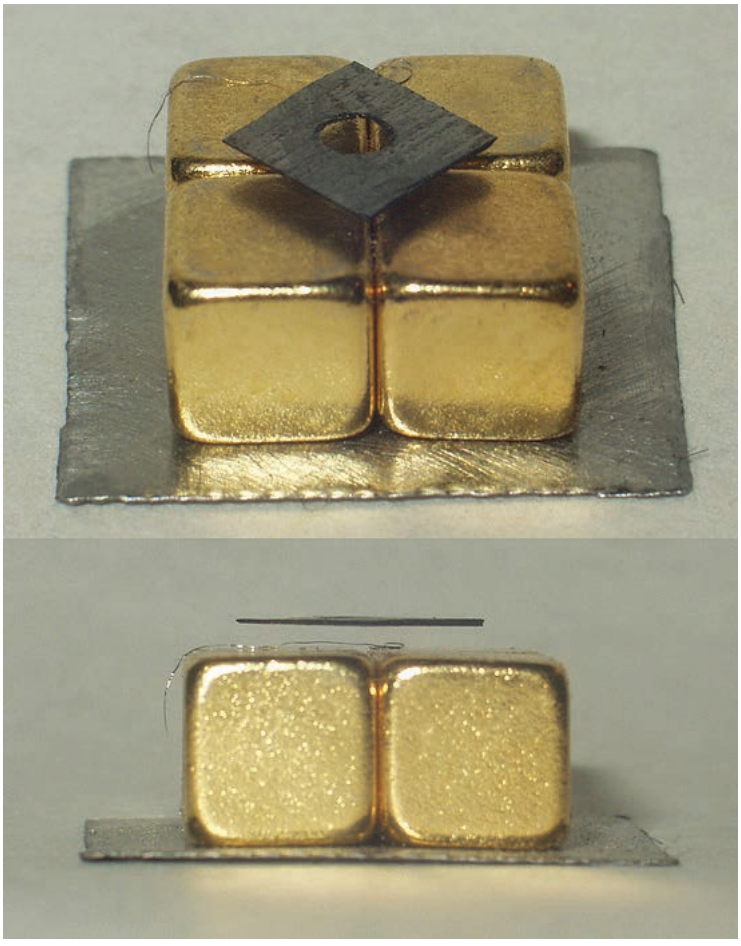

Figure 1.15. Diamagnetic Pyrolytic Graphite

VALENCE ELECTRONS

The valence electrons of an atom are those electrons that are in its outermost energy shell, are most easily removed, and are available for bonding. In other words, the valence electrons are the "active" electrons of an atom and to a large extent dominate the chemical behavior of the atom. For elements in Groups IA and IIA (Groups 1 and 2), only the highest *s* subshell electrons are valence electrons. For elements in Groups IIIA through VIIIA (Groups 13 through 18), the highest *s* and *p* subshell

electrons are valence electrons. For transition elements, the valence electrons are those in the highest *s* and *d* subshells, even though they have different principal quantum numbers. For the lanthanide and actinide series, the valence electrons are those in the highest *s* and *f* subshells, even though they have different principal quantum numbers. All elements in period three (starting with sodium) and below may accept electrons into their *d* subshell, which allows them to hold more than eight electrons in their valence shell. This allows them to violate the octet rule, as discussed in Chapter 3 of *MCAT General Chemistry Review*.

Example: Which electrons are the valence electrons of elemental vanadium, elemental selenium, and the sulfur atom in a sulfate ion?

Solution: Vanadium has five valence electrons: two in its 4*s* subshell and three in its 3*d* subshell.

Selenium has six valence electrons: two in its 4*s* subshell and four in its 4*p* subshell. Selenium's 3*d* electrons are not part of its valence shell.

Sulfur in a sulfate ion has 12 valence electrons: its original six plus six more from the oxygens to which it is bonded. Sulfur's 3*s* and 3*p* subshells can contain only eight of these 12 electrons; the other four electrons have entered the sulfur atom's 3*d* subshell, which is normally empty in elemental sulfur.

MCAT Concept Check 1.4:

Before you move on, assess your understanding of the material with these questions.

1. If given the following quantum numbers, which element(s) do they likely refer to? (Note: Assume that these quantum numbers describe the valence electrons in the element.)

n	*l*	Possible Elements
2	1	
3	0	
5	3	
4	2	

2. Write out and compare an orbital diagram for a neutral oxygen (O) atom and an O^{2-} ion.

_____

_____

_____

MCAT Expertise

The valence electron configuration of an atom helps us understand its properties and is ascertainable from the periodic table (the only "cheat sheet" available on the MCAT!). On Test Day, you will be able to access a periodic table by clicking on the button labeled "Periodic table" on the top right of the screen. Use it as needed!

3. Magnetic resonance angiography (MRA) is a technique that can resolve defects like stenotic (narrowed) arteries. A contrast agent like gadolinium or manganese injected into the blood stream interacts with the strong magnetic fields of the MRI device to produce such images. Based on their orbital configurations, are these contrast agents paramagnetic or diamagnetic?

_____

4. Determine how many valence electrons come from each subshell in the following atoms:

Atom	*s*-electrons	*p*-electrons	*d*-electrons	*f*-electrons	Total Valence Electrons
P in PO_4^{3-}					
O in PO_4^{3-}					
Ir					
Cf					

Conclusion

Congratulations! You've made it through the first chapter! Now that we have covered topics related to the most fundamental unit of matter—the atom—you're set to advance your understanding of the physical world in more complex ways. This chapter described the characteristics and behavior of the three subatomic particles: the proton, neutron, and electron. In addition, it compared and contrasted two models of the atom. The Bohr model is adequate for describing the structure of one-electron systems, such as the hydrogen atom or the helium ion, but fails to describe adequately the structure of more complex atoms. The quantum mechanical model theorizes that electrons are found not in discrete orbits, but in "clouds of probability," or orbitals, by which we can predict the likelihood of finding electrons within given regions of space surrounding the nucleus. Both theories tell us that the energy levels available to electrons are not infinite but discrete and that the energy difference between levels is a precise amount called a quantum. The four quantum numbers completely describe the location and energy of any electron within a given atom. Finally, we learned two simple recall methods for the order in which electrons fill the shells and subshells of an atom and that the valence electrons are the reactive electrons in an atom. In the next chapter, we'll take a look at how the elements are organized on the periodic table and will then turn our attention to their bonding behavior—based on valence electrons—in Chapter 3 of *MCAT General Chemistry Review*.

CONCEPT SUMMARY

Subatomic Particles

- A **proton** has a positive charge and mass around 1 amu; a **neutron** has no charge and mass around 1 amu; an **electron** has a negative charge and negligible mass.
- The **nucleus** contains the protons and neutrons, while the electrons move around the nucleus.
- The **atomic number** is the number of protons in a given element.
- The **mass number** is the sum of an element's protons and neutrons.

Atomic Mass *vs.* Atomic Weight

- **Atomic mass** is essentially equal to the mass number, the sum of an element's protons and neutrons.
  - **Isotopes** are atoms of a given element (same atomic number) that have different mass numbers. They differ in the number of neutrons.
  - Most isotopes are identified by the element followed by the mass number (such as carbon-12, carbon-13, and carbon-14).
  - The three isotopes of hydrogen go by different names: protium, deuterium, and tritium.
- **Atomic weight** is the weighted average of the naturally occurring isotopes of an element. The periodic table lists atomic weights, not atomic masses.

Rutherford, Planck, and Bohr

- Rutherford first postulated that the atom had a dense, positively charged nucleus that made up only a small fraction of the volume of the atom.
- In the **Bohr model of the atom**, a dense, positively charged nucleus is surrounded by electrons revolving around the nucleus in orbits with distinct energy levels.
- The energy difference between energy levels is called a **quantum**, first described by Planck.
  - Quantization means that there is not an infinite range of energy levels available to an electron; electrons can exist only at certain energy levels. The energy of an electron increases the farther it is from the nucleus.
  - The **atomic absorption spectrum** of an element is unique; for an electron to jump from a lower energy level to a higher one, it must absorb an amount of energy precisely equal to the energy difference between the two levels.
  - When electrons return from the excited state to the ground state, they emit an amount of energy that is exactly equal to the energy difference between the

two levels; every element has a characteristic **atomic emission spectrum**, and sometimes the electromagnetic energy emitted corresponds to a frequency in the visible light range.

Quantum Mechanical Model of Atoms

- The **quantum mechanical model** posits that electrons do not travel in defined orbits but rather are localized in orbitals; an **orbital** is a region of space around the nucleus defined by the probability of finding an electron in that region of space.
- The **Heisenberg uncertainty principle** states that it is impossible to know both an electron's position and its momentum *exactly* at the same time.
- There are four **quantum numbers**; these numbers completely describe any electron in an atom.
  - The **principal quantum number**, n, describes the average energy of a **shell**.
  - The **azimuthal quantum number**, l, describes the **subshells** within a given principal energy level (s, p, d, and f).
  - The **magnetic quantum number**, m_l, specifies the particular **orbital** within a subshell where an electron is likely to be found at a given moment in time.
  - The **spin quantum number**, m_s, indicates the spin orientation $\left(\pm\frac{1}{2}\right)$ of an electron in an orbital.
- The **electron configuration** uses **spectroscopic notation** (combining the n and l values as a number and letter, respectively) to designate the location of electrons.
  - For example, $1s^2 2s^2 2p^6 3s^2$ is the electron configuration for magnesium: a neutral magnesium atom has 12 electrons—two in the s subshell of the first energy level, two in the s subshell of the second energy level, six in the p subshell of the second energy level, and two in the s subshell of the third energy level; the two electrons in the $3s$ subshell are the valence electrons for the magnesium atom.
- Electrons fill the principal energy levels and subshells according to increasing energy, which can be determined by the $\boldsymbol{n + l}$ **rule**.
- Electrons fill orbitals according to **Hund's rule**, which states that subshells with multiple orbitals (p, d, and f) fill electrons so that every orbital in a subshell gets one electron before any of them gets a second.
  - **Paramagnetic** materials have unpaired electrons that align with magnetic fields, attracting the material to a magnet.
  - **Diamagnetic** materials have all paired electrons, which cannot easily be realigned; they are repelled by magnets.

- Valence electrons are those electrons in the outermost shell available for interaction (bonding) with other atoms.
  - For the representative elements (those in Groups 1, 2, and 13–18), the valence electrons are found in *s*- and/or *p*-orbitals.
  - For the transition elements, the valence electrons are found in *s*- and either *d*- or *f*-orbitals.
  - Many atoms interact with other atoms to form bonds that complete an octet in the valence shell.

ANSWERS TO CONCEPT CHECKS

1.1

1. Charge is determined by the number of electrons present. Atomic number is determined by the number of protons. Isotope is determined by the number of neutrons (while protons make up part of the mass number, it is the number of neutrons that explains the variability between isotopes).
2. ^{18}O: 8p^+, 10 n^0, 8 e^-. ^{18}F: 9p^+, 9 n^0, 9 e^-.

1.2

1. Atomic mass is (just slightly less than) the sum of the masses of protons and neutrons in a given atom of an element. Atoms of the same element with different mass numbers are isotopes of each other. The atomic weight is the weighted average of the naturally occurring isotopes of an element.
2. This ratio is an equivalent concept. It is therefore acceptable, as long as units can be cancelled in dimensional analysis.
3.

Isotope	Protons	Neutrons	Electrons
^{19}O	8	11	8
^{16}O	8	8	8
^{17}O	8	9	8
^{19}F	9	10	9
^{16}F	9	7	9
^{238}U	92	146	92
^{240}U	92	148	92

1.3

1. $E = -R_H\left[\frac{1}{n_i^2} - \frac{1}{n_f^2}\right] = -2.18\times10^{-18}\left[\frac{1}{2^2} - \frac{1}{4^2}\right] = -2.18\times10^{-18}\left[\frac{3}{16}\right]$
$= -4.09\times10^{-19}\ \text{J} = -2.55\ \text{eV}$; energy is absorbed.

2. 3 eV $(1.60\times10^{-19}\ \frac{\text{J}}{\text{eV}}) = 4.8\times10^{-19}$ J

$$E = \frac{hc}{\lambda} \rightarrow \lambda = \frac{hc}{E} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \frac{\text{m}}{\text{s}})}{(4.8\times10^{-19}\ \text{J})}$$
$$= 4.14\times10^{-7}\ \text{m} = 414\ \text{nm}$$

3. $$E = \frac{hc}{\lambda} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \frac{\text{m}}{\text{s}})}{(6.62\times10^{-7}\ \text{m})} = 3.00\times10^{-19}\ \text{J}$$

1.4

1.

n	*l*	Possible Elements
2	1	2*p*: B, C, N, O, F, Ne
3	0	3*s*: Na, Mg
5	3	5*f*: Actinide series
4	2	4*d*: Y, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, Cd

2. Both O and O^{2-} have fully filled 1*s*- and 2*s*-orbitals. O has four electrons in the 2*p* subshell; two are paired, and the other two each have their own orbital. O^{2-} has six electrons in the 2*p* subshell, all of which are paired in the three *p*-orbitals.
3. Both these molecules have unfilled valence electron shells with relatively few paired electrons; therefore, they are paramagnetic.
4.

Atom	*s*-electrons	*p*-electrons	*d*-electrons	*f*-electrons	Total Valence Electrons
P in PO_4^{3-}	2	6	2	0	10
O in PO_4^{3-}	2	6	0	0	8
Ir	2	0	7	0	9
Cf	2	0	0	10	12

EQUATIONS TO REMEMBER

(1.1) **Planck relation (frequency):** $E = hf$

(1.2) **Angular momentum of an electron (Bohr model):** $L = \frac{nh}{2\pi}$

(1.3) **Energy of an electron (Bohr model):** $E = -\frac{R_H}{n^2}$

(1.4) **Planck relation (wavelength):** $E = \frac{hc}{\lambda}$

(1.5) **Energy of electron transition (Bohr model):** $E = -R_H\left[\frac{1}{n_i^2} - \frac{1}{n_f^2}\right]$

(1.6) **Maximum number of electrons within a shell:** $2n^2$

(1.7) **Maximum number of electrons within a subshell:** $4l + 2$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following is the correct electron configuration for Zn^{2+}?

A. $1s^2 2s^2 2p^6 3s^2 3p^6 4s^0 3d^{10}$
B. $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^8$
C. $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10}$
D. $1s^2 2s^2 2p^6 3s^2 3p^6 4s^0 3d^8$

2. Which of the following quantum number sets is possible?

A. $n = 2; l = 2; m_l = 1; m_s = +\frac{1}{2}$
B. $n = 2; l = 1; m_l = -1; m_s = +\frac{1}{2}$
C. $n = 2; l = 0; m_l = -1; m_s = -\frac{1}{2}$
D. $n = 2; l = 0; m_l = 1; m_s = -\frac{1}{2}$

3. What is the maximum number of electrons allowed in a single atomic energy level in terms of the principal quantum number n?

A. $2n$
B. $2n + 2$
C. $2n^2$
D. $2n^2 + 2$

4. Which of the following equations describes the maximum number of electrons that can fill a subshell?

A. $2l + 2$
B. $4l + 2$
C. $2l^2$
D. $2l^2 + 2$

5. Which of the following atoms only has paired electrons in its ground state?

A. Sodium
B. Iron
C. Cobalt
D. Helium

6. An electron returns from an excited state to its ground state, emitting a photon at $\lambda = 500$ nm. What would be the magnitude of the energy change if one mole of these photons were emitted? (Note: $h = 6.626 \times 10^{-34}$ J · s)

A. 3.98×10^{-21} J
B. 3.98×10^{-19} J
C. 2.39×10^{3} J
D. 2.39×10^{5} J

7. Suppose an electron falls from $n = 4$ to its ground state, $n = 1$. Which of the following effects is most likely?

A. A photon is absorbed.
B. A photon is emitted.
C. The electron moves into a *p*-orbital.
D. The electron moves into a *d*-orbital.

8. Which of the following isotopes of carbon is LEAST likely to be found in nature?

A. ^{6}C
B. ^{12}C
C. ^{13}C
D. ^{14}C

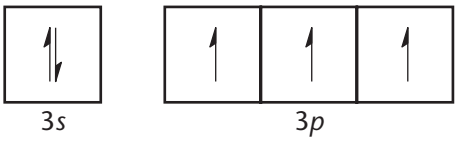
9. Which of the following best explains the inability to measure position and momentum exactly and simultaneously according to the Heisenberg uncertainty principle?

A. Imprecision in the definition of the meter and kilogram
B. Limits on accuracy of existing scientific instruments
C. Error in one variable is increased by attempts to measure the other
D. Discrepancies between the masses of nuclei and of their component particles

10. Which of the following electronic transitions would result in the greatest gain in energy for a single hydrogen electron?

A. An electron moves from $n = 6$ to $n = 2$.
B. An electron moves from $n = 2$ to $n = 6$.
C. An electron moves from $n = 3$ to $n = 4$.
D. An electron moves from $n = 4$ to $n = 3$.

11. Suppose that an atom fills its orbitals as shown:



Such an electron configuration most clearly illustrates which of the following laws of atomic physics?

A. Hund's rule
B. Heisenberg uncertainty principle
C. Bohr model
D. Rutherford model

12. How many total electrons are in a ^{133}Cs cation?

A. 54
B. 55
C. 78
D. 132

13. The atomic weight of hydrogen is 1.008 amu. What is the percent composition of hydrogen by isotope, assuming that hydrogen's only isotopes are ^{1}H and ^{2}D?

A. 92% H, 8% D
B. 99.2% H, 0.8% D
C. 99.92% H, 0.08% D
D. 99.992% H, 0.008% D

14. Consider the two sets of quantum numbers shown in the table, which describe two different electrons in the same atom.

n	l	m_l	m_s
2	1	1	$+\frac{1}{2}$
3	1	–1	$+\frac{1}{2}$

Which of the following terms best describes these two electrons?

A. Parallel
B. Opposite
C. Antiparallel
D. Paired

15. Which of the following species is represented by the electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 4s^1 3d^5$?

I. Cr
II. Mn^+
III. Fe^{2+}

A. I only
B. I and II only
C. II and III only
D. I, II, and III

Explanations to Discrete Practice Questions

1. A

Remember that when electrons are removed from an element, forming a cation, they will be removed from the subshell with the highest n value first. Zn^0 has 30 electrons, so it would have an electron configuration of $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10}$. The 4s subshell has the highest principal quantum number, so it is emptied first, forming $1s^2 2s^2 2p^6 3s^2 3p^6 4s^0 3d^{10}$. **Choice (B)** implies that electrons are pulled out of the d orbital, **choice (C)** presents the configuration of the uncharged zinc atom, and **choice (D)** shows the configuration that would exist if four electrons were removed.

2. B

The azimuthal quantum number l cannot be higher than $n - 1$, ruling out **choice (A)**. The m_l number, which describes the chemical's magnetic properties, can only be an integer value between $-l$ and l. It cannot be equal to ±1 if $l = 0$; this would imply that an s orbital has three subshells (–1, 0, and 1) when we know it can only have one. This rules out **choices (C)** and **(D)**.

3. C

For any value of n there will be a maximum of $2n^2$ electrons; that is, two per orbital. This can also be determined from the periodic table. There are only two elements (H and He) that have valence electrons in the $n = 1$ shell. Eight elements (Li to Ne) have valence electrons in the $n = 2$ shell. This is the only equation that matches this pattern.

4. B

This formula describes the number of electrons in terms of the azimuthal quantum number l, which ranges from 0 to $n - 1$, with n being the principal quantum number. A table of the maximum number of electrons per subshell is provided here:

Subshell	Azimuthal Quantum Number (l)	Number of Electrons
s	0	2
p	1	6
d	2	10
f	3	14

5. D

The only answer choice without unpaired electrons in its ground state is helium. Recall from the chapter that a diamagnetic substance is identified by the lack of unpaired electrons in its shell. A substance without unpaired electrons, like helium, cannot be magnetized by an external magnetic field and is actually slightly repelled. Elements that come at the end of a block (Group IIA, the group containing Zn, and the noble gases, most notably) have only paired electrons.

6. D

While daunting at first, the problem requires the MCAT favorite equation $E = \frac{hc}{\lambda}$, where $h = 6.626 \times 10^{-34}$ J · s (Planck's constant), c = $3.00 \times 10^8 \frac{\text{m}}{\text{s}}$ is the speed of light, and λ is the wavelength of the light. This question asks for the energy of one mole of photons, so we must multiply by Avogadro's number, $N_A = 6.02 \times 10^{23}$ mol^{-1}.

The setup is: $E = \frac{hc}{\lambda} \times N_A$

$$= \frac{(6.626 \times 10^{-34}\ \text{J} \cdot \text{s})(3.00 \times 10^8 \frac{\text{m}}{\text{s}})}{(500 \times 10^{-9}\ \text{m})} \times (6.02 \times 10^{23}\ \text{mol}^{-1})$$

$$\approx \frac{100}{500} \times 10^6\ \text{J} = 2 \times 10^5\ \text{J}$$

7. B

Because the electron is moving into the $n = 1$ shell, the only subshell available is the 1*s* subshell, which eliminates **choices (C)** and **(D)**. There will be some energy change, however, as the electron must lose energy to return to the minimum-energy ground state. That will require emitting radiation in the form of a photon.

8. A

Recall that the superscript refers to the mass number of an atom, which is equal to the number of protons plus the number of neutrons present in an element. Sometimes a text will list the atomic number, *Z*, as a subscript under the mass number, *A*. According to the periodic table, carbon contains six protons; therefore, its atomic number is 6. Isotopes all have the same number of protons, but differ in the number of neutrons. Almost all atoms with $Z > 1$ have at least one neutron. Carbon is most likely to have a mass number of 12, for six protons and six neutrons, as in **choice (B)**. **Choices (C)** and **(D)** are possible isotopes that would have more neutrons than ^{12}C. The ^{6}C isotope is unlikely. It would mean that there are 6 protons and 0 neutrons. As shown in Figure 1.4, this would be a highly unstable isotope.

9. C

The limitations placed by the Heisenberg uncertainty principle are caused by limitations inherent in the measuring process: if a particle is moving, it has momentum, but trying to measure that momentum necessarily creates uncertainty in the position. Even if we had an exact definition of the meter, as in **choice (A)**, or perfect measuring devices, as in **choice (B)**, we still wouldn't be able to measure position *and* momentum simultaneously *and* exactly.

10. B

For the electron to *gain* energy, it must absorb energy from photons to jump up to a higher energy level. There is a bigger jump between $n = 2$ and $n = 6$ than there is between $n = 3$ and $n = 4$.

11. A

The MCAT covers the topics in this chapter qualitatively more often than quantitatively. It is critical to be able to distinguish the fundamental principles that determine electron organization, which are usually known by the names of the scientists who discovered or postulated them. The Heisenberg uncertainty principle, **choice (B)**, refers to the inability to know the momentum and position of a single electron simultaneously. The Bohr model, **choice (C)**, was an early attempt to describe the behavior of the single electron in a hydrogen atom. The Rutherford model, **choice (D)**, described a dense, positively charged nucleus. The element shown here, phosphorus, is often used to demonstrate Hund's rule because it contains a half-filled *p* subshell. Hund's rule explains that electrons fill empty orbitals first before doubling up electrons in the same orbital.

12. A

The quickest way to solve this problem is to use the periodic table and find out how many protons are in Cs atoms; there are 55. Neutral Cs atoms would also have 55 electrons. A stable Cs cation will have a single positive charge because it has one unpaired *s*-electron. This translates to one fewer electron than the number of protons, or 54 electrons.

13. B

The easiest way to approach this problem is to set up a system of two algebraic equations, where H and D are the percentages of H (mass = 1 amu) and D (mass = 2 amu), respectively. Your setup should look like the following system:

$$H + D = 1 \text{ (percent H + percent D = 100\%)}$$
$$1\,H + 2\,D = 1.008 \text{ (atomic weight calculation)}$$

Rearranging the first equation and substituting into the second yields $(1 - D) + 2D = 1.008$, or $D = 0.008$. 0.008 is 0.8%, so there is 0.8% D.

14. A

The terms in the answer choices refer to the magnetic spin of the two electrons. The quantum number m_s represents this property as a measure of an electron's intrinsic spin. These electrons' spins are parallel, in that their spins are aligned in the same direction ($m_s = +\frac{1}{2}$ for both species).

15. B

When dealing with ions, you cannot directly approach electronic configurations based on the number of electrons they currently hold. First examine the neutral atom's configuration, and then determine which electrons are removed.

Neutral Atom's Configuration	Ion's Configuration
Cr^0: [Ar] $4s^1 3d^5$	—
Mn^0: [Ar] $4s^2 3d^5$	Mn^+: [Ar] $4s^1 3d^5$
Fe^0: [Ar] $4s^2 3d^6$	Fe^{2+}: [Ar] $4s^0 3d^6$

Due to the stability of half-filled *d*-orbitals, neutral chromium assumes the electron configuration of [Ar] $4s^1 3d^5$. Mn must lose one electron from its initial configuration to become the Mn^+ cation. That electron would come from the 4*s* subshell according to the rule that the first electron removed comes from the highest-energy shell. Fe must lose two electrons to become Fe^{2+}. They'll both be lost from the same orbital; the only way Fe^{2+} could hold the configuration in the question stem would be if one *d*-electron and one *s*-electron were lost together.

Concept Summary 60

Introduction

The pharmacological history of lithium is an interesting window into the scientific and medical communities' attempts to take advantage of the chemical and physical properties of an element for human benefit. By the mid-1800s, the medical community was showing great interest in theories that linked uric acid to a myriad of maladies. When it was discovered that solutions of lithium carbonate dissolved uric acid, therapeutic preparations containing lithium carbonate salt became popular. Even nonmedical companies tried to profit from lithium's reputation as a cure-all by adding it to their soft drinks.

Eventually, fascination with theories of uric acid wore off, and lithium's time in the spotlight seemed to be coming to an end. Then, in the 1940s, doctors began to recommend salt-restricted diets for cardiac patients. Lithium chloride was made commercially available as a sodium chloride (table salt) substitute. Unfortunately, lithium is quite toxic at fairly low concentrations, and when medical literature in the late 1940s reported several incidents of severe poisonings and multiple deaths—some associated with only minor lithium overdosing—U.S. companies voluntarily withdrew all lithium salts from the market. Right around this time, the Australian psychiatrist John Cade proposed the use of lithium salts for the treatment of mania. Cade's clinical trials were quite successful. In fact, his use of lithium salts to control mania was the first instance of successful medical treatment of a mental illness, and lithium carbonate became commonly prescribed in Europe for manic behavior. Not until 1970 did the U.S. Food and Drug Administration finally approve the use of lithium carbonate for manic illnesses.

Lithium (Li) is the element with the atomic number 3. It is a very soft alkali metal, and under standard conditions, it is the least dense solid element (specific gravity = 0.53). Lithium is so reactive that it does not naturally occur on earth in its elemental form and is found only in various salt compounds.

Why would medical scientists pay attention to this particular element? What would make doctors believe that lithium chloride would be a good substitute for sodium chloride for patients on salt-restricted diets? The answers lie in the periodic table.

2.1 The Periodic Table ★★

In 1869, the Russian chemist Dmitri Mendeleev published the first version of his **Periodic Table of the Elements**, which showed that ordering the known elements according to atomic weight revealed a pattern of periodically recurring physical and chemical properties. Since then, the periodic table has been revised, using the work of physicist Henry Moseley, to organize the elements based on increasing atomic number (the number of protons in an element) rather than atomic weight. Using this revised table, many properties of elements that had not yet been discovered could be predicted. The periodic table creates a visual representation of the **periodic law**, which states: *the chemical and physical properties of the elements are dependent, in a periodic way, upon their atomic numbers*.

Bridge

Recall from Chapter 1 of *MCAT General Chemistry Review* that periods (rows) graphically represent the principal quantum number, and groups (columns) help to determine the valence electron configuration.

The modern periodic table arranges the elements into **periods** (rows) and **groups** or **families** (columns), based on atomic number. There are seven periods representing the principal quantum numbers $n = 1$ through $n = 7$ for the *s*- and *p*-block elements. Each period is filled sequentially, and each element in a given period has one more proton and one more electron than the element to its left (in their neutral states). Groups contain elements that have the same electronic configuration in their **valence shell** and share similar chemical properties.

MCAT Expertise

Relating valence electrons to reactivity is important. Elements with similar valence electron configurations generally behave in similar ways, as long as they are the same type (metal, nonmetal, or metalloid).

The electrons in the valence shell, known as the **valence electrons**, are the farthest from the nucleus and have the greatest amount of potential energy. Their higher potential energy and the fact that they are held less tightly by the nucleus allows them to become involved in chemical bonds with the valence electrons of other atoms; thus, the valence shell electrons largely determine the chemical reactivity and properties of the element.

The Roman numeral above each group represents the number of valence electrons elements in that group have in their neutral state. The Roman numeral is combined with the letter A or B to separate the elements into two larger classes. The **A elements** are known as the **representative elements** and include groups IA through VIIIA.

The elements in these groups have their valence electrons in the orbitals of either *s* or *p* subshells. The **B elements** are known as the **nonrepresentative elements** and include both the **transition elements**, which have valence electrons in the *s* and *d* subshells, and the **lanthanide** and **actinide series**, which have valence electrons in the *s* and *f* subshells. For the representative elements, the Roman numeral and the letter designation determine the electron configuration. For example, an element in Group VA has five valence electrons with the configuration s^2p^3. As described in Chapter 1 of *MCAT General Chemistry Review*, the nonrepresentative elements may have unexpected electron configurations, such as chromium ($4s^1\,3d^5$) and copper ($4s^1\,3d^{10}$). In the modern IUPAC identification system, the groups are numbered 1 to 18 and are not subdivided into Group A and Group B elements.

MCAT Concept Check 2.1:

Before you move on, assess your understanding of the material with these questions.

1. Mendeleev's table was arranged by atomic weight, but the modern periodic table is arranged by:

_____

2. Which of the following are representative elements (A), and which are nonrepresentative (B)?

Element	A or B	Element	A or B	Element	A or B	Element	A or B
Ag		Al		K		P	
Pb		Li		Pu		U	
Cu		Cf		Zn		B	
N		Np		O		He	

2.2 Types of Elements

When we consider the trends of chemical reactivity and physical properties together, we can begin to identify groups of elements with similar characteristics. These larger collections are divided into three categories: metals, nonmetals, and metalloids (also called semimetals).

METALS

Metals are found on the left side and in the middle of the periodic table. They include the active metals, the transition metals, and the lanthanide and actinide series of elements. Metals are **lustrous** (shiny) solids, except for mercury, which

is a liquid under standard conditions. They generally have high melting points and densities, but there are exceptions, such as lithium, which has a density about half that of water. Metals have the ability to be deformed without breaking; the ability of metal to be hammered into shapes is called **malleability**, and its ability to be pulled or drawn into wires is called **ductility**. At the atomic level, a metal is defined by a low effective nuclear charge, low electronegativity (high **electropositivity**), large atomic radius, small ionic radius, low ionization energy, and low electron affinity. All of these characteristics are manifestations of the ability of metals to easily give up electrons.

Key Concept

Alkali and alkaline earth metals are both metallic in nature because they easily lose electrons from the *s* subshell of their valence shells.

Many of the transition metals (Group B elements) have two or more **oxidation states** (charges when forming bonds with other atoms). Because the valence electrons of all metals are only loosely held to their atoms, they are free to move, which makes metals good **conductors** of heat and electricity. The valence electrons of the active metals are found in the *s* subshell; those of the transition metals are found in the *s* and *d* subshells; and those of the lanthanide and actinide series elements are in the *s* and *f* subshells. Some transition metals—copper, nickel, silver, gold, palladium, and platinum—are relatively nonreactive, a property that makes them ideal for the production of coins and jewelry.

An example of a metal is shown in Figure 2.1 with an indium wire. The wire exhibits luster, malleability, and ductility. It is used as a wire because it also exhibits good heat and electrical conductivity.

Figure 2.1. Indium (In) Metal Wire

NONMETALS

Nonmetals are found predominantly on the upper right side of the periodic table. Nonmetals are generally brittle in the solid state and show little or no metallic luster. They have high ionization energies, electron affinities, and electronegativities, as well as small atomic radii and large ionic radii. They are usually poor conductors of heat and electricity. All of these characteristics are manifestations of the *inability* of nonmetals to easily give up electrons. Nonmetals are less unified in their chemical and physical properties than the metals.

Carbon, shown in Figure 2.2, is a stereotypical nonmetal that retains a solid structure but is brittle, nonlustrous, and generally a poor conductor of heat and electricity.

Figure 2.2. Activated Charcoal, Composed of the Nonmetal Carbon (C)

METALLOIDS

Separating the metals and nonmetals are a stair-step group of elements called the **metalloids**. The metalloids are also called **semimetals** because they share some characteristics with both metals and nonmetals. The electronegativities and ionization energies of the metalloids lie between those of metals and nonmetals. Their physical properties—densities, melting points, and boiling points—vary widely and can be combinations of metallic and nonmetallic characteristics. For example, silicon (Si) has a metallic luster but is brittle and a poor conductor. The reactivities of the metalloids are dependent on the elements with which they are reacting. Boron (B), for example, behaves like a nonmetal when reacting with sodium (Na) and like a metal when reacting with fluorine (F). The elements classified as metalloids

Real World

Metalloids share some properties with metals and others with nonmetals. For instance, metalloids make good semiconductors due to their partial conductivity of electricity.

form a "staircase" on the periodic table and include boron, silicon, germanium (Ge), arsenic (As), antimony (Sb), tellurium (Te), polonium (Po), and astatine (At). While there is debate over polonium and astatine's status as metalloids, most sources label them as such. Figure 2.3 color-codes the major classifications of elements on the periodic table.

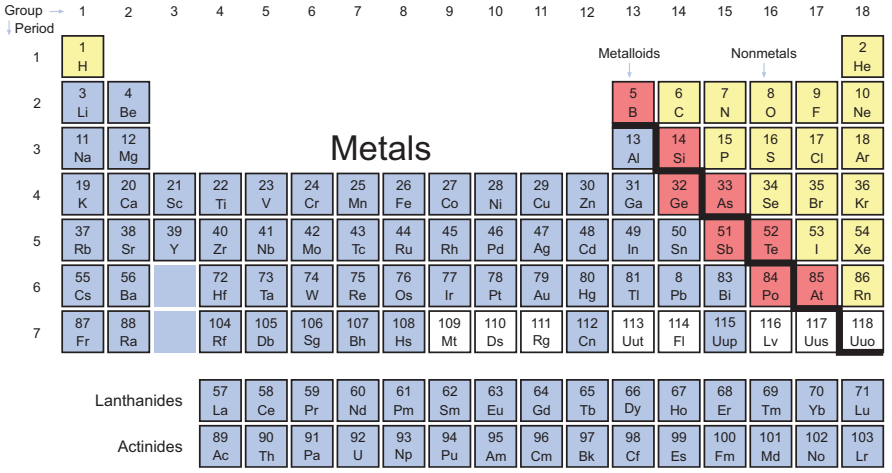

Figure 2.3. Periodic Table, Coded by Element Type

MCAT Concept Check 2.2:

Before you move on, assess your understanding of the material with these questions.

1. Based on their location in the periodic table, identify a few elements that likely possess the following properties:
   - Luster:

     _____
   - Poor conductivity of heat and electricity:

     _____
   - Good conductivity but brittle:

     _____

2. Classify the following elements as metals (M), nonmetals (NM), or metalloids (MO):

Element	Class	Element	Class	Element	Class	Element	Class
Ag		Al		K		P	
Pb		Li		Pu		U	
Cu		As		Zn		B	
Si		Np		O		He	

2.3 Periodic Properties of the Elements

The MCAT does *not* expect you to have memorized the entire periodic table. Fortunately, the periodic table is a guide unto itself, a self-referencing localization system for all of the elements. Remember, the modern table is organized in such a way to represent visually the periodicity of chemical and physical properties of the elements. The periodic table, then, can provide you with a tremendous amount of information that otherwise would have to be memorized. Note, though, that while you do not need to memorize the periodic table for the MCAT, you *do* need to understand the trends within the periodic table that help predict the chemical and physical behaviors of the elements.

Before exploring the periodic trends, let's take stock of three key rules that control how valence electrons work in an atom. First, as we've already mentioned, as one moves from left to right across a period, electrons and protons are added one at a time. As the positivity of the nucleus increases, the electrons surrounding the nucleus, including those in the valence shell, experience a stronger electrostatic pull toward the center of the atom. This causes the electron cloud, which is the outer boundary defined by the valence shell electrons, to move closer and bind more tightly to the nucleus. This electrostatic attraction between the valence shell electrons and the nucleus is known as the **effective nuclear charge** ($\mathbf{Z_{eff}}$), a measure of the net positive charge experienced by the outermost electrons. This pull is somewhat mitigated by nonvalence electrons that reside closer to the nucleus. For elements in the same period, Z_{eff} increases from left to right. The parts of an atom responsible for Z_{eff} are illustrated in Figure 2.4.

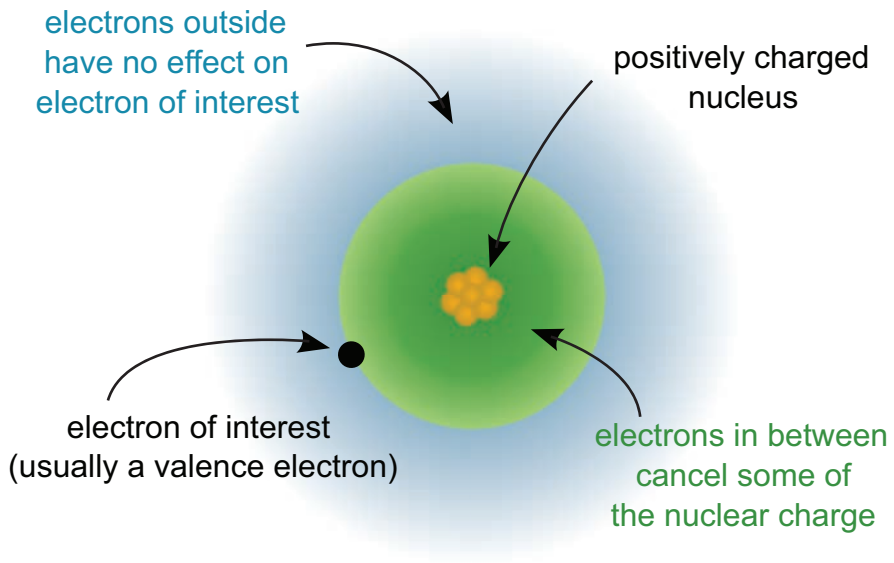

Figure 2.4. Factors that Determine Effective Nuclear Charge (Z_{eff})

MCAT Expertise

Don't try to memorize the periodic table. You will have access to it on Test Day through the test interface. *Do* understand its configuration and trends so that you can use it efficiently to get a higher score!

Bridge

Z_{eff} relies on the principles of electrostatic forces defined in Chapter 5 of *MCAT Physics and Math Review.* The values q_1 and q_2 can represent the net charge of the nucleus and valence electron shell, respectively. The larger each charge gets (going to the right in the periodic table), the higher the value of Z_{eff}.

Second, as one moves down the elements of a given group, the **principal quantum number** increases by one each time. This means that the valence electrons are increasingly separated from the nucleus by a greater number of filled principal energy levels, which can also be called inner shells. The result of this increased separation is a reduction in the electrostatic attraction between the valence electrons and the positively charged nucleus. These outermost electrons are held less tightly as the principal quantum number increases. As one goes down in a group, the increased shielding created by the inner shell electrons cancels the increased positivity of the nucleus. Thus, the Z_{eff} is more or less constant among the elements within a given group. Despite this fact, the valence electrons are held less tightly to the nucleus as one moves down a group due to the increased separation between valence electrons and the nucleus.

Third, elements can also gain or lose electrons in order to achieve a stable octet formation representative of the **noble** (**inert**) **gases** (Group VIIIA or Group 18). In Chapter 3 of *MCAT General Chemistry Review*, we will discuss how the **octet rule** is hardly a rule at all because there are many exceptions. For now, keep in mind that elements, especially the ones that have biological roles, tend to be most stable with eight electrons in their valence shell.

These three facts are guiding principles as we work toward an understanding of the trends demonstrated in the periodic table. In fact, the trend for effective nuclear charge across a period and the impact of increasing the number of inner shells down a group will help derive all the trends we discuss below.

ATOMIC AND IONIC RADII

Key Concept

Atomic radius refers to the size of a neutral element, while an ionic radius is dependent on *how* the element ionizes based on its element type and group number.

Think of an atom as a cloud of electrons surrounding a dense core of protons and neutrons. The **atomic radius** of an element is thus equal to one-half of the distance between the centers of two atoms of an element that are briefly in contact with each other. The distance between two centers of circles in contact is akin to a diameter, making this radius calculation simple. The atomic radius cannot be measured by examining a single atom because the electrons are constantly moving around, making it impossible to mark the outer boundary of the electron cloud.

MCAT Expertise

Atomic radius is essentially opposite that of all other periodic trends. While others increase going up and to the right, atomic radius increases going down and to the left.

As we move across a period from left to right, protons and electrons are added one at a time to the atoms. Because the electrons are being added only to the outermost shell and the number of inner-shell electrons remains constant, the increasing positive charge of the nucleus pulls the outer electrons more closely inward and holds them more tightly. The Z_{eff} increases left to right across a period, and as a result, atomic radius decreases from left to right across a period.

As we move down a group, the increasing principal quantum number implies that the valence electrons will be found farther away from the nucleus because the number of inner shells is increasing, separating the valence shell from the nucleus. Although the Z_{eff} remains essentially constant, the atomic radius increases down a group. Within each group, the largest atom will be at the bottom, and within each period, the largest atom will be in Group IA (Group 1). For reference, the largest atomic radius in the periodic table belongs to cesium (Cs, 260 pm), and the smallest belongs to helium (He, 25 pm). Francium is typically not considered because it is exceptionally rare in nature. Figure 2.5 displays a graph of atomic radius *vs.* atomic number, with Group IA elements possessing the largest atomic radius in each row.

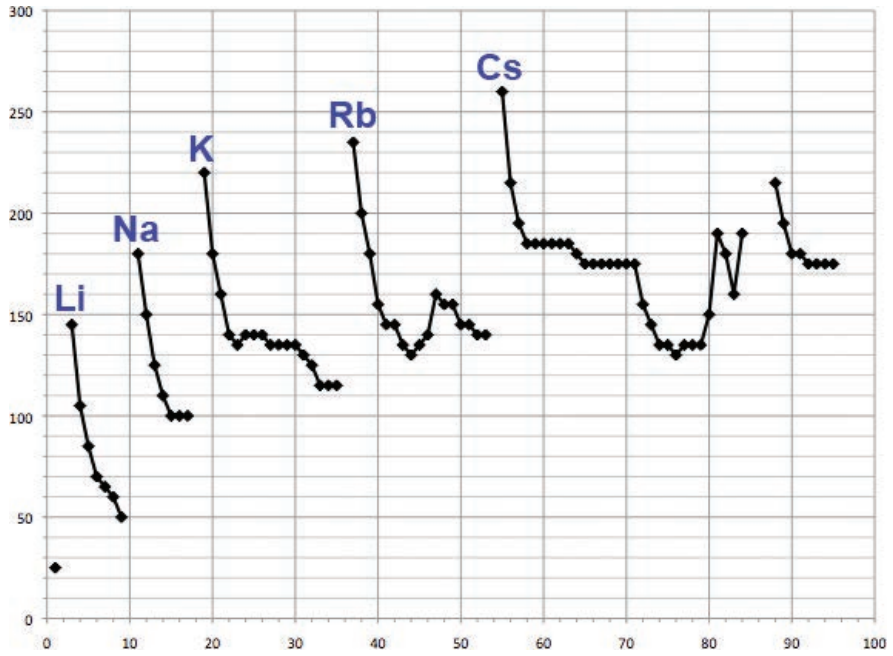

Figure 2.5. Atomic Radius (in pm) *vs.* Atomic Number

Unlike atomic radii, **ionic radii** will require some critical thinking and periodic table geography to determine. In order to understand ionic radii, we must make two generalizations. One is that metals lose electrons and become positive, while nonmetals gain electrons and become negative. The other is that metalloids can go in either direction, but tend to follow the trend based on which side of the metalloid line they fall on. Thus, silicon (Si) behaves more like a nonmetal, while germanium (Ge) tends to act more like a metal. On the MCAT, these generalizations can also be inferred from information found in passages and questions, such as oxidation states in compounds.

For nonmetals close to the metalloid line, their group number dictates that they require more electrons than other nonmetals to achieve the electronic configuration seen in Group VIIIA. These nonmetals gain electrons while their nuclei maintain the

same charge. Therefore, these nonmetals close to the metalloid line possess a larger ionic radius than their counterparts closer to Group VIIIA.

For metals, the trend is similar but opposite. Metals closer to the metalloid line have more electrons to lose to achieve the electronic configuration seen in Group VIIIA. Because of this, the ionic radius of metals near the metalloid line is dramatically smaller than that of other metals. Metals closer to Group IA have fewer electrons to lose and therefore experience a less drastic reduction in radius during ionization. These changes are illustrated in Figure 2.6. Note that tellurium (Te) behaves as a nonmetal and boron (B) behaves as a metal; under varying conditions, these metalloids can have opposite behavior.

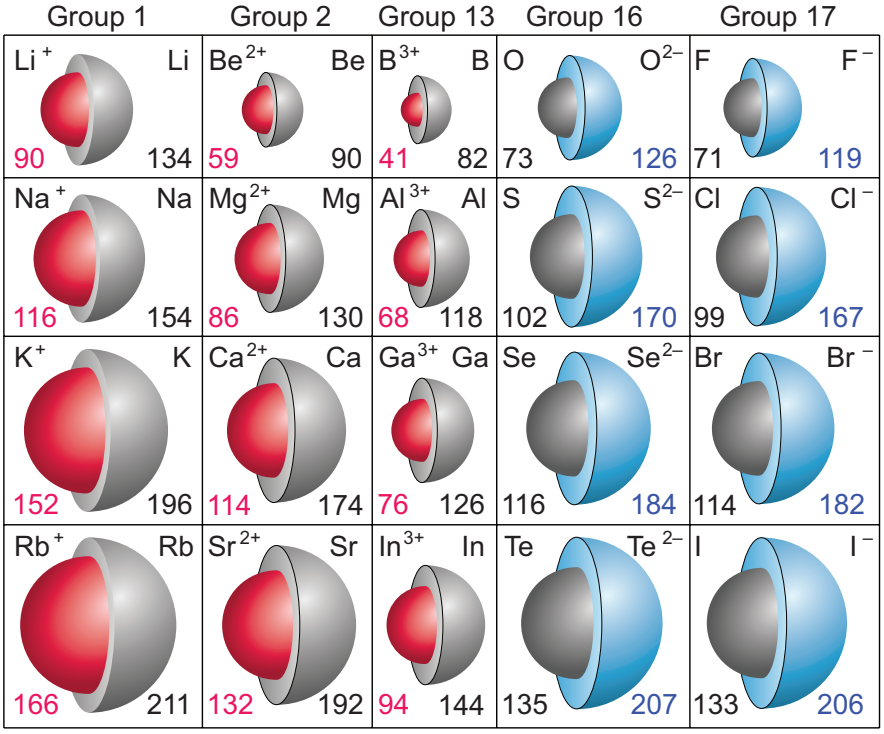

Figure 2.6. Ionic Radii (in pm) for Various Metals and Nonmetals
Neutral atoms are shown in grey; cations in red; anions in blue.

IONIZATION ENERGY

Ionization energy (**IE**), also known as **ionization potential**, is the energy required to remove an electron from a gaseous species. Removing an electron from an atom always requires an input of heat, which makes it an **endothermic process**. The greater the atom's Z_{eff} or the closer the valence electrons are to the nucleus, the more tightly bound they are. This makes it more difficult to remove one or more electrons, increasing the ionization energy. Thus, ionization energy increases from left to right across a period and from bottom to top in a group. The subsequent

removal of a second or third electron requires increasing amounts of energy because the removal of more than one electron means that the electrons are being removed from an increasingly cationic (positive) species. The energy necessary to remove the first electron is called the **first ionization energy**; the energy necessary to remove the second electron from the univalent cation (X^+) to form the divalent cation (X^{2+}) is called the **second ionization energy**, and so on. For example:

$$Mg\,(g) \rightarrow Mg^+\,(g) + e^- \qquad \text{first ionization energy} = 738\ \frac{kJ}{mol}$$

$$Mg^+\,(g) \rightarrow Mg^{2+}\,(g) + e^- \qquad \text{second ionization energy} = 1450\ \frac{kJ}{mol}$$

Elements in Groups IA and IIA (Groups 1 and 2), such as lithium and beryllium, have such low ionization energies that they are called the **active metals**. The active metals do not exist naturally in their neutral forms; they are always found in ionic compounds, minerals, or ores. The loss of one electron from the alkali metals (Group IA) or the loss of two electrons from the alkaline earth metals (Group IIA) results in the formation of a stable, filled valence shell. In contrast, the Group VIIA (Group 17) elements—the halogens—do not typically give up their electrons. In fact, in their ionic form, they are generally anions. The first ionization energies of the elements are shown in Figure 2.7.

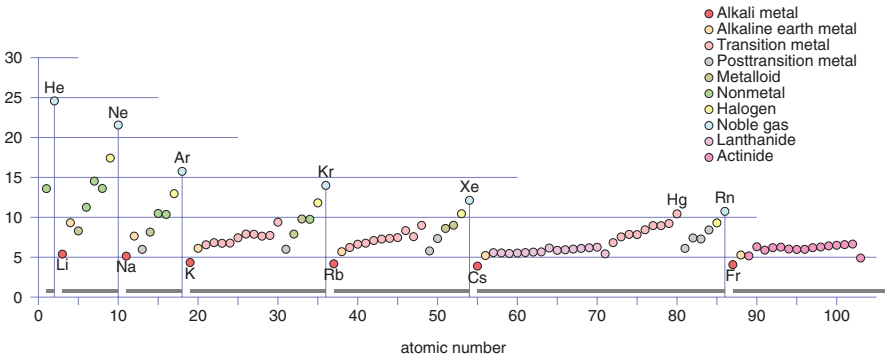

Figure 2.7. First Ionization Energies (in eV) of the Elements

The values for second ionization energies are disproportionally larger for Group IA monovalent cations (like Na^+) but generally not that much larger for Group IIA or subsequent monovalent cations (like Mg^+). This is because removing one electron from a Group IA metal results in a noble gas-like electron configuration.

Group VIIIA (Group 18) elements, or noble or inert gases, are the least likely to give up electrons. They already have a stable electron configuration and are unwilling to disrupt that stability by giving up an electron. Therefore, noble gases are among the elements with the highest ionization energies.

MCAT Expertise

First ionization energy (IE) will always be smaller than second IE, which will always be smaller than third IE. However, the degree to which the IE increases provides clues about the identity of the atom. If losing a certain number of electrons gives an element a noble gas-like electron configuration, then removing a subsequent electron will cost much more energy. For example

$Mg^{2+}\,(g) \rightarrow Mg^{3+}\,(g) + e^-$

third ionization energy = 7730 $\frac{kJ}{mol}$

ELECTRON AFFINITY

Halogens are the most "greedy" group of elements on the periodic table when it comes to electrons. By acquiring one additional electron, a halogen is able to complete its octet and achieve a noble gas configuration. This **exothermic** process expels energy in the form of heat. **Electron affinity** refers to the energy dissipated by a gaseous species when it gains an electron. Note the electron affinity is essentially the opposite concept from ionization energy. Because this is an exothermic process, ΔH_{rxn} has a negative sign; however, the electron affinity is reported as a positive number. This is because electron affinity refers to the energy dissipated: if 200 $\frac{kJ}{mol}$ of energy is released, $\Delta H_{rxn} = -200 \frac{kJ}{mol}$, and the electron affinity is 200 $\frac{kJ}{mol}$. The stronger the electrostatic pull (the higher the Z_{eff}) between the nucleus and the valence shell electrons, the greater the energy release will be when the atom gains the electron. Thus, electron affinity increases across a period from left to right. Because the valence shell is farther away from the nucleus as the principal quantum number increases, electron affinity decreases in a group from top to bottom. Groups IA and IIA (Groups 1 and 2) have very low electron affinities, preferring to give up electrons to achieve the octet configuration of the noble gas in the previous period. Conversely, Group VIIA (Group 17) elements have very high electron affinities because they need to gain only one electron to achieve the octet configuration of the noble gases (Group VIIIA or Group 18) in the same period. Although the noble gases would be predicted to have the highest electron affinities according to the trend, they actually have electron affinities on the order of zero because they already possess a stable octet and cannot readily accept an electron. Most metals also have low electron affinity values, as can be seen in Figure 2.8.

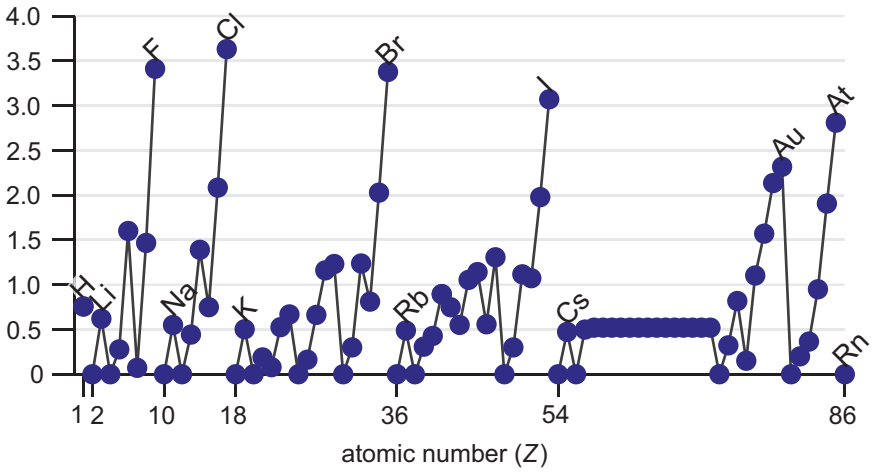

Figure 2.8. Electron Affinities (in eV) of the Elements

ELECTRONEGATIVITY

Electronegativity is a measure of the attractive force that an atom will exert on an electron in a chemical bond. The greater the electronegativity of an atom, the more it attracts electrons within a bond. Electronegativity values are related to ionization energies: the lower the ionization energy, the lower the electronegativity; the higher the ionization energy, the higher the electronegativity. The first three noble gases are exceptions: despite their high ionization energies, these elements have negligible electronegativity because they do not often form bonds.

The electronegativity value is a relative measure, and there are different scales used to express it. The most common scale is the **Pauling electronegativity scale**, which ranges from 0.7 for cesium, the least electronegative (most electropositive) element, to 4.0 for fluorine, the most electronegative element. Electronegativity increases across a period from left to right and decreases in a group from top to bottom. Figure 2.9 shows the electronegativity values of the elements.

H 2.1																	He
Li 1.0	Be 1.5											B 2.0	C 2.5	N 3.0	O 3.5	F 4.0	Ne
Na 0.9	Mg 1.2											Al 1.5	Si 1.8	P 2.1	S 2.5	Cl 3.0	Ar
K 0.8	Ca 1.0	Sc 1.3	Ti 1.5	V 1.6	Cr 1.6	Mn 1.5	Fe 1.8	Co 1.9	Ni 1.8	Cu 1.9	Zn 1.6	Ga 1.6	Ge 1.8	As 2.0	Se 2.4	Br 2.8	Kr

Figure 2.9. Pauling Electronegativity Values of the Elements

The periodic trends are summarized together in Figure 2.10.

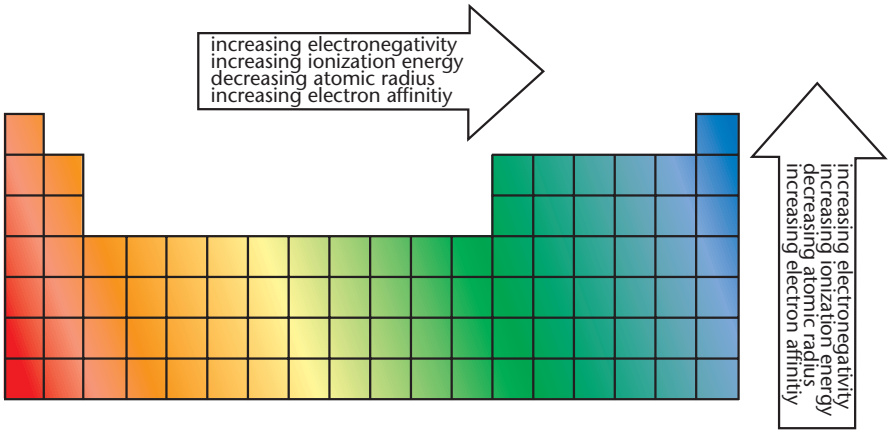

Figure 2.10. Periodic Trends

Key Concept

- Cs = largest, least electronegative, lowest ionization energy, least exothermic (lowest) electron affinity
- F = smallest, most electronegative, highest ionization energy, most exothermic (highest) electron affinity

Key Concept

Periodic Trends

Left ⟶ Right
- Atomic radius ↓
- Ionization energy ↑
- Electron affinity ↑
- Electronegativity ↑

Top ⟶ Bottom
- Atomic radius ↑
- Ionization energy ↓
- Electron affinity ↓
- Electronegativity ↓

Note: Atomic radius is always opposite the other trends. Ionic radius is variable.

MCAT Concept Check 2.3:
Before you move on, assess your understanding of the material with these questions.

1. Rank the following elements by decreasing first ionization energy: calcium (Ca), carbon (C), germanium (Ge), potassium (K)
   1. _____
   2. _____
   3. _____
   4. _____

2. Rank the following elements by increasing electron affinity: barium (Ba), copper (Cu), sulfur (S), yttrium (Y)
   1. _____
   2. _____
   3. _____
   4. _____

3. Rank the following elements by decreasing electronegativity: antimony (Sb), neon (Ne), oxygen (O), thallium (Tl)
   1. _____
   2. _____
   3. _____
   4. _____

4. Rank the following elements by increasing atomic radius: niobium (Nb), praseodymium (Pr), tantalum (Ta), xenon (Xe)
   1. _____
   2. _____
   3. _____
   4. _____

2.4 The Chemistry of Groups ★★

What follows is a discussion of the major groups you are likely to encounter on the MCAT. While it is rare to be tested on every group, it is important to understand the overarching trends we have already discussed and how they relate across different groups.

ALKALI METALS (IA)

The **alkali metals** (Group IA or Group 1) possess most of the classic physical properties of metals, except that their densities are lower than those of other metals (as described for lithium earlier in this chapter). The alkali metals have only one loosely bound electron in their outermost shells. Their Z_{eff} values are very low, giving them the largest atomic radii of all the elements in their respective periods. This low Z_{eff} value also explains the other trends: low ionization energies, low electron affinities, and low electronegativities. Alkali metals easily lose one electron to form univalent cations, and they react readily with nonmetals—especially the halogens—as in NaCl. Figure 2.11 illustrates the reaction of an alkali metal with water, a stereotypically violent reaction.

Real World

Due to their high reactivity with water and air, most alkali metals are stored in mineral oil.

Figure 2.11. Reaction of Sodium with Water
Group IA metals react violently with water, forming strong bases.

ALKALINE EARTH METALS (IIA)

The **alkaline earth metals** (Group IIA or Group 2), also possess many properties characteristic of metals. They share most of the characteristics of the alkali metals, except that they have slightly higher effective nuclear charges and thus slightly smaller atomic radii. They have two electrons in their valence shell, both of which are easily removed to form divalent cations. Together, the alkali and alkaline earth metals are called the active metals because they are so reactive that they are not naturally found in their elemental (neutral) state.

Bridge

Many of the molecules discussed in metabolism, covered in Chapters 9 through 12 of *MCAT Biochemistry Review,* utilize lighter nontoxic elements from the chalcogen group (oxygen and sulfur). Many of the heavier chalcogens are toxic metals.

CHALCOGENS (VIA)

The **chalcogens** (Group VIA or Group 16) are an eclectic group of nonmetals and metalloids. While not as reactive as the halogens, they are crucial for normal biological functions. They each have six electrons in their valence electron shell and, due to their proximity to the metalloids, generally have small atomic radii and large ionic radii. Oxygen is the most important element in this group for many reasons; it is one of the primary constituents of water, carbohydrates, and other biological molecules. Sulfur is also an important component of certain amino acids, and vitamins. Selenium also is an important nutrient for microorganisms and has a role in protection from oxidative stress. The remainder of this group is primarily metallic and generally toxic to living organisms. It is important to note that, at high concentrations, many of these elements—no matter how biologically useful—can be toxic or damaging.

MCAT Expertise

Halogens are frequently tested on the MCAT. Remember that they only need one more electron to have a noble gas-like electron configuration (full valence shell).

HALOGENS (VIIA)

The **halogens** (Group VIIA or Group 17) are highly reactive nonmetals with seven valence electrons. These elements are desperate to complete their octets by gaining one additional electron. The physical properties of this group are variable. At standard conditions, the halogens range from gaseous (F_2 and Cl_2) to liquid (Br_2) to solid (I_2) forms. Their chemical reactivity is more uniform, and, due to their very high electronegativities and electron affinities, they are especially reactive toward the alkali and alkaline earth metals. Fluorine (F) has the highest electronegativity of all the elements. The halogens are so reactive that they are not naturally found in their elemental state but rather as ions (called **halides**) or diatomic molecules. Diatomic halogens at standard conditions can be seen in Figure 2.12.

Figure 2.12. Halogens in Standard State (Diatomic Molecules)
From left to right: chlorine (Cl_2), bromine (Br_2), and iodine (I_2).

NOBLE GASES (VIIIA)

The **noble gases** (Group VIIIA or Group 18) are also known as **inert gases** because they have minimal chemical reactivity due to their filled valence shells. They have high ionization energies, little or no tendency to gain or lose electrons, and (for He, Ne, and Ar, at least), no measurable electronegativities. The noble gases have extremely low boiling points and exist as gases at room temperature. Noble gases have found a commercial niche as lighting sources, as seen in Figure 2.13, due to their lack of reactivity.

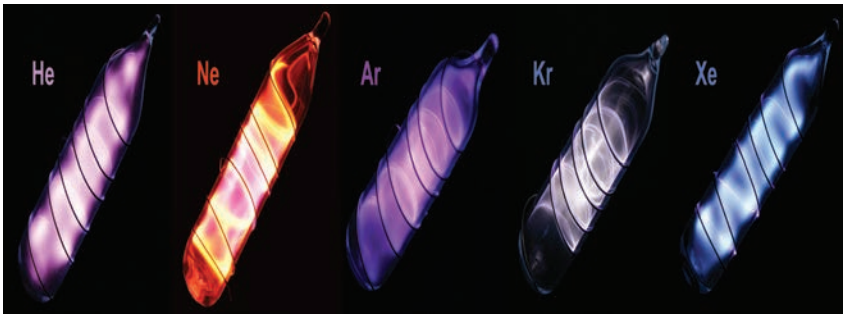

Figure 2.13. Noble Gases in Discharge Lamps

TRANSITION METALS (B)

The **transition elements** (Groups IB to VIIIB or Groups 3 to 12) are considered to be metals and as such have low electron affinities, low ionization energies, and low electronegativities. These metals are very hard and have high melting and boiling points. They tend to be quite malleable and are good conductors due to the loosely held electrons that progressively fill the *d*-orbitals in their valence shells. One of the unique properties of the transition metals is that many of them can have different possible charged forms or **oxidation states** because they are capable of losing different numbers of electrons from the *s*- and *d*-orbitals in their valence shells. For instance, copper (Cu) can exist in either the +1 or the +2 oxidation state, and manganese (Mn) can exist in the +2, +3, +4, +6, or +7 oxidation state. Because of this ability to attain different positive oxidation states, transition metals form many different ionic compounds. These different oxidation states often correspond to different colors; solutions with transition metal-containing complexes are often vibrant, as shown in Figure 2.14.

Figure 2.14. Solutions of Transition Metal-Containing Compounds
From left to right: cobalt(II) nitrate, $Co(NO_3)_2$ (red); potassium dichromate, $K_2Cr_2O_7$ (orange); potassium chromate, K_2CrO_4 (yellow); nickel(II) chloride, $NiCl_2$ (green); copper(II) sulfate, $CuSO_4$ (blue); potassium permanganate, $KMnO_4$ (violet)

Bridge

Many transition metals act as cofactors for enzymes, including vanadium, chromium, manganese, iron, cobalt, nickel, copper, and zinc. Cofactors and coenzymes are discussed in Chapter 2 of *MCAT Biochemistry Review*.

These complex ions tend to associate in solution either with molecules of water (**hydration complexes**, such as $CuSO_4 \cdot 5\ H_2O$) or with nonmetals, (such as $[Co(NH_3)_6]Cl$). This ability to form complexes contributes to the variable solubility of certain transition metal-containing compounds. For example, AgCl is insoluble in water but quite soluble in aqueous ammonia due to the formation of the complex ion $[Ag(NH_3)_2]^+$. The formation of complexes causes the *d*-orbitals to split into two energy sublevels. This enables many of the complexes to absorb certain frequencies of light—those containing the precise amount of energy required to raise electrons from the lower- to the higher-energy *d*-orbitals. The frequencies not absorbed (known as the subtraction frequencies) give the complexes their characteristic colors.

This brings up an important point about the perception of color: when we perceive an object as a particular color, it because that color is *not* absorbed—but rather reflected—by the object. If an object absorbs a given color of light and reflects all others, our brain mixes these **subtraction frequencies** and we perceive the **complementary color** of the frequency that was absorbed. This is best illustrated with an example. *Carotene* is a photosynthetic pigment that strongly absorbs blue light but reflects other colors. Thus, our brains interpret the color of carotene as the result of white light *minus* blue light, which is yellow light. The complementary colors are shown in Figure 2.15; while the MCAT is unlikely to ask you to name the complement of a given color, the relationship between complementary colors, as explained here, is fair game. It should also be noted that the manner in which colors mix in this scheme is distinctly different from mixing, say, paint colors. The differences between these two schemes, termed additive and subtractive color mixing respectively, are outside the scope of the MCAT.

Figure 2.15. Red–Green–Blue (Additive) Color Wheel
Each color is directly across the circle from its complementary color; commonly referenced complementary pairs include red/cyan, green/magenta, and blue/yellow.

MCAT Concept Check 2.4:

Before you move on, assess your understanding of the material with this question.

1. For each of the properties listed below, write down the groups of the periodic table that exhibit those properties.
   - High reactivity to water:

     _____
   - Six valence electrons:

     _____
   - Contain at least one metal:

     _____
   - Multiple oxidation states:

     _____
   - Negative oxidation states:

     _____
   - Possess a full octet in the neutral state:

     _____

Conclusion

Now that we have completed our review of the Periodic Table of the Elements, commit to understanding (not just memorizing) the trends of physical and chemical properties of the elements. They will help you quickly answer many questions on the MCAT. As you progress through the chapters of this book, a foundational understanding of the elements will help you develop a richer, more nuanced understanding of their general and particular behaviors. Topics in general chemistry that may have given you trouble in the past will be understandable from the perspective of the behaviors and characteristics that you have reviewed here.

More broadly, you will see a diverse array of elements from the groups we have discussed here that are critical or detrimental to biological function. In addition, you may begin to see why the human body utilizes certain elements for specific purposes, taking advantage of the periodic trends discussed here.

CONCEPT SUMMARY

The Periodic Table

- The **Periodic Table of the Elements** organizes the elements according to their atomic numbers and reveals a pattern of similar chemical and physical properties among elements.
  - Rows are called **periods** and are based on the same principal energy level, *n*.
  - Columns are called **groups**. Elements in the same group have the same valence shell electron configuration.

Types of Elements

- The elements on the periodic table belong to one of three types.
  - **Metals** are shiny (**lustrous**), conduct electricity well, and are **malleable** and **ductile**. Metals are found on left side and middle of the periodic table.
  - **Nonmetals** are dull, poor conductors of electricity, and are brittle. Nonmetals are found on right side of the periodic table.
  - **Metalloids** possess characteristics of both metals and nonmetals and are found in a stair-step pattern starting with boron (B).

Periodic Properties of the Elements

- **Effective nuclear charge** (Z_{eff}) is the net positive charge experienced by electrons in the valence shell and forms the foundation for all periodic trends.
  - Z_{eff} increases from left to right across a period, with little change in value from top to bottom in a group.
  - Valence electrons become increasingly separated from the nucleus as the principal energy level, *n*, increases from top to bottom in a group.
- **Atomic radius** decreases from left to right across a period and increases from top to bottom in a group.
- **Ionic radius** is the size of a charged species. The largest nonmetallic ionic radii and the smallest metallic ionic radii exist at the metalloid boundary.
  - Cations are generally smaller than their corresponding neutral atom.
  - Anions are generally larger than their corresponding neutral atom.
- **Ionization energy** is the amount of energy necessary to remove an electron from the valence shell of a gaseous species; it increases from left to right across a period and decreases from top to bottom in a group.
- **Electron affinity** is the amount of energy released when a gaseous species gains an electron in its valence shell; it increases from left to right across a period and decreases from top to bottom in a group.

- **Electronegativity** is a measure of the attractive force of the nucleus for electrons within a bond; it increases from left to right across a period and decreases from top to bottom in a group.

The Chemistry of Groups

- **Alkali metals** typically take on an oxidation state of +1 and prefer to lose an electron to achieve a noble gas-like configuration; they and the alkaline earth metals are the most reactive of all metals.
- **Alkaline earth metals** take on an oxidation state of +2 and can lose two electrons to achieve noble gas-like configurations.
- **Chalcogens** take on oxidation states of –2 or +6 (depending on whether they are nonmetals or metals, respectively) in order to achieve noble gas configuration. They are very biologically important.
- **Halogens** typically take on an oxidation state of –1 and prefer to gain an electron to achieve noble gas-like configurations; these nonmetals have the highest electronegativities.
- **Noble gases** have a fully filled valence shell in their standard state and prefer not to give up or take on additional electrons; they have very high ionization energies and (for He, Ne, and Ar), virtually nonexistent electronegativities and electron affinities.
- **Transition metals** are unique because they take on multiple oxidation states, which explains their ability to form colorful complexes with nonmetals in solution and their utility in certain biological systems.

ANSWERS TO CONCEPT CHECKS

2.1

1. The modern periodic table is arranged in order by atomic number.
2.

Element	A or B	Element	A or B	Element	A or B	Element	A or B
Ag	B	**Al**	A	**K**	A	**P**	A
Pb	A	**Li**	A	**Pu**	B	**U**	B
Cu	B	**Cf**	B	**Zn**	B	**B**	A
N	A	**Np**	B	**O**	A	**He**	A

2.2

1. Metals have luster. Nonmetals have poor conductivity. Metalloids exhibit brittleness but good conductivity. Any answers within each of these categories are acceptable.
2.

Element	Class	Element	Class	Element	Class	Element	Class
Ag	M	**Al**	M	**K**	M	**P**	NM
Pb	M	**Li**	M	**Pu**	M	**U**	M
Cu	M	**As**	MO	**Zn**	M	**B**	MO
Si	MO	**Np**	M	**O**	NM	**He**	NM

2.3

1. Ionization energy: carbon > germanium > calcium > potassium
2. Electron affinity: barium < yttrium < copper < sulfur
3. Electronegativity: oxygen > antimony > thallium > neon
4. Atomic radius: xenon < niobium < tantalum < praseodymium

2.4

1.
   - High reactivity to water: Groups 1 and 2
   - Six valence electrons: Groups 6 and 16
   - Contain at least one metal: Groups 1 through 15
   - Multiple oxidation states: All groups; most notably Groups 3 through 12 (transition metals)
   - Negative oxidation states: Almost all groups; most notably Groups 14 through 17 (nonmetals)
   - Possess a full octet in the neutral state: Group 18

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Lithium and sodium have similar chemical properties. For example, both can form ionic bonds with chloride. Which of the following best explains this similarity?

A. Both lithium and sodium ions are positively charged.
B. Lithium and sodium are in the same group of the periodic table.
C. Lithium and sodium are in the same period of the periodic table.
D. Both lithium and sodium have low atomic weights.

2. Carbon and silicon are the basis of biological life and synthetic computing, respectively. While these elements share many chemical properties, which of the following best describes a difference between the two elements?

A. Carbon has a smaller atomic radius than silicon.
B. Silicon has a smaller atomic radius than carbon.
C. Carbon has fewer valence electrons than silicon.
D. Silicon has fewer valence electrons than carbon.

3. What determines the length of an element's atomic radius?

I. The number of valence electrons
II. The number of electron shells
III. The number of neutrons in the nucleus

A. I only
B. II only
C. I and II only
D. I, II, and III

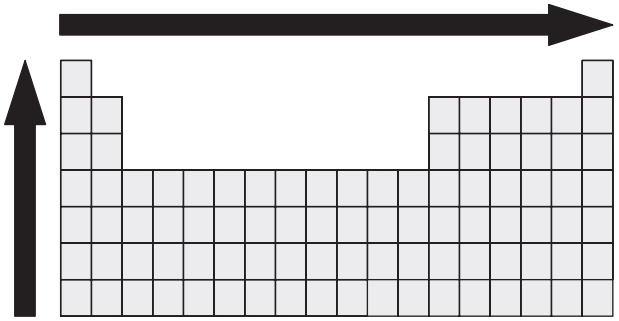
4. Ionization energy contributes to an atom's chemical reactivity. Which of the following shows an accurate ranking of ionization energies from lowest to highest?

A. first ionization energy of Be < second ionization energy of Be < first ionization energy of Li
B. first ionization energy of Be < first ionization energy of Li < second ionization energy of Be
C. first ionization energy of Li < first ionization energy of Be < second ionization energy of Be
D. first ionization energy of Li < second ionization energy of Be < first ionization energy of Be

5. Antimony is used in some antiparasitic medications—specifically those targeting *Leishmania donovani*. What type of element is antimony?

A. Metal
B. Metalloid
C. Halogen
D. Nonmetal

6. The properties of atoms can be predicted, to some extent, by their location within the periodic table. Which property or properties increase in the direction of the arrows shown?



I. Electronegativity

II. Atomic radius

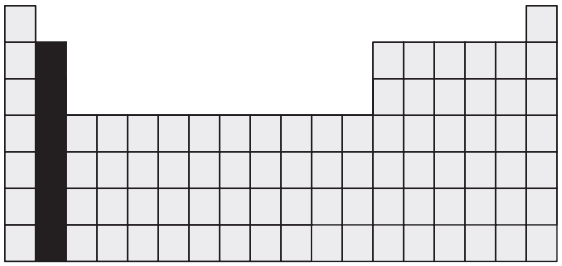
III. First ionization energy

A. I only
B. I and II only
C. I and III only
D. II and III only

7. Metals are often used for making wires that conduct electricity. Which of the following properties of metals explains why?

A. Metals are malleable.
B. Metals have low electronegativities.
C. Metals have valence electrons that can move freely.
D. Metals have high melting points.

8. Which of the following is an important property of the group of elements shaded in the periodic table below?



A. These elements are the best electrical conductors in the periodic table.
B. These elements form divalent cations.
C. The second ionization energy for these elements is lower than the first ionization energy.
D. The atomic radii of these elements decrease as one moves down the column.

9. When dissolved in water, which of the following ions is most likely to form a complex ion with H_2O?

A. Na^+
B. Fe^{2+}
C. Cl^-
D. S^{2-}

10. How many valence electrons are present in elements in the third period?

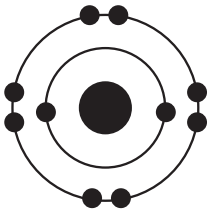
A. 2
B. 3
C. The number decreases as the atomic number increases.
D. The number increases as the atomic number increases.

11. Which of the following elements has the highest electronegativity?

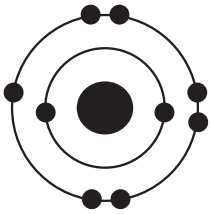
A. Mg
B. Cl
C. Zn
D. I

12. Of the four atoms depicted here, which has the highest electron affinity?

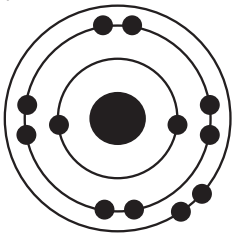
A.



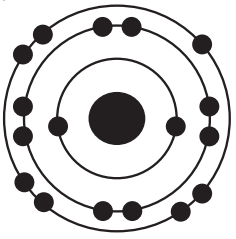
B.



C.



D.



13. Which of the following atoms or ions has the largest effective nuclear charge?

A. Cl
B. Cl^-
C. K
D. K^+

14. Why do halogens often form ionic bonds with alkaline earth metals?

A. The alkaline earth metals have much higher electron affinities than the halogens.
B. By sharing electrons equally, the alkaline earth metals and halogens both form full octets.
C. Within the same row, the halogens have smaller atomic radii than the alkaline earth metals.
D. The halogens have much higher electron affinities than the alkaline earth metals.

15. What is the highest-energy orbital of elements with valence electrons in the $n = 3$ shell?

A. *s*-orbital
B. *p*-orbital
C. *d*-orbital
D. *f*-orbital

Explanations to Discrete Practice Questions

1. B

The periodic table is organized into periods (rows) and groups (columns). Groups (columns) are particularly significant because they represent sets of elements with the same valence electron configuration, which in turn will dictate many of the chemical properties of those elements. Although **choice (A)** is true, the fact that both ions are positively charged does not explain the similarity in chemical properties; most metals produce positively charged ions. **Choice (C)** is not true because lithium and sodium are in the same group, not period. Finally, although lithium and sodium do have relatively low atomic weights, so do several other elements that do not share the same properties, eliminating **choice (D)**.

2. A

As one moves from top to bottom in a group (column), extra electron shells accumulate, despite the fact that the valence configurations remain identical. These extra electron shells provide shielding between the positive nucleus and the outermost electrons, decreasing the electrostatic attraction and increasing the atomic radius. Because carbon and silicon are in the same group, and silicon is farther down in the group, silicon will have a larger atomic radius because of its extra electron shell.

3. C

Atomic radius is determined by multiple factors. Of the choices given, the number of valence electrons does have an impact on the atomic radius. As one moves across a period (row), protons and valence electrons are added, and the electrons are more strongly attracted to the central protons. This attraction tightens the atom, shrinking the atomic radius. The number of electron shells is also significant, as demonstrated by the trend when moving down a group (column). As more electron shells are added that separate the positively charged nucleus from the outermost electrons, the electrostatic forces are weakened, and the atomic radius increases. The number of neutrons is irrelevant because it does not impact these attractive forces.

4. C

Ionization energy increases from left to right, so the first ionization energy of lithium is lower than that of beryllium. Second ionization energy is always larger than first ionization energy, so beryllium's second ionization energy should be the highest value. This is because removing an additional electron from Be^+ requires one to overcome a significantly larger electrostatic force.

5. B

Antimony (Sb) is on the right side of the periodic table, but not far right enough to be a nonmetal, **choice (D)**. It certainly does not lie far enough to the right to fall in Group VIIA (Group 17), which would classify it as a halogen, **choice (C)**. While sources have rarely classified antimony as a metal, **choice (A)**, it is usually classified as a metalloid, **choice (B)**.

6. C

Electronegativity describes how strong an attraction an element will have for electrons in a bond. A nucleus with a larger effective nuclear charge will have a higher electronegativity; Z_{eff} increases toward the right side of a period. A stronger nuclear pull will also lead to increased first ionization energy, as the forces make it more difficult to remove an electron. The vertical arrow can be explained by

the size of the atoms. As size decreases, the positive charge becomes more effective at attracting electrons in a chemical bond (higher electronegativity), and the energy required to remove an electron (ionization energy) increases.

7. C

All four descriptions of metals are true, but the most significant property that contributes to the ability of metals to conduct electricity is the fact that they have valence electrons that can move freely. Malleability, **choice (A)**, is the ability to shape a material with a hammer, which does not play a role in conducting electricity. The low electronegativity and high melting points of metals, **choices (B)** and **(D)**, also do not play a major role in the conduction of electricity.

8. B

This block represents the alkaline earth metals, which form divalent cations, or ions with a +2 charge. All of the elements in Group IIA have two electrons in their outermost *s* subshell. Because loss of these two electrons would leave a full octet as the outermost shell, becoming a divalent cation is a stable configuration for all of the alkaline earth metals. Although some of these elements might be great conductors, they are not as effective as the alkali metals, eliminating **choice (A)**. **Choice (C)** is also incorrect because, although forming a divalent cation is a stable configuration for the alkaline earth metals, the second ionization energy is still always higher than the first. Finally, **choice (D)** is incorrect because atomic radii increase when moving down a group of elements because the number of electron shells increases.

9. B

Iron is a transition metal. Transition metals can often form more than one ion. Iron, for example, can be Fe^{2+} or Fe^{3+}. The transition metals, in these various oxidation states, can often form hydration complexes with water. Part of the significance of these complexes is that, when a transition metal can form a complex, its solubility within the related solvent will increase. The other ions given might dissolve readily in water, but because none of them are transition metals, they will not likely form complexes.

10. D

This question is simple if one recalls that periods refer to the rows in the periodic table, while groups or families refer to the columns. Within the same period, an additional valence electron is added with each step toward the right side of the table.

11. B

This question requires knowledge of the trends of electronegativity within the periodic table. Electronegativity increases as one moves from left to right for the same reasons that effective nuclear charge increases. Electronegativity decreases as one moves down the periodic table because there are more electron shells separating the nucleus from the outermost electrons. In this question, chlorine is the furthest toward the top-right corner of the periodic table.

12. B

Electron affinity is related to several factors, including atomic size and filling of the valence shell. As atomic radius increases, the distance between the nucleus and the outermost electrons increases, thereby decreasing the attractive forces between protons and electrons. As a result, increased atomic radius will lead to lower electron affinity. Because atoms are in a low-energy state when their outermost valence electron shell is filled, atoms needing only one or two electrons to complete this shell will have high electron affinities. In this example, **choices (B)** and **(D)** need only one more electron to have a noble gas-like electron configuration; because **choice (B)** is smaller, it will have the highest electron affinity.

13. D

The effective nuclear charge refers to the strength with which the protons in the nucleus can pull on electrons. This phenomenon helps to explain electron affinity, electronegativity, and ionization energy. In **choice (A)**, the nonionized chlorine atom, the nuclear charge is balanced by the surrounding electrons: 17 p^+/17 e^-. The chloride ion, **choice (B)**, has a lower effective nuclear charge because there are more electrons than protons: 17 p^+/18 e^-. Next, elemental potassium, **choice (C)**, has the lowest effective nuclear charge because it contains additional inner shells that

shield its valence electron from the nucleus. **Choice (D)**, ionic potassium, has a higher effective nuclear charge than any of the other options do because it has the same electron configuration as Cl^- (and the same amount of shielding from inner shell electrons as neutral Cl) but contains two extra protons in its nucleus: 19 p^+/18 e^-.

14. D

Ionic bonds are formed through unequal sharing of electrons. These bonds typically occur because the electron affinities of the two bonded atoms differ greatly. For example, the halogens have high electron affinities because adding a single electron to their valence shells would create full valence shells. In contrast, the alkaline earth metals have very low electron affinities and are more likely to be electron donors because the loss of two electrons would leave them with full valence shells. **Choice (A)** states the opposite and is incorrect because the halogens have high electron affinity and the alkaline earth metals have low electron affinity. **Choice (B)** is incorrect because equal sharing of electrons is a classic description of covalent bonding, not ionic. **Choice (C)** is a true statement, but is not relevant to why ionic bonds form.

15. C

When $n = 3$, $l = 0$, 1, or 2. The highest value for l in this case is 2, which corresponds to the d subshell. Although the 3d block appears to be part of the fourth period, it still has the principal quantum number $n = 3$. In general, the subshells within an energy shell increase in energy as follows: $s < p < d < f$ (although there is no 3f subshell).

Concept Summary 98

Introduction

The Maillard reaction is one of the most important chemical processes that occurs while cooking. The reaction mechanism itself is one with which you are closely familiar from your studies of organic chemistry: a nucleophilic reaction between the amino terminus of the peptide chain of a protein and the carbonyl functionality of a sugar to form an *N*-substituted glycosylamine. This compound undergoes a complex series of rearrangements and other reactions to produce a set of compounds that gives cooked food its pleasing color and delectable flavor. This reaction is especially important for browning meat.

When the surface of the meat comes into contact with the hot surface of a pan or grill, the proteins and sugars on the meat's exterior begin interacting via the Maillard reaction. The pan must be sufficiently hot to bring the exterior of the meat to a temperature of 155°C (310°F), the optimal temperature for the reaction to occur. So how does a grill master achieve the impossible: generating very high heat for the exterior but not overcooking the interior? The answer lies, in part, in drying the meat. When meat that has a lot of water on its exterior surface hits the hot pan, the first process that takes place is the boiling of the water. Boiling is a phase change from liquid to gas and occurs at a constant temperature; water's boiling point is 100°C (212°F). Because this temperature is considerably lower than that necessary for the Maillard reaction, no browning will occur and the flavor compounds will not form. The lesson here is—if you want a tasty steak—always dry the surface of your meat!

Of course, the real lesson is the topic of discussion for this chapter: bonding and chemical interactions. We will not address complex chemical bonding, such as that which takes place in the Maillard reaction, in this chapter. Rather, this chapter will address the basics of chemical bonding and interactions. Here, we will investigate the nature

and behavior of covalent and ionic bonds. We will also review a system by which bonding electrons are accounted for—Lewis structures—and address the main principles of valence shell electron pair repulsion (VSEPR) theory. Finally, we will recount the various modes of interaction between molecules: intermolecular forces.

3.1 Bonding

The atoms of most elements, except for a few noble gases, can combine to form **molecules**. The atoms within these molecules are held together by strong attractive forces called **chemical bonds**, which are formed via the interaction of the valence electrons of the combining atoms. The chemical and physical properties of the resulting compound are usually very different from those of the constituent elements. For example, elemental sodium, an alkali metal, is so reactive that it can actually produce fire when reacting with water because the reaction is highly exothermic. Diatomic chlorine gas is so toxic that it was used for chemical warfare during World War I. However, when sodium and chlorine react, the biologically important compound NaCl (table salt) is produced.

THE OCTET RULE

How do atoms join together to form compounds? In the example above, how do the sodium and the chlorine atoms form sodium chloride? For many molecules, the constituent atoms bond according to the **octet rule**, which states that an atom tends to bond with other atoms so that it has eight electrons in its outermost shell, thereby forming a stable electron configuration similar to that of the noble gases. An example of an octet configuration is shown for the noble gas argon (Ar) in Figure 3.1.

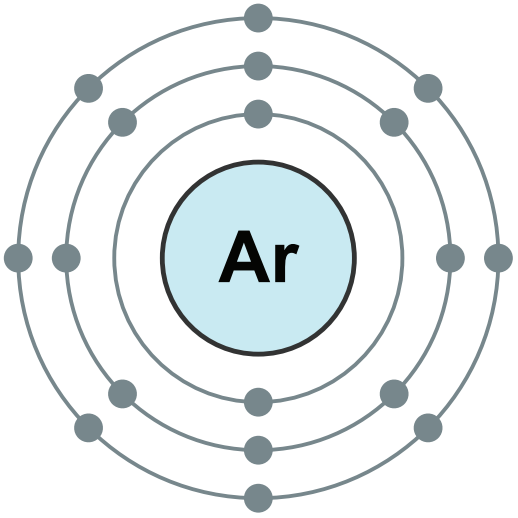

Figure 3.1. Electron Configuration of Argon
As a noble gas, argon has a complete octet in its valence shell.

However, this is more of a "rule of thumb," because there are more elements that can be exceptions to the rule than those that follow the rule. These "exceptional" elements include hydrogen, which can only have two valence electrons (achieving the configuration of helium); lithium and beryllium, which bond to attain two and four valence electrons, respectively; boron, which bonds to attain six valence electrons; and all elements in period 3 and greater, which can expand the valence shell to include more than eight electrons by incorporating *d*-orbitals. For example, in certain compounds, chlorine can form seven covalent bonds, thereby holding 14 electrons in its valence shell.

A simple way to remember all the exceptions is as follows:

- **Incomplete octet**: These elements are stable with fewer than eight electrons in their valence shell and include hydrogen (stable with 2 electrons), helium (2), lithium (2), beryllium (4), and boron (6).
- **Expanded octet**: Any element in period 3 and greater can hold more than eight electrons, including phosphorus (10), sulfur (12), chlorine (14), and many others.
- **Odd numbers of electrons**: Any molecule with an odd number of valence electrons cannot distribute those electrons to give eight to each atom; for example, nitric oxide (NO) has eleven valence electrons.

Another way to remember the exceptions is to remember the common elements that almost always abide by the octet rule: carbon, nitrogen, oxygen, fluorine, sodium, and magnesium. Note that nonmetals gain electrons and metals lose electrons to achieve their respective complete octets.

Key Concept

The octet rule is the desire of all atoms to achieve noble gas configuration. However, keep in mind that there are many exceptions to this rule.

TYPES OF BONDS

We classify chemical bonds into two distinct types: ionic and covalent.

In **ionic bonding**, one or more electrons from an atom with a low ionization energy, typically a metal, are transferred to an atom with a high electron affinity, typically a nonmetal. An illustration of such a process is shown for our initial example, sodium chloride, in Figure 3.2.

Figure 3.2. Formation of an Ionic Bond
Sodium (Na) has a low ionization energy, easily releasing an electron; chlorine (Cl) has a high electron affinity, easily absorbing that electron into its valence shell. In this example, both atoms achieve an octet formation.

The resulting electrostatic attraction between opposite charges is what holds the ions together. This is the nature of the bond in sodium chloride, where the positively charged sodium cation is electrostatically attracted to the negatively charged

chloride anion. It is important to note that this type of electrostatic attraction creates lattice structures consisting of repeating rows of cations and anions, rather than individual molecular bonds, as shown in Figure 3.3.

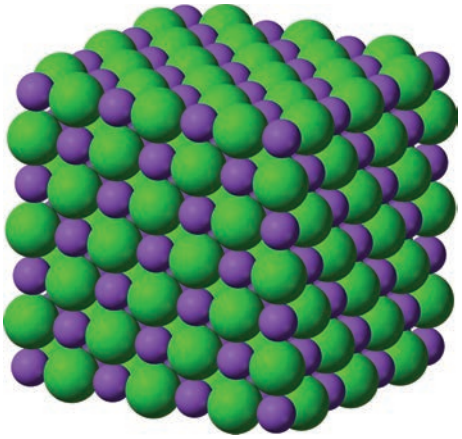

Figure 3.3. Crystal Lattice Structure of Sodium Chloride
Sodium = purple; chloride = green

Bridge

Electronegativity, discussed in Chapter 2 of *MCAT General Chemistry Review,* is a property that addresses how an individual atom acts within a bond and will help us understand the formation of molecules from atoms with different electronegativities.

In **covalent bonding**, an electron pair is shared between two atoms, typically nonmetals, that have relatively similar values of electronegativity. The degree to which the pair of electrons is shared equally or unequally between the two atoms determines the degree of polarity in the covalent bond. For example, if the electron pair is shared equally, the covalent bond is nonpolar; and if the pair is shared unequally, the bond is polar. If both of the shared electrons are contributed by only one of the two atoms, the bond is called **coordinate covalent**.

An example of nonpolar covalent bonding is shown for diatomic fluorine in Figure 3.4. Each atom has seven electrons in its valence shell, and by sharing one of these electrons from each atom, they can each form an octet. Unlike ionic crystal lattices, covalent compounds consist of individually bonded molecules.

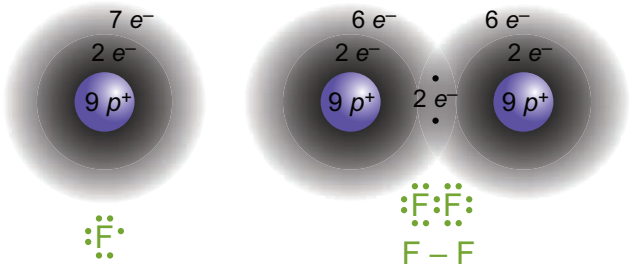

Figure 3.4. Formation of a Covalent Bond
Fluorine (F) has seven valence electrons; by sharing one electron from each atom, both fluorine atoms achieve an octet formation.

MCAT Concept Check 3.1:
Before you move on, assess your understanding of the material with these questions.

1. Describe the atomic differences between ionic and covalent compounds:
   - Ionic:

     _____
   - Covalent:

     _____
2. List three elements that do not follow the octet rule and explain why:

Element	Why It Violates the Octet Rule

3. Which periodic trend determines whether a covalent bond is polar or nonpolar? _____

3.2 Ionic Bonds

Ionic bonds form between atoms that have significantly different electronegativities. The atom that loses the electrons becomes a **cation**, and the atom that gains electrons becomes an **anion**. The ionic bond is the result of an electrostatic force of attraction between the opposite charges of these ions. Electrons are not shared in an ionic bond. For this electron transfer to occur, the difference in electronegativity must be greater than 1.7 on the Pauling scale.

The MCAT won't expect you to memorize the Pauling scale, but recognize that ionic bonds are generally formed between a metal and a nonmetal. For example, alkali and alkaline earth metals of Groups IA and IIA (Groups 1 and 2, respectively) readily form ionic bonds with the halogens of Group VIIA (Group 17). The atoms of the active metals loosely hold onto their electrons, whereas the halogens are more likely to gain an electron to complete their valence shell. The differences in bonding behavior for these classes of elements, and their differences in electronegativity values (ΔEN), explain the formation of ionic compounds such as cesium chloride ($\Delta EN = 2.3$), potassium iodide ($\Delta EN = 1.7$), and sodium fluoride ($\Delta EN = 3.1$).

Mnemonic

MeTals lose electrons to become
caTions = posiTive (+) ions
Nonmetals gain electrons to become
aNions = Negative (–) ions

Ionic compounds have characteristic physical properties that you should recognize for Test Day. Because of the strength of the electrostatic force between the ionic constituents of the compound, ionic compounds have very high melting and boiling points. For example, the melting point of sodium chloride is 801°C. Many ionic compounds dissolve readily in water and other polar solvents and, in the molten or aqueous state, are good conductors of electricity. In the solid state, the ionic constituents of the compound form a **crystalline lattice** consisting of repeating positive and negative ions, as shown earlier in Figure 3.3. With this arrangement, the attractive forces between oppositely charged ions are maximized, and the repulsive forces between ions of like charge are minimized.

MCAT Concept Check 3.2:

Before you move on, assess your understanding of the material with these questions.

1. Why do ionic bonds tend to form between metals and nonmetals?

_____

_____

2. Describe five characteristics of ionic compounds.
   - _____
   - _____
   - _____
   - _____
   - _____

MCAT Expertise

Think of bonds as a tug-of-war between two atoms. When the difference in electronegativity is great (more than 1.7), then the "stronger" atom wins all of the electrons and becomes the anion. When the electronegativity values are relatively similar, then we have a stalemate, or a covalent bond with mostly equal sharing of electrons.

3.3 Covalent Bonds

When two or more atoms with similar electronegativities interact, the energy required to form ions through the complete transfer of one or more electrons is greater than the energy that would be released upon the formation of an ionic bond. That is, when two atoms of similar tendency to attract electrons form a compound, it is energetically unfavorable to create ions. Rather than transferring electrons to form octets, the atoms share electrons. The bonding force between the atoms is not ionic;

instead, there is an attraction that each electron in the shared pair has for the two positive nuclei of the bonded atoms.

Covalent compounds contain discrete molecular units with relatively weak intermolecular interactions. As a result, compounds like carbon dioxide (CO_2) tend to have lower melting and boiling points. In addition, because they do not break down into constituent ions, they are poor conductors of electricity in the liquid state or in aqueous solutions.

PROPERTIES OF COVALENT COMPOUNDS

The formation of one covalent bond may not be sufficient to fill the valence shell for a given atom. Thus, many atoms can form bonds with more than one other atom, and most atoms can form multiple bonds with other atoms. Two atoms sharing one, two, or three pairs of electrons are said to be joined by a **single**, **double**, or **triple covalent bond**, respectively. The number of shared electron pairs between two atoms is called the **bond order**; hence, a single bond has a bond order of one, a double bond has a bond order of two, and a triple bond has a bond order of three. There are three important characteristics of a covalent bond to explain: bond length, bond energy, and polarity.

Bond Length

Bond length is the average distance between the two nuclei of atoms in a bond. As the number of shared electron pairs increases, the two atoms are pulled closer together, resulting in a decrease in bond length. Thus, for a given pair of atoms, a triple bond is shorter than a double bond, which is shorter than a single bond.

Bond Energy

Bond energy is the energy required to break a bond by separating its components into their isolated, gaseous atomic states. The greater the number of pairs of electrons shared between the atomic nuclei, the more energy is required to break the bonds holding the atoms together. Thus, triple bonds have the greatest bond energy, and single bonds have the lowest bond energy. We will discuss bond energy and calculations involving bond enthalpy in Chapter 7 of *MCAT General Chemistry Review*. By convention, the greater the bond energy is, the stronger the bond.

Polarity

Polarity occurs when two atoms have a relative difference in electronegativities. When these atoms come together in covalent bonds, they must negotiate the degree to which the electron pairs will be shared. The atom with the higher electronegativity gets the larger share of the electron density. A polar bond creates a dipole, with the positive end of the dipole at the less electronegative atom and the negative end at the more electronegative atom, as shown in Figure 3.5.

Key Concept

You will see this inverse relationship between bond length and strength in both organic and general chemistry.

	Bond Length	Bond Strength
C–C	longest	weakest
C=C	medium	medium
C≡C	shortest	strongest

Know this relationship on Test Day and you'll earn quick points!

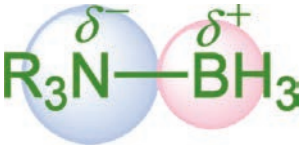

Figure 3.5. Polar Covalent Bond in an Amine Borane
Nitrogen takes on a partial negative charge (δ^-), boron takes on a partial positive charge (δ^+).

Mnemonic

Here's a quick way to remember the naturally occurring diatomic elements on the periodic table: they form the number **7** on the periodic table (except for H), there are **7** of them, and most of them are in Group **VII**A: H_2, N_2, O_2, F_2, Cl_2, Br_2, I_2.

MCAT Expertise

The range of electronegativities for nonpolar bonds is roughly 0 to 0.5. Polar bonds are found from 0.5 to 1.7, and ionic bonds are at 1.7 and above. Some chemistry courses allude to a grey area from 1.7 to 2.0. For the MCAT, if a molecule in this range has a metal and nonmetal, then it is effectively ionic; otherwise, it is polar covalent.

When atoms that have identical or nearly identical electronegativities share electron pairs, they do so with equal distribution of the electrons. This is called a **nonpolar covalent bond**, and there is no separation of charge across the bond. Note that only bonds between atoms of the same element will have exactly the same electronegativity and therefore exhibit a purely equal distribution of electrons. The seven common diatomic molecules are H_2, N_2, O_2, F_2, Cl_2, Br_2, and I_2. At the same time, many bonds are close to nonpolar. Any bond between atoms with a difference in electronegativity less than 0.5 is generally considered nonpolar.

Polar Covalent Bond

Atoms that differ moderately in their electronegativities will share electrons unevenly, resulting in **polar covalent bonds**. While the difference in their electronegativities (between 0.5 and 1.7) is not enough to result in the formation of an ionic bond, it is sufficient to cause a separation of charge across the bond. This results in the more electronegative element acquiring a greater portion of the electron density, taking on a **partial negative charge** (δ^-), and the less electronegative element acquiring a smaller portion of the electron density, taking on a **partial positive charge** (δ^+). For instance, the covalent bond in HCl is polar because the two atoms have a moderate difference in electronegativity ($\Delta EN = 0.9$). In this bond, the chlorine atom gains a partial negative charge, and the hydrogen atom gains a partial positive charge. The difference in charge between the atoms is indicated by an arrow crossed at its tail end (giving the appearance of a "plus" sign) and pointing toward the negative end, as shown in Figure 3.6.

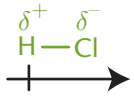

Figure 3.6. Dipole Moment of HCl

A molecule that has such a separation of positive and negative charges is called a polar molecule. The **dipole moment** of the polar bond or polar molecule is a vector quantity given by the equation:

$$\mathbf{p} = q\mathbf{d}$$

Equation 3.1

where **p** is the dipole moment, q is the magnitude of the charge, and **d** is the displacement vector separating the two partial charges. The dipole moment vector, represented by an arrow pointing from the positive to the negative charge, is measured in **Debye units** (coulomb–meters).

COORDINATE COVALENT BONDS

In a **coordinate covalent bond**, both of the shared electrons originated on the same atom. Generally, this means that a lone pair of one atom attacked another atom with an unhybridized *p*-orbital to form a bond, as shown in Figure 3.7. Once such a bond forms, however, it is indistinguishable from any other covalent bond. The distinction is only helpful for keeping track of the valence electrons and formal charges. Coordinate covalent bonds are typically found in Lewis acid–base reactions, described in Chapter 10 of *MCAT General Chemistry Review*. A Lewis acid is any compound that will accept a lone pair of electrons, while a Lewis base is any compound that will donate a pair of electrons to form a covalent bond.

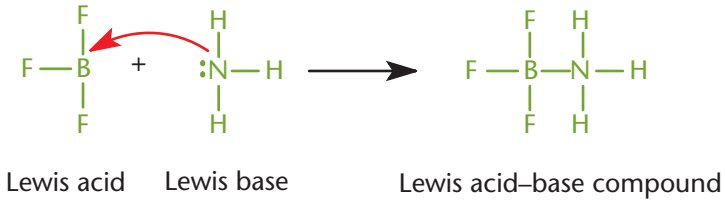

Figure 3.7. Coordinate Covalent Bond

Here, NH_3 donates a pair of electrons to form a coordinate covalent bond; thus, it acts as a Lewis base. At the same time, BF_3 accepts this pair of electrons to form the coordinate covalent bond; thus, it acts as a Lewis acid.

COVALENT BOND NOTATION

The electrons involved in a covalent bond are in the valence shell and are **bonding electrons**, while those electrons in the valence shell that are not involved in covalent bonds are **nonbonding electrons**. The unshared electron pairs are also known as lone pairs because they are associated only with one atomic nucleus. Because atoms can bond with other atoms in many different combinations, the **Lewis structure** system of notation was developed to keep track of the bonded and nonbonded electron pairs.

Think of Lewis structures as a bookkeeping method for electrons. The number of valence electrons attributed to a particular atom in the Lewis structure of a molecule is not necessarily the same as the number of valence electrons in the neutral atom.

Bridge

The chemistry that creates coordinate covalent bonds appears in many guises. These reactions can be called nucleophile–electrophile reactions, described in Chapter 4 of *MCAT Organic Chemistry Review*; Lewis acid–base reactions, described in Chapter 10 of *MCAT General Chemistry Review*, or complexation reactions, described in Chapter 9 of *MCAT General Chemistry Review*.

This difference accounts for the **formal charge** of an atom in a Lewis structure. Often, more than one Lewis structure can be drawn for a molecule. If the possible Lewis structures differ in their bond connectivity or arrangement, then the Lewis structures represent different possible compounds. However, if the Lewis structures show the same bond connectivity and differ only in the arrangement of the electron pairs, then these structures represent different **resonance** forms of a single compound. Note that Lewis structures do not represent the actual or even theoretical geometry of a real compound. Their usefulness lies in showing the different possible ways in which atoms may be combined to form different compounds or resonance forms of a single compound.

When more than one arrangement can be made, one can assess the likelihood of each arrangement by checking the formal charges on the atoms in each arrangement. The arrangement that minimizes the number and magnitude of formal charges is usually the most stable arrangement of the compound.

Lewis Structures

A Lewis structure, or **Lewis dot diagram**, is the chemical symbol of an element surrounded by dots, each representing one of the *s* or *p* valence electrons of the atom. The Lewis symbols of the elements in the second period of the periodic table are shown in Table 3.1.

·Li	Lithium	·N·	Nitrogen
·Be·	Beryllium	·O:	Oxygen
·B·	Boron	·F:	Fluorine
·C·	Carbon	:Ne:	Neon

Table 3.1. Lewis Symbols for Period 2 Elements

Just as a Lewis symbol is used to represent the distribution of valence electrons in an atom, it can also be used to represent the distribution of valence electrons in a molecule. For example, the Lewis symbol for a fluoride ion, F^-, is $:\ddot{F}:^-$; the Lewis structure of the diatomic molecule F_2 is $:\ddot{F}-\ddot{F}:$. Certain rules must be followed in assigning a Lewis structure to a molecule. The steps for drawing a Lewis structure are outlined here, using HCN as an example.

- Draw out the backbone of the compound—that is, the arrangement of atoms. In general, the least electronegative atom is the central atom. Hydrogen (always) and the halogens F, Cl, Br, and I (usually) occupy a terminal position.

Key Concept

In drawing Lewis dot structures, remember that some atoms can expand their octets by utilizing the *d*-orbitals in their outer shell. This will only take place with atoms in period 3 or greater.

MCAT Expertise

The number of dots in Lewis Structure notation comes from group numbers. Lithium is in Group IA and therefore has one electron (dot). Carbon is in Group IVA and has four dots.

In HCN, H must occupy an end position. Of the remaining two atoms, C is the least electronegative and, therefore, occupies the central position. Therefore, the skeletal structure is as follows:

$$H - C - N$$

- Count all the valence electrons of the atoms. The number of valence electrons of the molecule is the sum of the valence electrons of all atoms present:

  H has 1 valence electron

  C has 4 valence electrons

  N has 5 valence electrons; therefore,

  HCN has a total of 10 valence electrons.

- Draw single bonds between the central atom and the atoms surrounding it. Each single bond corresponds to a pair of electrons:

$$H : C : N$$

- Complete the octets of all atoms bonded to the central atom, using the remaining valence electrons left be assigned. Recall that H is an exception to the octet rule because it can only have two valence electrons. In this example, H already has two valence electrons from its bond with C.

$$H : C : \ddot{\underset{\cdot\cdot}{N}} :$$

- Place any extra electrons on the central atom. If the central atom has less than an octet, try to write double or triple bonds between the central and surrounding atoms using the lone pairs on the surrounding atoms.

The HCN structure above does not satisfy the octet rule for C because C only has four valence electrons. Therefore, two lone electron pairs from the N atom must be moved to form two more bonds with C, creating a triple bond between C and N. To make it easier to visualize, bonding electron pairs are represented as lines. You should be familiar with both dot and line notation for bonds.

$$H - C \equiv N:$$

Now, the octet rule is satisfied for all three atoms; C and N have eight valence electrons, and H has two valence electrons.

Formal Charge

To determine if a Lewis structure is representative of the actual arrangement of atoms in a compound, one must calculate the formal charge of each atom. In doing so, assume a perfectly equal sharing of all bonded electron pairs, regardless of actual differences in electronegativity. In other words, assume that each

electron pair is split evenly between the two nuclei in the bond. The difference between the number of electrons assigned to an atom in a Lewis structure and the number of electrons normally found in that atom's valence shell is the **formal charge**. A simple equation you can use to calculate formal charge is:

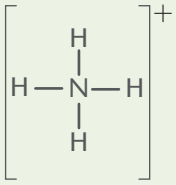
$$\text{formal charge} = V - N_{\text{nonbonding}} - \frac{1}{2}N_{\text{bonding}}$$

Equation 3.2

where V is the normal number of electrons in the atom's valence shell, $N_{\text{nonbonding}}$ is the number of nonbonding electrons, and N_{bonding} is the number of bonding electrons (double the number of bonds because each bond has two electrons). The charge of an ion or compound is equal to the sum of the formal charges of the individual atoms comprising the ion or compound.

Example: Calculate the formal charge on the central N atom of $[NH_4]^+$.

Solution: The Lewis structure of $[NH_4]^+$ is:



Nitrogen is in group VA; thus it has five valence electrons. In $[NH_4]^+$, N has 4 bonds (eight bonding electrons and zero nonbonding electrons).

Thus, $V = 5$; $N_{\text{bonding}} = 8$; $N_{\text{nonbonding}} = 0$

Formal charge = $5 - 0 - \frac{1}{2}(8) = +1$

Thus, the formal charge on the N atom in $[NH_4]^+$ is +1.

One can also use logic to determine formal charge. As drawn, N has four bonds. Assuming equal sharing of the electrons in the bonds, this means N has four valence electrons. In its normal state, N has five valence electrons. Thus, nitrogen has one fewer electron that its normal state, and has a +1 charge.

Let us offer a brief note of explanation on the difference between formal charge and oxidation number: formal charge underestimates the effect of electronegativity differences, whereas oxidation numbers overestimate the effect of electronegativity differences, assuming that the more electronegative atom has a 100 percent share of the bonding electron pair. For example, in a molecule of CO_2 (carbon dioxide), the formal charge on each of the atoms is 0, but the oxidation number of each of the oxygen atoms is –2 and of the carbon is +4. In reality, the

distribution of electron density between the carbon and oxygen atoms lies somewhere between the extremes predicted by the formal charges and the oxidation states.

Resonance

As suggested earlier, it may be possible to draw two or more Lewis structures that demonstrate the same arrangement of atoms but that differ in the specific placement of the electrons. These are called **resonance structures** and are represented with a double-headed arrow between them. The actual electronic distribution in the compound is a hybrid, or composite, of all of the possible resonance structures. For example, SO_2 has three resonance structures, as shown in Figure 3.8.

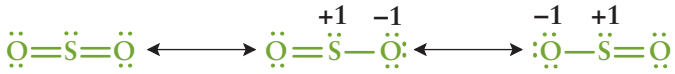


Figure 3.8. Resonance Structures for SO_2
The double-headed arrows indicate that these molecules are involved in a resonance hybrid.

The nature of the bonds within the actual compound is a hybrid of these three structures. If one were to evaluate the spectral data, it would indicate that the two S–O bonds are identical and equivalent. This phenomenon is known as resonance, and the actual structure of the compound is called the **resonance hybrid**.

The first resonance structure in Figure 3.8 is significantly more stable than the other two structures. Consequently, it is the major contributor to the resonance hybrid. In general, the more stable the structure, the more it contributes to the character of the resonance hybrid. In Figure 3.8, the minor contributors contain formal charges, indicating decreased stability. One can use formal charge to assess the stability of resonance structures according to the following guidelines:

- A Lewis structure with small or no formal charges is preferred over a Lewis structure with large formal charges
- A Lewis structure with less separation between opposite charges is preferred over a Lewis structure with a large separation of opposite charges
- A Lewis structure in which negative formal charges are placed on more electronegative atoms is more stable than one in which the negative formal charges are placed on less electronegative atoms

Bridge

Resonance is an important topic in both general and organic chemistry. It allows for greater stability, delocalizing electrons and charges over what is known as a π (pi) system. Resonance in organic molecules is discussed in Chapter 3 of *MCAT Organic Chemistry Review.*

Example: Write the resonance structures for $[NCO]^-$.

Solution:

1. C is the least electronegative of the three given atoms. Therefore, the C atom occupies the central position in the skeletal structure of $[NCO]^-$:

   N – C – O

2. N has 5 valence electrons;

   C has 4 valence electrons;

   O has 6 valence electrons;

   and the species has one negative charge.

   Total valence electrons = 5 + 4 + 6 + 1 = 16

3. Draw single bonds between the central C atom and the surrounding atoms, N and O. Draw a pair of electrons to represent each bond.

   N : C : O

4. Complete the octets of N and O with the remaining 12 electrons.

   $:\ddot{N}:C:\ddot{O}:$

5. The C octet is incomplete. There are three ways in which double and triple bonds can be formed to complete the C octet: two lone pairs from the O atom can be used to form a triple bond between the C and O atoms:

   $:\overset{-2}{\ddot{N}}-\overset{0}{C}\equiv\overset{+1}{\ddot{O}}$

   Or one lone electron pair can be taken from both O and N to form two double bonds, one between N and C, the other between O and C:

   $:\overset{-1}{\ddot{N}}=\overset{0}{C}=\overset{0}{\ddot{O}}:$

   Or two lone electron pairs can be taken from the N atom to form a triple bond between the C and N atoms:

   $:\overset{0}{N}\equiv\overset{0}{C}-\overset{-1}{\ddot{O}}:$

   All three are resonance structures of $[NCO]^-$

6. Assign formal charges to each atom of each resonance structure.

   The most stable structure is this:

   $:\overset{0}{N}\equiv\overset{0}{C}-\overset{-1}{\ddot{O}}:$

   because the charges are minimized, and the negative formal charge is on the most electronegative atom, O.

Exceptions to the Octet Rule

As stated previously, the octet rule has many exceptions. In addition to hydrogen, helium, lithium, beryllium, and boron, which are exceptions because they cannot or do not usually reach the octet, all elements in or beyond the third period may be exceptions because they can take on more than eight electrons in their valence shells. These electrons can be placed into orbitals of the *d* subshell, and as a result, atoms of these elements can form more than four bonds. On Test Day, don't automatically discount a Lewis structure with a central atom that has more than four bonds—the testmakers may be testing your ability to recognize that many atoms can expand their valence shells beyond the octet.

Consider the sulfate ion, SO_4^{2-}. In the Lewis structure for the sulfate ion, giving the sulfur 12 valence electrons permits three of the five atoms to be assigned a formal charge of zero. The sulfate ion can be drawn in at least six resonance forms, many of which have two double bonds attached to a different combination of oxygen atoms. Figure 3.9 shows two of the possible forms.

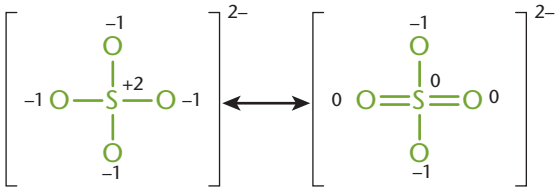

Figure 3.9. Two Different Resonance Forms of the Sulfate Ion

GEOMETRY AND POLARITY

Because Lewis dot structures do not suggest or reflect the actual geometric arrangement of atoms in a compound, we need another system to provide this information. One such system is known as the **valence shell electron pair repulsion (VSEPR) theory**.

Valence Shell Electron Pair Repulsion (VSEPR) Theory

VSEPR theory uses Lewis dot structures to predict the molecular geometry of covalently bonded molecules. It states that the three-dimensional arrangement of atoms surrounding a central atom is determined by the repulsions between bonding and nonbonding electron pairs in the valence shell of the central atom. These electron pairs arrange themselves as far apart as possible, thereby minimizing repulsive forces. The following steps are used to predict the geometrical structure of a molecule using the VSEPR theory:

- Draw the Lewis dot structure of the molecule
- Count the total number of bonding and nonbonding electron pairs in the valence shell of the central atom

MCAT Expertise

Don't be surprised if you can draw more than two resonance structures for a molecule or ion. Becoming proficient at drawing and, more importantly, recognizing resonance structures will save you time on Test Day.

- Arrange the electron pairs around the central atom so that they are as far apart as possible. For example, the compound AX_2 has the Lewis structure X : A : X. The A atom has two bonding electron pairs in its valence shell. To position these electron pairs as far apart as possible, their geometric structure should be linear:

$$X - A - X$$

A summary of electronic geometries as predicted by VSEPR theory is shown in Table 3.2.

MCAT Expertise

According to the AAMC's official content lists, you need to be prepared to draw and identify structural formulas for molecules involving H, C, N, O, F, S, P, Si, and Cl. Rather than memorizing these elements, however, just be familiar with the process of creating a Lewis diagram for any element and predicting its three-dimensional shape from VSEPR theory.

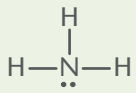
Regions of Electron Density	Example	Geometric Arrangement of Electron Pairs Around the Central Atom	Shape	Angle between Electron Pairs
2	$BeCl_2$	X – A – X	linear	180°
3	BH_3		trigonal planar	120°
4	CH_4		tetrahedral	109.5°
5	PCl_5		trigonal bipyramidal	90°, 120°, 180°
6	SF_6		octahedral	90°, 180°

Table 3.2. VSEPR Theory
This table lists the five most common electronic configurations of molecules.

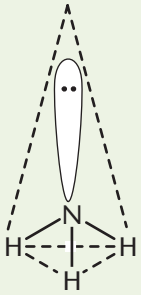
Example: Predict the molecular geometry of NH_3.

Solution:

1. The Lewis structure of NH_3 is:



2. The central atom, N, has three bonding electron pairs and one nonbonding electron pair, for a total of four electron pairs.
3. The four electron pairs will be farthest apart when they occupy the corners of a tetrahedron. Because one of the four electron pairs is a lone pair, the observed molecular geometry is trigonal pyramidal, shown below.



In describing the shape of a molecule, only the arrangement of atoms (not electrons) is considered. Even though the electron pairs are arranged tetrahedrally, the shape of NH_3 is pyramidal. It is not trigonal planar because the lone pair repels the three bonding electron pairs, causing them to move as far apart as possible.

Example: Predict the geometry of CO_2.

Solution: The Lewis structure of CO_2 is $\ddot{O} :: C :: \ddot{O}$

The double bond behaves just like a single bond for the purposes of predicting molecular shape. This compound has two groups of electrons around the carbon. According to the VSEPR theory, the two sets of electrons will orient themselves 180° apart, on opposite sides of the carbon atom, minimizing electron repulsion. Therefore, the molecular structure of CO_2 is linear: $\ddot{O} = C = \ddot{O}$

One subtlety that the MCAT loves to test is the difference between electronic geometry and molecular geometry. **Electronic geometry** describes the spatial arrangement of all pairs of electrons around the central atom, including both the bonding and the lone pairs. In contrast, the **molecular geometry** describes the spatial arrangement of only the bonding pairs of electrons. For example, consider that CH_4 (methane), NH_3

Key Concept
