The shapes from Table 3.2 refer to *electronic geometry*, which is different from *molecular geometry*. In the worked example, notice that the ammonia molecule has a tetrahedral *electronic* structure, but is considered to have a *molecular* structure that is trigonal pyramidal.

MCAT Expertise

CH_4, NH_3, and H_2O all have a tetrahedral electronic geometry, but differ in their molecular shapes:
CH_4 is tetrahedral, NH_3 is pyramidal, and H_2O is bent or angular.

(ammonia), and H_2O all have the same electronic geometry: in each compound, four pairs of electrons surround the central atom. This is tetrahedral electronic geometry. However, because each molecule has a different number of lone pairs, they have different molecular geometries. Methane has tetrahedral geometry, ammonia is trigonal pyramidal, and water is identified as angular or bent.

The distinction is important, and the MCAT will primarily focus on molecular geometry. However, there is one important implication of electronic geometry: the determination of the **ideal bond angle**. Tetrahedral electronic geometry, for example, is associated with an ideal bond angle of 109.5°; however, nonbonding pairs are able to exert more repulsion than bonding pairs because these electrons reside closer to the nucleus. Thus, the angle in ammonia is closer to 107°, and the angle in water is 104.5°.

Polarity of Molecules

When two atoms of different electronegativities bond covalently, sharing one or more pairs of electrons, the resulting bond is polar, with the more electronegative atom possessing the greater share of the electron density. However, the presence of bond dipoles does not necessarily result in a molecular dipole; that is, an overall separation of charge across the molecule. We must first consider the molecular geometry and the vector addition of the bond dipoles based upon that molecular geometry. A compound with nonpolar bonds is always nonpolar. However, a compound with polar bonds may be polar or nonpolar, depending upon the spatial orientation of the polar bonds in the molecule. If the compound has a molecular geometry such that the bond dipole moments cancel each other out (that is, if the vector sum is zero), then the result is a nonpolar compound. For example, CCl_4 (carbon tetrachloride) has four polar C–Cl bonds, but because the molecular geometry of carbon tetrachloride is tetrahedral, the four bond dipoles point to the vertices of the tetrahedron and, therefore, cancel each other out, resulting in a nonpolar compound, as shown in Figure 3.10.

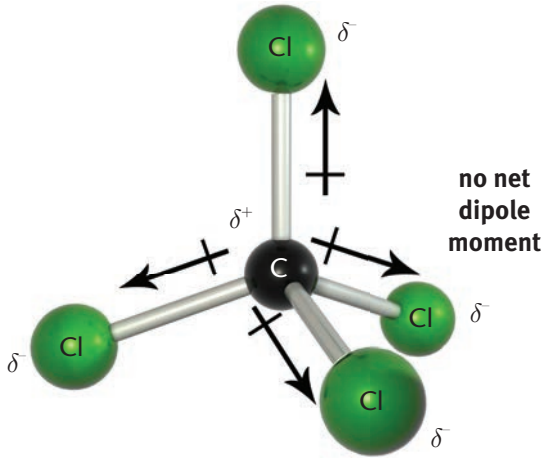

Figure 3.10. CCl_4 is a Nonpolar Compound with Four Polar Bonds

However, when the molecular geometry is arranged such that the bond dipoles do not cancel each other out, the molecule will have a net dipole moment and will therefore be polar. For instance, the O–H bonds in H_2O are polar, with each hydrogen atom assuming a partial positive charge and the oxygen assuming a partial negative charge. Recall that the molecular geometry of water is angular (bent). Therefore, the vector summation of the bond dipoles results in a molecular dipole moment from the partially positive hydrogen end to the partially negative oxygen end, as illustrated in Figure 3.11.

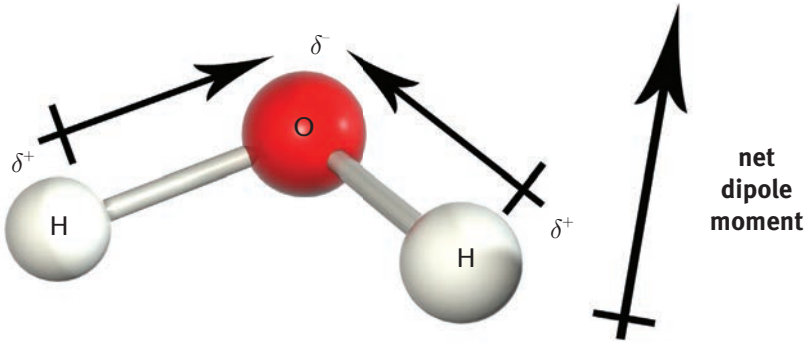

Figure 3.11. H_2O is a Polar Molecule with Two Polar Bonds

ATOMIC AND MOLECULAR ORBITALS

To finish the discussion of covalent bonds, we need to address the concept of atomic and molecular orbitals. Recall the model of the atom as a dense, positively charged nucleus surrounded by a cloud of electrons organized into orbitals (regions in space surrounding the nucleus within which there are certain probabilities of finding an electron). The four quantum numbers describe the energy and position of an electron in an atom. While the principal quantum number, n, indicates the average energy level of the shell, the azimuthal quantum number, l, describes the subshells within each principal energy level. When $l = 0$, this indicates the s subshell, which has one orbital that is spherical in shape. The 1s-orbital ($n = 1$, $l = 0$, $m_l = 0$) is plotted in Figure 3.12.

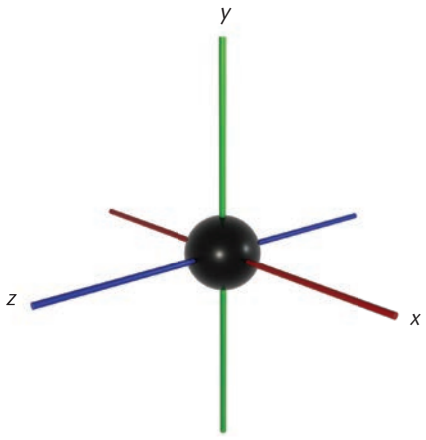

Figure 3.12. 1s-Orbital

MCAT Expertise

Be careful! If you spot a polar bond in a molecule, the molecule can be either polar or nonpolar. On the contrary, when you see only nonpolar bonds in a molecule, the structure *must* be nonpolar. Always draw out relevant structures on your scratch paper on Test Day.

Bridge

Quantum Numbers (Chapter 1 of *MCAT General Chemistry Review*) revisited:
For any value of n, there are n values of l ($0 \longrightarrow n - 1$).

- $l = 0 \longrightarrow s$
- $l = 1 \longrightarrow p$
- $l = 2 \longrightarrow d$
- $l = 3 \longrightarrow f$

For any value of l, there are $2l + 1$ values of m_l (number of orbitals); values range from $-l$ to l.

When $l = 1$, this indicates the p subshell, which has three orbitals shaped like barbells along the x-, y-, and z-axes at right angles to each other. The $2p$-orbitals ($n = 2$, $l = 1$, $m_l = -1$, 0, and +1) are plotted in Figure 3.13.

Although well beyond the scope of the MCAT, mathematical analysis of the wave functions of the orbitals is used to determine and assign plus and minus signs to each lobe of the p-orbitals. The shapes of the five d-orbitals and the seven f-orbitals are more complex and do not need to be memorized for the MCAT.

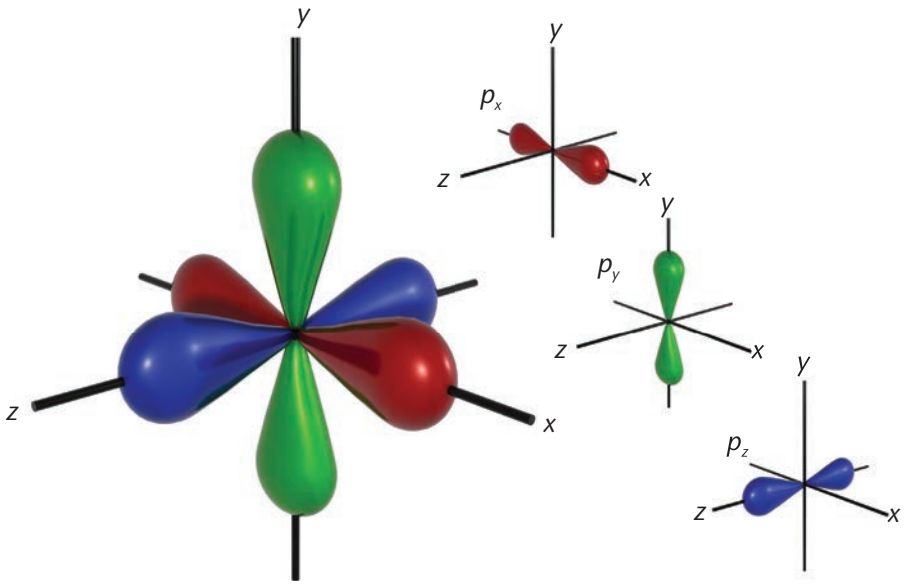

Figure 3.13. *p*-Orbitals on the *x*-, *y*-, and *z*-Axes

When two atoms bond to form a compound, the atomic orbitals interact to form a **molecular orbital** that describes the probability of finding the bonding electrons in a given space. Molecular orbitals are obtained by combining the wave functions of the atomic orbitals. Qualitatively, the overlap of two atomic orbitals describes this molecular orbital. If the signs of the two atomic orbitals are the same, a **bonding orbital** forms. If the signs are different, an **antibonding orbital** forms.

Two different patterns of overlap are observed in the formation of molecular bonds. When orbitals overlap head-to-head, the resulting bond is a **sigma (σ) bond**. σ bonds allow for free rotation about their axes because the electron density of the bonding orbital is a single linear accumulation between the atomic nuclei.

When the orbitals overlap in such a way that there are two parallel electron cloud densities, a **pi (π) bond** is formed. π bonds do not allow for free rotation because the electron densities of the orbitals are parallel and cannot be twisted in such a way that allows continuous overlapping of the clouds of electron densities.

MCAT Concept Check 3.3:

Before you move on, assess your understanding of the material with these questions.

1. Describe the relationship between bond strength, bond length, and bond energy.

_____

_____

_____

2. For what values of ΔEN will a nonpolar covalent bond form? Polar covalent? Ionic?
   - Nonpolar covalent: _____
   - Polar covalent: _____
   - Ionic: _____

3. Draw a Lewis dot structure for the carbonate ion (CO_3^{2-}) and its two other resonance structures.

4. Predict the molecular geometries of the following molecules:
   - PCl_5: _____
   - MgF_2: _____
   - AlF_3: _____
   - UBr_6: _____
   - SiH_4: _____

3.4 Intermolecular Forces

Atoms and compounds participate in weak electrostatic interactions. The strength of these **intermolecular forces** can impact certain physical properties, such as melting and boiling points. The weakest of the intermolecular interactions are the dispersion forces, also known as London forces. Next are the dipole–dipole interactions, which are of intermediate strength. Finally, we have the strongest type of interaction, the hydrogen bond, which is a misnomer because there is no actual sharing or transfer of electrons. We must keep in mind, however, that even hydrogen bonds, the strongest

Bridge

These intermolecular forces are the bonding forces that keep a substance together in its solid or liquid state and determine whether two substances are miscible or immiscible in solution. Solutions and solubility are discussed in Chapter 9 of *MCAT General Chemistry Review.*

of these interactions, only have about 10 percent of the strength of a covalent bond. Therefore, these electrostatic interactions can be overcome with small or moderate amounts of energy.

LONDON DISPERSION FORCES

The bonding electrons in nonpolar covalent bonds may appear to be shared equally between two atoms, but at any point in time, they will be located randomly throughout the orbital. In a given moment, the electron density may be unequally distributed between the two atoms. This results in a rapid polarization and counterpolarization of the electron cloud and the formation of short-lived dipole moments. Subsequently, these dipoles interact with the electron clouds of neighboring compounds, inducing the formation of more dipoles. The momentarily negative end of one molecule will cause the closest region in any neighboring molecule to become temporarily positive itself. This causes the other end of the neighboring molecule to become temporarily negative, which in turn induces other molecules to become temporarily polarized, and the cycle begins again. The attractive interactions of these short-lived and rapidly shifting dipoles are known as **London dispersion forces**, a type of **van der Waals force**.

Dispersion forces are the weakest of all of the intermolecular interactions because they are the result of induced dipoles that change and shift moment to moment. They do not extend over long distances and are, therefore, significant only when molecules are in close proximity. The strength of the London force also depends on the degree and ease by which the molecules can be polarized—that is, how easily the electrons can be shifted around. Large molecules are more easily polarizable than comparable smaller molecules and thus possess greater dispersion forces.

Real World

While dispersion forces (a type of van der Waals force) are the weakest of the intermolecular attractions, when there are millions of these interactions there is an amazing power of adhesion. This is demonstrated by geckos' feet; the animal's ability to climb smooth, vertical, and even inverted surfaces is due to dispersion forces.

Despite their weak nature, don't underestimate the importance of dispersion forces. If it weren't for them, the noble gases would not liquefy at any temperature because no other intermolecular forces exist between the noble gas atoms. The low temperatures at which noble gases liquefy are indicative of the very small magnitude of the dispersion forces between the atoms.

DIPOLE–DIPOLE INTERACTIONS

Polar molecules tend to orient themselves in such a way that the oppositely charged ends of the respective molecular dipoles are closest to each other: the positive region of one molecule is close to the negative region of another molecule. This arrangement is energetically favorable because an attractive electrostatic force is formed between the two molecules. This attractive force is denoted by dashed lines in most molecular notations and indicates a temporary bonding interaction, as shown in Figure 3.14.

Figure 3.14. Dipole–Dipole Interactions in HCl

Dipole–dipole interactions are present in the solid and liquid phases but become negligible in the gas phase because of the significantly increased distance between gas particles. Polar species tend to have higher melting and boiling points than nonpolar species of comparable molecular weight due to these interactions. Realize that London forces and dipole–dipole interactions are different not in kind but in duration. Both are electrostatic forces between opposite partial charges; the difference is only in the transience or permanence of the molecular dipole.

HYDROGEN BONDS

Hydrogen bonds are a favorite topic on the MCAT. A hydrogen bond is a specific, unusually strong form of dipole–dipole interaction that may be intra- or intermolecular. Hydrogen bonds are not actually bonds—there is no sharing or transfer of electrons between two atoms. When hydrogen is bonded to one of three highly electronegative atoms—nitrogen, oxygen, or fluorine—the hydrogen atom carries only a small amount of the electron density in the covalent bond.

The hydrogen atom essentially acts as a naked proton. The positively charged hydrogen atom interacts with the partial negative charge of fluorine, oxygen, or nitrogen on nearby molecules. Substances that display hydrogen bonding tend to have unusually high boiling points compared to compounds of similar molecular weights that do not exhibit hydrogen bonding. The difference derives from the energy required to break the hydrogen bonds. Hydrogen bonding, shown in Figure 3.15, is particularly important in the behavior of water, alcohols, amines, and carboxylic acids.

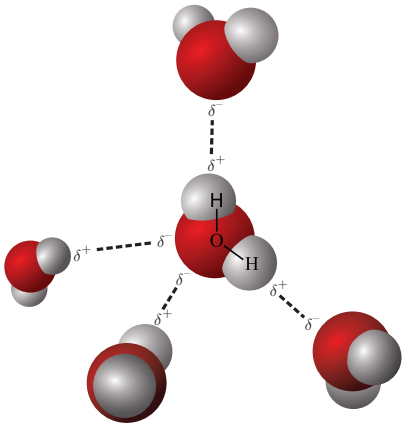

Figure 3.15. Hydrogen Bonding in Water

Bridge

In organic chemistry, carbonyl groups possess distinct dipoles that facilitate nucleophilic attacks. This is the focus of almost all of the reactions in Chapters 6 to 9 of *MCAT Organic Chemistry Review.*

Mnemonic

Hydrogen bonds: Pick up the **FON** (phone):
Hydrogen bonds exist in molecules containing a hydrogen bonded to **F**luorine, **O**xygen, or **N**itrogen.

Many biochemical molecules, such as nucleotides, have different regions that are stabilized by hydrogen bonding, as shown in Figure 3.16. It is not an overstatement to say that—were it not for water's ability to form hydrogen bonds and exist in the liquid state at room temperature—we would not exist (at least not in the form we recognize as "human").

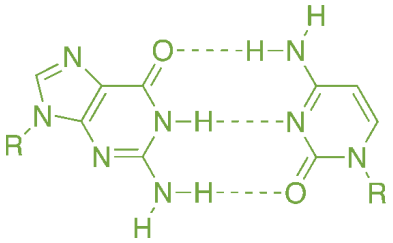

Figure 3.16. Hydrogen Bonding between Guanine and Cytosine

MCAT Concept Check 3.4:

Before you move on, assess your understanding of the material with these questions.

1. Rank the major intermolecular forces from strongest to weakest:
   1. _____
   2. _____
   3. _____
2. Describe what occurs during dipole–dipole interactions.

   _____

   _____
3. In order to exhibit hydrogen bonding, what must be true of a given molecule?

   _____

   _____

Conclusion

This chapter built on our knowledge of the atom and the trends demonstrated by the elements in the periodic table to explain the different ways by which atoms partner together to form compounds, either by exchanging electrons to form ions, which are then held together by electrostatic attractions between opposite charges; or by

sharing electrons to form covalent bonds. We discussed the nature and characteristics of covalent bonds, noting their relative lengths and energies, as well as polarities. A review of Lewis dot structures and VSEPR theory will prepare you for predicting likely bond arrangements, resonance structures, and molecular geometries. Finally, we compared the relative strengths of the most important intermolecular electrostatic interactions, noting that even the strongest of these—hydrogen bonding—is still much weaker than an actual covalent bond. The next time you're "browning" some of your food in a pan or the oven, take a moment to consider what's happening at the atomic and molecular level. It's not just cooking; it's science!

CONCEPT SUMMARY

Bonding

- Chemical bonds can be ionic or covalent.
- Elements will form bonds to attain a noble gas-like electron configuration.
- The **octet rule** states that elements will be most stable with eight valence electrons. However, there are many exceptions to this rule:
  - Elements with an incomplete octet are stable with fewer than eight electrons and include H, He, Li, Be, and B.
  - Elements with an expanded octet are stable with more than eight electrons and include all elements in period 3 or greater.
  - Compounds with an odd number of electrons cannot have eight electrons on each element.

Ionic Bonds

- An **ionic bond** is formed via the transfer of one or more electrons from an element with a relatively low ionization energy to an element with a relatively high electron affinity.
  - Ionic bonds occur between elements with large differences in electronegativity ($\Delta EN > 1.7$), usually between metals and nonmetals.
  - A positively charged ion is called a **cation**. A negatively charged ion is called an **anion**.
  - The resulting electrostatic attraction between the ions causes them to remain in close proximity, forming the bond.
  - Ionic compounds form **crystalline lattices**—large, organized arrays of ions.
- Ionic compounds have unique physical and chemical properties.
  - Ionic compounds tend to dissociate in water and other polar solvents.
  - Ionic solids tend to have high melting points.

Covalent Bonds

- A **covalent bond** is formed via the sharing of electrons between two elements of similar electronegativities.
- **Bond order** refers to whether a covalent bond is a single bond, double bond, or triple bond. As bond order increases, **bond strength** increases, **bond energy** increases, and **bond length** decreases.
- Covalent bonds can be categorized as nonpolar or polar based on the nature of the elements involved.
  - **Nonpolar bonds** result in molecules in which both atoms have exactly the same electronegativity; some bonds are considered nonpolar when

there is a very small difference in electronegativity between the atoms ($\Delta EN < 0.5$), even though they are technically slightly polar.

- **Polar bonds** form when there is a significant difference in electronegativities ($\Delta EN = 0.5$ to 1.7), but not enough to transfer electrons and form an ionic bond. In a polar bond, the more electronegative element takes on a partial negative charge, and the less electronegative element takes on a partial positive charge.

- **Coordinate covalent bonds** result when a single atom provides both bonding electrons while the other atom does not contribute any; coordinate covalent bonds are most often found in Lewis acid–base chemistry.
- **Lewis dot symbols** are a chemical representation of an atom's valence electrons.
- Drawing a complete Lewis dot structure requires a balance of valence, bonding, and nonbonding electrons in a molecule or ion.
- **Formal charges** exist when an atom is surrounded by more or fewer valence electrons than it has in its neutral state (assuming equal sharing of electrons in a bond).
- For any molecule with a π (pi) system of electrons, **resonance structures** exist; these represent all of the possible configurations of electrons—stable and unstable—that contribute to the overall structure.
- The **valence shell electron pair repulsion** (**VSEPR**) **theory** predicts the three-dimensional molecular geometry of covalently bonded molecules. In this theory, electrons—whether bonding or nonbonding—arrange themselves to be as far apart as possible from each other in three-dimensional space, leading to characteristic geometries.
  - Nonbonding electrons exert more repulsion than bonding electrons because they reside closer to the nucleus.
  - **Electronic geometry** refers to the position of all electrons in a molecule, whether bonding or nonbonding. **Molecular geometry** refers to the position of only the bonding pairs of electrons in a molecule.
- The **polarity of molecules** is dependent on the dipole moment of each bond and the sum of the dipole moments in a molecular structure.
  - All polar molecules contain polar bonds.
  - Nonpolar molecules may contain nonpolar bonds, or polar bonds with dipole moments that cancel each other.
- σ and π bonds describe the patterns of overlap observed when molecular bonds are formed.
  - **Sigma (σ) bonds** are the result of head-to-head overlap.
  - **Pi (π) bonds** are the result of the overlap of two parallel electron cloud densities.

Intermolecular Forces

- **Intermolecular forces** are electrostatic attractions between molecules. They are significantly weaker than covalent bonds (which are weaker than ionic bonds).
  - **London dispersion forces** are the weakest interactions, but are present in all atoms and molecules. As the size of the atom or structure increases, so does the corresponding London dispersion force.
  - **Dipole–dipole interactions**, which occur between the oppositely charged ends of polar molecules, are stronger than London forces; these interactions are evident in the solid and liquid phases but negligible in the gas phase due to the distance between particles.
  - **Hydrogen bonds** are a specialized subset of dipole–dipole interactions involved in intra- and intermolecular attraction; hydrogen bonding occurs when hydrogen is bonded to one of three very electronegative atoms—fluorine, oxygen, or nitrogen.

ANSWERS TO CONCEPT CHECKS

3.1

1. Ionic bonds form between ions and involve gain or loss of electrons. Covalent bonds occur when electrons are shared between atoms.
2. Any three examples that form incomplete octets (H, He, Li, Be, B) or expanded octets (Period 3 and greater) are acceptable.
3. The polarity in a covalent bond is determined by differences in electronegativity between the two atoms involved.

3.2

1. Metals lose electrons because they have low ionization energies, while nonmetals gain electrons because they have high electron affinities. These processes are complementary, leading to the formation of an ionic bond.
2. Some characteristics of ionic compounds include high melting and boiling points due to electrostatic attractions, solubility of ions in water due to interactions with polar solvents, good conductors of heat and electricity, crystal lattice arrangement to minimize repulsive forces, and large electronegativity differences between ions, among other possible answers.

3.3

1. Bond strength is defined by the electrostatic attraction between nuclei and electrons; multiple bonds (higher bond order) increases strength. Bond length is a consequence of these attractions. The stronger the bond, the shorter it is. Bond energy is the minimum amount of energy needed to break a bond. The stronger the bond, the higher the bond energy.
2. Nonpolar covalent bonds form with $\Delta EN = 0$ to 0.5. Polar covalent bonds form with $\Delta EN = 0.5$ to 1.7. Ionic bonds form with $\Delta EN = 1.7$ or higher.
3. 4. PCl_5: trigonal bipyramidal, MgF_2: linear, AlF_3: trigonal planar, UBr_6: octahedral, SiH_4: tetrahedral

3.4

1. Hydrogen bonding > dipole–dipole interactions > dispersion (London) forces
2. A dipole consists of a segment of a molecule with partial positive and partial negative regions. The positive end of one molecule is attracted to the negative end of another molecule, and vice-versa.
3. To experience hydrogen bonding, a molecule must contain a hydrogen bonded to a very electronegative atom (nitrogen, oxygen, or fluorine).

EQUATIONS TO REMEMBER

(3.1) **Dipole moment: $\mathbf{p} = q\mathbf{d}$**

(3.2) **Formal charge:** $V - N_{\text{nonbonding}} - \frac{1}{2}N_{\text{bonding}}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. What is the character of the bond in carbon monoxide?

A. Ionic
B. Polar covalent
C. Nonpolar covalent
D. Coordinate covalent

2. Which of the following molecules contains the oxygen atom with the most negative formal charge?

A. H_2O
B. CO_3^{2-}
C. O_3
D. CH_2O

3. Which of the following structures contribute(s) most to NO_2's resonance hybrid?

I. 
II. 
III. 
A. I only
B. III only
C. I and II only
D. I, II, and III

4. Which of the following correctly ranks the compounds below by ascending boiling point?

I. Acetone
II. KCl
III. Kr
IV. Isopropyl alcohol

A. I < II < IV < III
B. III < IV < I < II
C. II < IV < I < III
D. III < I < IV < II

5. Both CO_3^{2-} and ClF_3 have three atoms bonded to a central atom. What is the best explanation for why CO_3^{2-} has trigonal planar electronic geometry, while ClF_3 has trigonal bipyramidal electronic geometry?

A. CO_3^{2-} has multiple resonance structures, while ClF_3 does not.
B. CO_3^{2-} has a charge of –2, while ClF_3 has no charge.
C. ClF_3 has lone pairs on its central atom, while CO_3^{2-} has none.
D. CO_3^{2-} has lone pairs on its central atom, while ClF_3 has none.

6. Which of the following has the largest dipole moment?

A. HCN
B. H_2O
C. CCl_4
D. SO_2

7. Despite the fact that both C_2H_2 and HCN contain triple bonds, the lengths of these triple bonds are not equal. Which of the following is the best explanation for this finding?

A. In C_2H_2, the bond is shorter because it is between atoms of the same element.
B. The two molecules have different resonance structures.
C. Carbon is more electronegative than hydrogen.
D. Nitrogen is more electronegative than carbon.

8. Which of the following is the best explanation of the phenomenon of hydrogen bonding?

A. Hydrogen has a strong affinity for holding onto valence electrons.
B. Hydrogen can only hold two valence electrons.
C. Electronegative atoms disproportionately carry shared electron pairs when bonded to hydrogen.
D. Hydrogen bonds have ionic character.

9. Which of the following best describes the number and character of the bonds in an ammonium cation?

A. Three polar covalent bonds
B. Four polar covalent bonds, of which none are coordinate covalent bonds
C. Four polar covalent bonds, of which one is a coordinate covalent bond
D. Four polar covalent bonds, of which two are coordinate covalent bonds

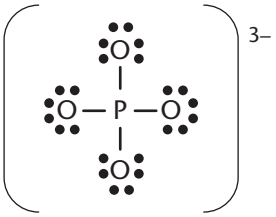
10. Although the octet rule dictates much of molecular structure, some atoms can violate the octet rule by being surrounded by more than eight electrons. Which of the following is the best explanation for why some atoms can exceed the octet?

A. Atoms that exceed the octet already have eight electrons in their outermost electron shell.
B. Atoms that exceed the octet only do so when bonding with transition metals.
C. Atoms that exceed the octet can do so because they have *d*-orbitals in which extra electrons can reside.
D. Some atoms can exceed the octet because they are highly electronegative.

11. Which of the following types of intermolecular forces provides the most accurate explanation for why noble gases can liquefy?

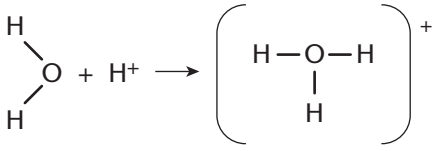
A. Hydrogen bonding
B. Ion–dipole interactions
C. Dispersion forces
D. Dipole–dipole interactions

12. In the structure shown, which atom(s) have the most positive charge?



A. The phosphorus atom has the most positive charge.
B. All atoms share the charge equally.
C. The four oxygen atoms share the highest charge.
D. The oxygen atom at the peak of the trigonal pyramidal geometry has the most positive charge.

13. Which of the following is the best name for the new bond formed in the reaction shown?



A. Nonpolar covalent bond
B. Ionic bond
C. Coordinate covalent bond
D. Hydrogen bond

14. Both BF_3 and NH_3 have three atoms bonded to the central atom. Which of the following is the best explanation for why the geometry of these two molecules is different?

A. BF_3 has three bonded atoms and no lone pairs, which makes its geometry trigonal pyramidal.

B. NH_3 is nonpolar, while BF_3 is polar.

C. NH_3 has three bonded atoms and one lone pair, which makes its geometry trigonal pyramidal.

D. BF_3 is nonpolar, while NH_3 is polar.

15. Which of the following best describes an important property of bond energy?

A. Bond energy increases with increasing bond length.

B. The more shared electron pairs comprising a bond, the higher the energy of that bond.

C. Single bonds are more difficult to break than double bonds.

D. Bond energy and bond length are unrelated.

Explanations to Discrete Practice Questions

1. B

Carbon monoxide, CO, has a triple bond between carbon and oxygen, with the carbon and oxygen each retaining one lone pair. In polar covalent bonds, the difference in electronegativity between the bonded atoms is great enough to cause electrons to move disproportionately toward the more electronegative atom but not great enough to transfer electrons completely. This is the case for CO. Oxygen is significantly more electronegative than carbon, so electrons will be disproportionately carried on the oxygen, leaving the carbon atom with a slight positive charge.

2. B

To answer this question, one must understand the contribution of resonance structures to average formal charge. In **choice (B)**, there are three possible resonance structures. Each of the three oxygen atoms carries a formal charge of –1 in two out of the three structures. This averages to approximately $-\frac{2}{3}$ charge on each oxygen atom, which is more negative than in the other answer choices. Both water and formaldehyde, **choices (A)** and **(D)**, have no formal charge on the oxygen. Ozone, **choice (C)**, has a $-\frac{1}{2}$ on two of the three oxygens and a +1 charge on the central oxygen.

3. C

The two greatest contributors are structures I and II. Resonance structures are representations of how charges are shared across a molecule. In reality, the charge distribution is a weighted average of contributing resonance structures. The most stable resonance structures are those that minimize charge on the atoms in the molecule; the more stable the structure, the more it will contribute to the overall charge distribution in the molecule. Structures I and II minimize formal charges, so will be the largest contributors to the resonance hybrid.

4. D

The key to answering this question is to understand the types of intermolecular forces that exist in each of these molecules because larger intermolecular forces correspond to higher boiling points. Kr is a noble gas with a full octet, so the only intermolecular forces present are London dispersion forces, the weakest type of intermolecular forces. Acetone and isopropyl alcohol are both polar, so both have dipole–dipole interactions, which are stronger than dispersion forces. However, isopropyl alcohol can also form hydrogen bonds, increasing its boiling point. Finally, the strongest interactions are ionic bonds, which exist in potassium chloride.

5. C

The central carbon in carbonate has no lone pairs. It has three resonance structures, each of which involves a double bond between carbon and one of the three oxygens. Having made four bonds, carbon has no further orbitals for bonding or to carry lone pairs. This makes carbonate's geometry trigonal planar. Alternatively, ClF_3 also has three bonds; however, chloride still maintains two extra lone pairs. These lone pairs each inhabit one orbital, meaning that the central chloride must organize five items about itself: three bonds to fluorides and two lone pairs. The best configuration for maximizing the distance between all of these groups is trigonal bipyramidal. **Choices (A)** and **(B)** are true statements but do not account for the difference in geometry.

6. A

The best way to approach this problem is to draw the structure of each of these molecules, then consider the electronegativity of each bond as it might contribute to an overall dipole moment. HCN is the correct answer because of the large differences in electronegativity aligned in a linear fashion. There is a strong dipole moment in the direction of nitrogen, without any other moments canceling it out. Water, **choice (B)**, has two dipole moments, one from each hydrogen pointing in the direction of oxygen. The molecule is bent, and the dipole moments partially cancel out. There is a molecular dipole, but it is not as strong as in HCN. Sulfur dioxide, **choice (C)**, has a similar bent configuration, and its dipole will again be smaller than that of HCN. Further, oxygen and sulfur do not have as large a difference in electronegativity, so even the individual bond dipoles are smaller than those in the other molecules. CCl_4, **choice (D)**, has tetrahedral geometry. Although each of the individual C–Cl bonds is highly polar, the orientation of these bonds causes the dipoles to cancel each other out fully, yielding no overall dipole moment.

7. D

Bond lengths decrease as the bond order increases, and they also decrease with larger differences in electronegativity. In this case, because both C_2H_2 and HCN have triple bonds, we cannot compare the bond lengths based on bond order. We must then rely on other periodic trends. The bond length decreases when moving to the right along the periodic table's rows because more electronegative atoms have shorter atomic radii. The nitrogen in HCN is likely to hold its electrons closer, or in a shorter radius, than the carbons in C_2H_2.

8. C

Electronegative atoms bonded to hydrogen disproportionately pull covalently bonded electrons toward themselves, which leaves hydrogen with a partial positive character. That partial positive charge is attracted to nearby negative or partial negative charges, such as those on other electronegative atoms.

9. C

First recall that ammonium is NH_4^+, while ammonia is NH_3. Ammonium is formed by the association of NH_3, an uncharged molecule with a lone pair on the nitrogen, with a positively charged hydrogen cation. In other words, NH_3 is a Lewis base, while H^+ is a Lewis acid. This type of bonding between a Lewis acid and base is a coordinate covalent bond.

10. C

All atoms in the third period or greater have *d*-orbitals, which can hold an additional 10 electrons. The typical "octet" electrons reside in *s*- and *p*-orbitals, but elements in period 3 or higher can place electrons into these *d*-orbitals.

11. C

All of the listed types of forces describe interactions between different types of molecules. However, noble gases are entirely uncharged and do not have polar covalent bonds, ionic bonds, or dipole moments. Therefore, the only intermolecular forces experienced by noble gases are London dispersion forces. Although these interactions are small in magnitude, they are necessary for condensation into a liquid.

12. A

In this Lewis diagram, the phosphate molecule has an overall formal charge of –3. The four oxygen atoms would each be assigned a formal charge of –1. Given the overall charge of –3 and the –1 charge on each oxygen, the phosphorus must have a formal charge of +1.

13. C

The reaction in this question shows a water molecule, which has two lone pairs of electrons on the central oxygen, combining with a free hydrogen cation. The resulting molecule, H_3O^+ has formed a new bond between H^+ and H_2O. This bond is created via the sharing of one of oxygen's lone pairs with the free H^+ ion. This represents the donation of a shared pair of electrons from a Lewis base (H_2O) to a Lewis acid (H^+, electron acceptor). This type of bond is called a coordinate covalent bond.

14. C

NH_3 has three hydrogen atoms bonded to the central nitrogen, which also has a lone pair. These four groups—three atoms, one lone pair—lead NH_3 to assume tetrahedral electronic geometry yet trigonal pyramidal molecular geometry. The nitrogen in ammonia is sp^3-hybridized. By hybridizing all three *p*-orbitals and the one *s*-orbital, four groups are arranged about the central atom, maximizing the distances between the groups to minimize the energy of the molecule with a tetrahedral configuration. In contrast, BF_3 has three atoms and no lone pairs, resulting in sp^2-hybridization. Its shape is called trigonal planar.

15. B

This answer requires an understanding of the trends that cause higher or lower bond energies. Bonds of high energy are those that are difficult to break. These bonds tend to have more shared pairs of electrons and, thus, cause a stronger attraction between the two atoms in the bonds. This stronger attraction also means that the bond length of a high-energy, high-order bond such as a triple bond is shorter than that of its lower-energy counterparts such as single or double bonds.

Concept Summary 136

Introduction

Oh—what is that smell? It smells like rancid almonds. Then you notice a few green bugs whose backs give the impression of a shield. *Stink bugs!* A stink bug "stinks" because it produces a highly concentrated solution of volatile compounds that we perceive as malodorous, noxious, and irritating. Interestingly enough, the primary compounds in the stink bug's stink bomb are hydrogen cyanide—a highly toxic compound that inhibits *cytochrome c oxidase*, thereby blocking aerobic respiration—and benzaldehyde. Like many other aromatic compounds, benzaldehyde vaporizes at room temperature and reaches the olfactory system as gas particles. Benzaldehyde is also the key ingredient in artificial almond extract. At low concentrations, it produces a pleasant aroma of toasted almonds. However, at high concentrations, its odor is that of rotten, putrid almonds, and it is a noxious irritant to the skin, eyes, and respiratory tract.

Benzaldehyde is a compound composed of seven carbon atoms, six hydrogen atoms, and one oxygen atom. One mole of benzaldehyde has a mass of approximately 106 grams. It can react with other atoms or compounds to form new **compounds**—pure substances composed of two or more elements in a fixed proportion. Compounds can be broken down by chemical means to produce their constituent elements or other compounds. They are characterized by describing their physical and chemical properties.

This chapter focuses on compounds and their reactions. It reviews the various ways in which compounds are represented, using empirical and molecular formulas and percent composition. There is a brief overview of the major classes of chemical reactions, which we will examine more closely in subsequent chapters, and finally, there is a recap of the steps involved in balancing chemical equations with a particular focus on identifying limiting reagents and calculating reaction yields.

4.1 Molecules and Moles ★★★

A **molecule** is a combination of two or more atoms held together by covalent bonds. Molecules are the smallest units of compounds that display their identifying properties. Molecules can be composed of two or more atoms of the same element (such as N_2 and O_2) or may be composed of atoms of different elements, as in CO_2 (carbon dioxide), $SOCl_2$ (thionyl chloride), and C_6H_5CHO (benzaldehyde). Because reactions usually involve a very large number of molecules—far too many to count individually—we usually measure amounts of compounds in terms of moles or grams, using molar mass to interconvert between these units.

Bridge

Ionic compounds form from combinations of elements with large electronegativity differences, such as sodium and chlorine. Molecular compounds form from elements of similar electronegativity, such as carbon with oxygen. The difference between ionic and covalent bonds is discussed in Chapter 3 of *MCAT General Chemistry Review*.

Ionic compounds do not form true molecules because of the way in which the oppositely charged ions arrange themselves in the solid state. As solids, they can be considered as nearly infinite three-dimensional arrays of the charged particles that comprise the compound. As described in Chapter 3 of *MCAT General Chemistry Review*, solid NaCl is a coordinated lattice in which each of the Na^+ ions is surrounded by Cl^- ions and each of the Cl^- ions is surrounded by Na^+ ions. This makes it rather difficult to clearly define a sodium chloride molecule, and the term **formula unit**, representing the empirical formula of the compound, is used instead. Because no molecule actually exists, molecular weight becomes meaningless, and the term **formula weight** is used instead.

MOLECULAR WEIGHT

Remember that the term **atomic weight** is a misnomer because it is actually a weighted average of the masses of the naturally occurring isotopes of an element, not their weights. The same applies here to our discussion of **molecular weight**. Molecular weight, then, is simply the sum of the atomic weights of all the atoms in a molecule, and its units are atomic mass units (amu) per molecule. Similarly, the **formula weight** of an ionic compound is found by adding up the atomic weights of the constituent ions according to its empirical formula, and its units are also amu per molecule.

Example: What is the molecular weight of $SOCl_2$?

Solution: To find the molecular weight of $SOCl_2$, add together the atomic weights of each of the atoms.

1 S: 1 × 32.1 amu	=	32.1 amu
1 O: 1 × 16.0 amu	=	16.0 amu
2 Cl: 2 × 35.5 amu	=	71.0 amu
Total molecular weight	=	119.1 amu per molecule

MOLE

A **mole** is a quantity of any substance (atoms, molecules, dollar bills, kittens—anything) equal to the number of particles that are found in 12 grams of carbon-12 $\left({}^{12}_{6}\mathrm{C}\right)$. This number of particles is defined as **Avogadro's number** (N_A), 6.022×10^{23} mol^{-1}. One mole of a compound has a mass in grams equal to the molecular or formula weight of the compound in amu. For example, one molecule of H_2CO_3 (carbonic acid) has a mass of 62 amu; one mole of the compound has a mass of 62 grams. The mass of one mole of a compound is called its **molar mass** and is usually expressed in $\frac{\mathrm{g}}{\mathrm{mol}}$. The term *molecular weight* is sometimes used incorrectly to imply molar mass; remember, molecular weight is measured in $\frac{\mathrm{amu}}{\mathrm{molecule}}$, not $\frac{\mathrm{g}}{\mathrm{mol}}$.

Key Concept

Remember that Avogadro's number (and the mole) are just units of convenience, like the dozen is a convenient unit for eggs.

The formula for determining the number of moles of a sample substance is:

$$\text{Moles} = \frac{\text{Mass of sample (g)}}{\text{Molar mass}\left(\frac{\mathrm{g}}{\mathrm{mol}}\right)}$$

Equation 4.1

This equation is often used in stoichiometry and titration problems.

Example: How many moles are in 9.53 g of $MgCl_2$?

Solution: First, find the molar mass of $MgCl_2$.

$$1 \times 24.3\,\frac{\mathrm{g}}{\mathrm{mol}} + 2 \times 35.5\,\frac{\mathrm{g}}{\mathrm{mol}} = 95.3\,\frac{\mathrm{g}}{\mathrm{mol}}$$

Now, solve for the number of moles.

$$\frac{9.53\,\mathrm{g}}{95.3\,\frac{\mathrm{g}}{\mathrm{mol}}} = 0.10\ \mathrm{mol\ MgCl_2}$$

EQUIVALENT WEIGHT

Equivalent weight and the related concept of **equivalents** are a source of confusion for many students. Part of the problem may be the context in which equivalents and equivalent weights are usually discussed: acid–base reactions, oxidation–reduction

reactions, and precipitation reactions, all three of which can be sources of confusion and anxiety on their own. Therefore, let's start with a more basic discussion of equivalents.

Often, certain elements or compounds can act more potently than others in performing certain reactions. For example, one mole of HCl has the ability to donate one mole of hydrogen ions (H^+) in solution, but one mole of H_2SO_4 has the ability to donate two moles of hydrogen ions, and one mole of H_3PO_4 has the ability to donate three moles of hydrogen ions. To gather one mole of hydrogen ions for a particular acid–base reaction, we could use one mole of HCl, a half-mole of H_2SO_4, or one-third of a mole of H_3PO_4. Or, consider the difference between Na and Mg: One mole of sodium has the ability to donate one mole of electrons, while one mole of magnesium has the ability to donate two moles of electrons. This provides context for the concept of **equivalents**: How many moles of the *thing we are interested in* (protons, hydroxide ions, electrons, or ions) will one mole of a given compound produce? Sodium will donate one mole of electrons (one equivalent), but magnesium will donate two moles of electrons (two equivalents).

Bridge

The idea of *equivalents* is related to the concept of normality, which is explained in the discussion of acids and bases in Chapter 10 of *MCAT General Chemistry Review*.

So far, this discussion has been focused on the mole-to-mole relationship between, say, an acid compound and the hydrogen ions it donates. However, sometimes we need to work in units of mass rather than moles. Just as one mole of HCl will donate one mole of hydrogen ions, a certain mass of HCl (about 36.5 g) will also donate one equivalent of hydrogen ions. This amount of a compound, measured in grams, that produces one equivalent of the particle of interest is called the **gram equivalent weight** and can be calculated from:

$$\text{Gram equivalent weight} = \frac{\text{Molar mass}}{n}$$

Equation 4.2

MCAT Expertise

Whenever confronting a stoichiometry problem, always look for normality by identifying an equivalent unit (protons, hydroxide ions, electrons, ions) and then multiplying it by the number of moles or molar concentration to find the normal concentration.

where n is the number of particles of interest produced or consumed per molecule of the compound in the reaction. For example, one would need 31 grams of H_2CO_3 (molar mass = 62 $\frac{g}{mol}$) to produce one equivalent of hydrogen ions because each molecule of H_2CO_3 can donate two hydrogen ions ($n = 2$). Simply put, the equivalent weight of a compound is the mass that provides one mole of the particle of interest.

If the amount of a compound in a reaction is known and we need to determine how many equivalents are present, use the equation:

$$\text{Equivalents} = \frac{\text{Mass of compound (g)}}{\text{Gram equivalent weight (g)}}$$

Equation 4.3

Finally, we can now introduce the measurement of normality. **Normality** (N) is a measure of concentration, given in the units $\frac{\text{equivalents}}{L}$. On the MCAT, it is most commonly used for hydrogen ion concentration. Thus, a 1 N solution of acid contains a concentration of hydrogen ions equal to 1 mole per liter; a 2 N

solution of acid contains a concentration of hydrogen ions equal to 2 moles per liter. The actual concentration of the acidic compound may be the same or different from the normality because different compounds are able to donate different numbers of hydrogen ions. In a 1 *N* HCl solution, the molarity of HCl is 1 *M* because HCl is a monoprotic acid; in a 1 *N* H_2CO_3 solution, the molarity of H_2CO_3 is 0.5 *M* because H_2CO_3 is a diprotic acid. Note that normality calculations always assume that a reaction will proceed to completion; while carbonic acid does not fully dissociate in solution, it can be reacted with enough base for each molecule to give up both of its protons. The conversion from normality to molarity of a given solute is:

$$\text{Molarity} = \frac{\text{Normality}}{n}$$

Equation 4.4

where n is the number of protons, hydroxide ions, electrons, or ions produced or consumed by the solute.

Figure 4.1 shows the titration of the diprotic acid H_2CO_3 with a base. The *x*-axis indicates that two equivalents of base are needed to neutralize both protons of this acid.

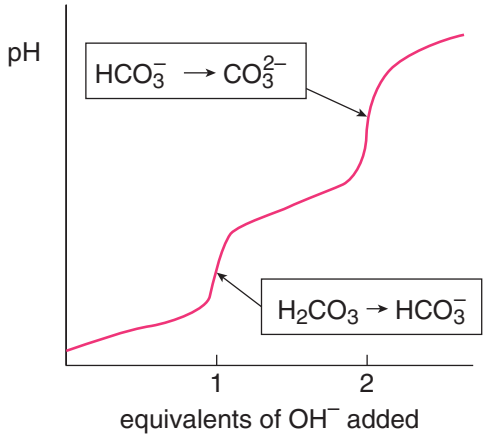

Figure 4.1. Titration of Carbonic Acid with a Base
Carbonic acid is diprotic, so two equivalents of base are required to neutralize both protons of the acid.

There is a real benefit to working with equivalents and normality because it allows a direct comparison of the quantities of the entity we are most interested in. In an acid–base reaction, we care about the hydrogen or hydroxide ions; where the ions come from is not really the primary concern. It is convenient to be able to say that one equivalent of acid (hydrogen ions) will neutralize one equivalent of base (hydroxide ions), but the same could not necessarily be said if we were dealing with moles of acidic compounds and moles of basic compounds. For example, one mole of HCl will not completely neutralize one mole of $Ca(OH)_2$ because one mole of HCl will donate one equivalent of acid, but $Ca(OH)_2$ will donate two equivalents of base.

Key Concept

In acid–base chemistry, the gram equivalent weight represents the mass of acid that yields one mole of protons, or the mass of base that yields one mole of hydroxide ions.

Example: What is the gram equivalent weight of sulfuric acid?

Solution: First, find the molar mass of H_2SO_4.

$$2 \times 1.0 \frac{g}{mol} + 1 \times 32.1 \frac{g}{mol} + 4 \times 16.0 \frac{g}{mol} = 98.1 \frac{g}{mol}$$

Next, identify the equivalents: protons (H^+), because these are transferred in acid–base reactions. The number of protons in sulfuric acid (n) is 2.

Now, calculate the gram equivalent weight.

$$\text{Gram equivalent weight} = \frac{\text{Molar mass}}{n} = \frac{98.1 \frac{g}{mol\ H_2SO_4}}{2 \frac{mol\ H^+}{mol\ H_2SO_4}}$$

$$= 49.05 \frac{g}{mol\ H^+}$$

Example: What is the normality of a 2 M $Mg(OH)_2$ solution?

Solution: First, identify the number of equivalents (n). There are two hydroxide ions (OH^-), which is the most likely equivalent of interest because magnesium hydroxide is a base.

Then, calculate the normality.

$$\text{Normality} = \text{molarity} \times n = 2\ M \times 2 \frac{mol\ OH^-}{mol\ Mg(OH)_2} = 4\ N\ Mg(OH)_2$$

MCAT Concept Check 4.1:

Before you move on, assess your understanding of the material with these questions.

1. Calculate the molar masses of the following substances:
   - NaBr:

     _____
   - $CuCl_2$:

     _____
   - $C_6H_{12}O_6$:

     _____
2. Calculate the number of moles in 100 g of each of the following substances:
   - NaBr:

     _____
   - $CuCl_2$:

     _____
   - $C_6H_{12}O_6$:

     _____

3. How do the number of molecules in 18 g of H_2O compare to the number of formula units in 58.5 g of NaCl?

_____

4. Determine the normality of the following solutions: (Note: The species of interest is H^+.)
   - 0.25 *M* H_3PO_4:

     _____
   - 95 g PO_4^{3-} in 100 mL solution:

     _____

4.2 Representation of Compounds ★★

There are different ways of representing compounds and their constituent atoms. We've already reviewed a couple of these systems in Chapter 3 of *MCAT General Chemistry Review*: Lewis dot structures and VSEPR theory. In organic chemistry, it is common to encounter skeletal representations of compounds, called **structural formulas**, that show the various bonds between the constituent atoms of a compound. Inorganic (general) chemistry typically represents compounds by showing the constituent atoms without representing the actual bond connectivity or atomic arrangement. For example, the formula $C_6H_{12}O_6$ (glucose) tells us that this particular compound consists of six atoms of carbon, twelve atoms of hydrogen, and six atoms of oxygen, but there is no indication of how the different atoms are arranged or how many bonds exist between each of the atoms.

LAW OF CONSTANT COMPOSITION

The **law of constant composition** states that any pure sample of a given compound will contain the same elements in an identical mass ratio. For example, every sample of water will contain two hydrogen atoms for every one oxygen atom, or—in terms of mass—for every one gram of hydrogen, there will be eight grams of oxygen.

EMPIRICAL AND MOLECULAR FORMULAS

There are two ways to express the formula of a compound. The **empirical formula** gives the simplest whole-number ratio of the elements in the compound. The **molecular formula** gives the exact number of atoms of each element in the compound and is a multiple of the empirical formula. For example, the empirical formula for benzene is CH, while the molecular formula is C_6H_6. For some compounds, the empirical and

Bridge

Many of these representations are discussed in more detail in Chapter 2 of *MCAT Organic Chemistry Review*. Understanding the theory behind such representations will help convert between different projections and representations with ease.

Real World

Even biologically important molecules such as water and amino acids on Earth are, by composition, the same anywhere else in the universe, even though densities and other physical properties may differ.

Bridge

An empirical formula of CH_2O is indicative of a monosaccharide. Common monosaccharides include glucose, fructose, and galactose. The structures of these monosaccharides—and of carbohydrates in general—are discussed in Chapter 4 of *MCAT Biochemistry Review*.

molecular formulas are identical, as is the case for H_2O. As previously discussed, ionic compounds, such as NaCl or $CaCO_3$, will only have empirical formulas.

PERCENT COMPOSITION

MCAT Expertise

Percent composition is a common way for stoichiometry to be tested on the MCAT. Practice these problems to build up speed and efficiency for Test Day.

The **percent composition** of an element (by mass) is the percent of a specific compound that is made up of a given element. To determine the percent composition of an element in a compound, the following formula is used:

$$\text{Percent composition} = \frac{\text{Mass of element in formula}}{\text{Molar mass}} \times 100\%$$

Equation 4.5

One can calculate the percent composition of an element by using either the empirical or the molecular formula. It is also possible to determine the molecular formula given both the percent compositions and molar mass of a compound. The following examples demonstrate such calculations.

Example: What is the percent composition of chromium in $K_2Cr_2O_7$?

Solution: The molar mass of $K_2Cr_2O_7$ is:

$$2 \times 39.1 \frac{g}{mol} + 2 \times 52.0 \frac{g}{mol} + 7 \times 16.0 \frac{g}{mol} = 294.2 \frac{g}{mol}$$

Calculate the percent composition of Cr:

$$\text{Percent composition} = \frac{2 \times 52.0 \frac{g}{mol}}{294.2 \frac{g}{mol}} \times 100\% = 0.354 \times 100\% = 35.4\%$$

Example: What are the empirical and molecular formulas of a compound that contains 40.9% carbon, 4.58% hydrogen, and 54.52% oxygen and has a molar mass of 264 $\frac{g}{mol}$?

Method One: First, determine the number of moles of each element in the compound by assuming a 100-gram sample; this converts the percentage of each element present directly into grams of that element. Then convert grams to moles:

$$\text{moles C} = \frac{40.9\ g}{12 \frac{g}{mol}} \approx 3.4\ \text{mol}$$

$$\text{moles H} = \frac{4.58\ g}{1 \frac{g}{mol}} \approx 4.6\ \text{mol}$$

$$\text{moles O} = \frac{54.52\ g}{16 \frac{g}{mol}} \approx 3.4\ \text{mol}$$

Next, find the simplest whole number ratio of the elements by dividing the number of moles by the smallest number obtained in the previous step.

$$\text{C: } \frac{3.4}{3.4} = 1.00\text{; H: } \frac{4.6}{3.4} = 1.33\text{; O: } \frac{3.4}{3.4} = 1.00$$

Finally, the empirical formula is obtained by converting the numbers obtained into whole numbers by multiplying them by an integer value.

$$C_1H_{1.33}O_1 \times 3 = C_3H_4O_3$$

$C_3H_4O_3$ is the empirical formula. To determine the molecular formula, divide the molar mass by the empirical formula weight. The resulting value gives the number of empirical formula units in the molecular formula.

The formula weight of $C_3H_4O_3$ is:

$$3 \times 12.0 \frac{g}{mol} + 4 \times 1.0 \frac{g}{mol} + 3 \times 16.0 \frac{g}{mol} = 88 \frac{g}{mol}$$

$$\frac{264 \frac{g}{mol}}{88 \frac{g}{mol}} = 3$$

$C_3H_4O_3 \times 3 = C_9H_{12}O_9$. The molecular formula is $C_9H_{12}O_9$.

Method Two: When the molar mass is given, it is generally easier to find the molecular formula first. This is accomplished by multiplying the molar mass by the given percentages to find the mass of each element present in one mole of compound, then dividing by the respective atomic weights to find the mole ratio of the elements:

$$\text{moles C} = \frac{(0.409)(264\text{ g})}{12 \frac{g}{mol}} \approx 9\text{ mol}$$

$$\text{moles H} = \frac{(0.0458)(264\text{ g})}{1 \frac{g}{mol}} \approx 12\text{ mol}$$

$$\text{moles O} = \frac{(0.5452)(264\text{ g})}{16 \frac{g}{mol}} \approx 9\text{ mol}$$

Thus, the molecular formula $C_9H_{12}O_9$ is the direct result. The empirical formula can now be found by reducing the subscript ratio to the simplest integer values ($C_3H_4O_3$).

MCAT Expertise

When there are two methods for approaching a problem, be well-versed in both. Knowing multiple ways to solve a problem will help you tackle questions efficiently.

Key Concept

The molecular formula is either the same as the empirical formula or a multiple of it. To calculate the molecular formula, you need to know the mole ratio (this will give you the empirical formula) and the molar mass (molar mass divided by empirical formula weight will give the multiplier for the empirical formula-to-molecular formula conversion).

MCAT Concept Check 4.2:
Before you move on, assess your understanding of the material with these questions.

1. What are some similarities and differences between molecular and empirical formulas?
   - Similarities:

     _____

   - Differences:

     _____

2. Find the percent composition (by mass) of sodium, carbon, and oxygen in sodium carbonate (Na_2CO_3):
   - Sodium:

     _____

   - Carbon:

     _____

   - Oxygen:

     _____

3. Experimental data from the combustion of an unknown compound indicates that it is 28.5% iron, 24.0% sulfur, and 49.7% oxygen by mass. What is its empirical formula?

_____

_____

_____

4.3 Types of Chemical Reactions ★

Bridge

Many of the reactions we will discuss here have analogues in *MCAT Organic Chemistry Review* and *MCAT Biochemistry Review*. Be sure to understand the relationships between the products and reactants because it will help simplify more advanced reactions.

This section reviews the major classes of chemical reactions. We will begin with a classification of major types of reactions seen on the MCAT and then discuss methods to recognize their products. It is important to understand the conventions of reaction mechanisms. In the following section, we will discuss how to properly balance chemical equations.

COMBINATION REACTIONS

Key Concept

Combination reactions have more reactants than products: **A + B → C**

A **combination reaction** has two or more reactants forming one product. The formation of water by burning hydrogen gas in air is an example of a combination reaction. This reaction is highlighted in Figure 4.2.

$$2\ H_2\ (g) + O_2\ (g) \rightarrow 2\ H_2O\ (g)$$

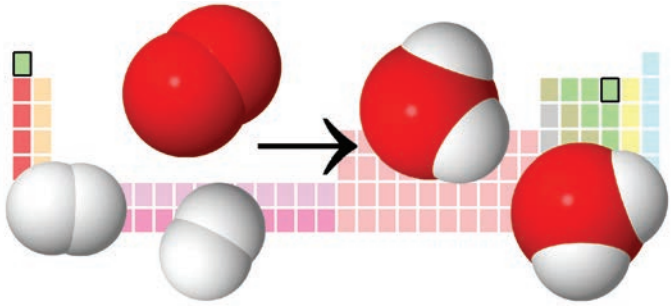

Figure 4.2. Formation of Water from Hydrogen and Oxygen

DECOMPOSITION REACTIONS

A **decomposition** reaction is the opposite of a combination reaction: a single reactant breaks down into two or more products, usually as a result of heating, high-frequency radiation, or electrolysis. An example of decomposition is the breakdown of mercury(II) oxide. (The Δ [delta] sign over a reaction arrow represents the addition of heat.)

$$2\ HgO\ (s) \xrightarrow{\Delta} 2\ Hg\ (l) + O_2\ (g)$$

An example of a reaction that utilizes high-frequency light is the decomposition of silver chloride in the presence of sunlight, shown in Figure 4.3. The ultraviolet component of sunlight has sufficient energy to catalyze certain chemical reactions.

Key Concept

Decomposition reactions generally have more products than reactants.

A → B + C

Figure 4.3. Decomposition of AgCl under Ultraviolet Light

Key Concept

Combustion involves oxidation (using O_2 or similar) of a fuel (typically a hydrocarbon).

MCAT Expertise

Combustion reactions are usually conducted with hydrocarbon fuels, but they can also use elements like sulfur or other compounds like sugars. The products can differ, but carbon dioxide and water are almost always present. Therefore, it is important to recognize the reactants and products of this reaction type because you may see it in various contexts.

COMBUSTION REACTIONS

A **combustion reaction** is a special type of reaction that involves a fuel—usually a hydrocarbon—and an oxidant (normally oxygen). In its most common form, these reactants form the two products of carbon dioxide and water. For example, the balanced equation expressing the combustion of methane is shown in Figure 4.4.

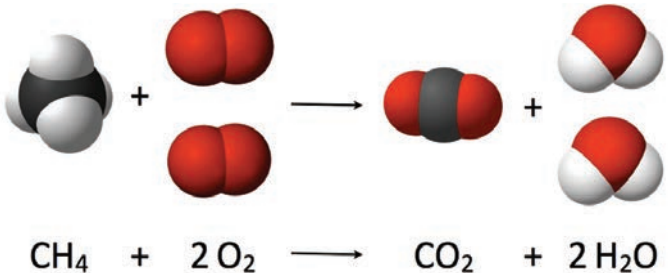

Figure 4.4. Combusion of Methane

SINGLE-DISPLACEMENT REACTIONS

A **single-displacement reaction** occurs when an atom or ion in a compound is replaced by an atom or ion of another element. For example, solid copper metal will displace silver ions in a clear solution of silver nitrate to form a blue copper nitrate solution and solid silver metal. The products of this reaction are shown in Figure 4.5.

$$Cu\ (s) + AgNO_3\ (aq) \rightarrow Ag\ (s) + CuNO_3\ (aq)$$

Figure 4.5. Single Displacement Reaction of Cu and $AgNO_3$
Solid silver deposits on the copper wire while copper ions dissolve in solution.

Single-displacement reactions are often further classified as oxidation–reduction reactions, which will be discussed in great detail in Chapter 11 of *MCAT General Chemistry Review*. For example, Ag in $AgNO_3$ has an oxidation state of +1, but

when it leaves the compound, it gains one electron (the Ag^+ is reduced to Ag). On the other hand, copper loses an electron (oxidation) when it joins the nitrate ion.

DOUBLE-DISPLACEMENT REACTIONS

In **double-displacement reactions**, also called **metathesis reactions**, elements from two different compounds swap places with each other to form two new compounds. This type of reaction occurs when one of the products is removed from the solution as a precipitate or gas or when two of the original species combine to form a weak electrolyte that remains undissociated in solution. For example, when solutions of calcium chloride and silver nitrate are combined, insoluble silver chloride forms in a solution of calcium nitrate.

$$CaCl_2\ (aq) + 2\ AgNO_3\ (aq) \rightarrow Ca(NO_3)_2\ (aq) + 2\ AgCl\ (s)$$

A series of double displacement reactions are shown in Figure 4.6. Shown are test tubes in which $Zn(NO_3)_2$ is dissolved in solutions to precipitate solid zinc salts. From left to right, the solutions are $(NH_4)_2S$, NaOH, and Na_2CO_3.

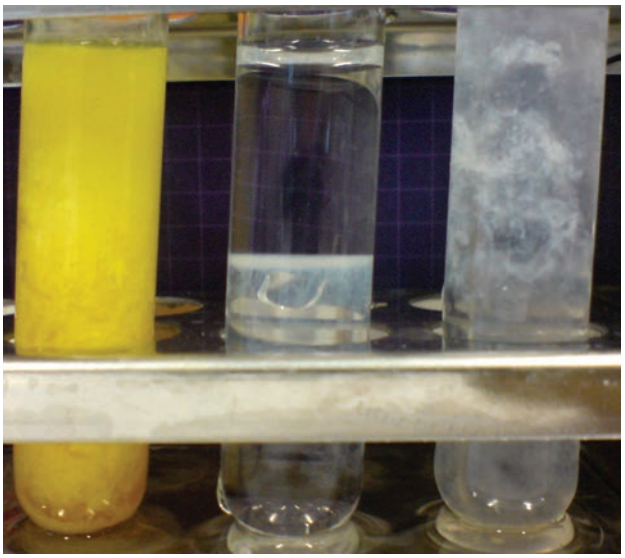

Figure 4.6. Double-Displacement Reactions forming Various Zinc Salts
Left: $(NH_4)_2S$ solution, producing ZnS (*s*). Middle: NaOH solution, producing $Zn(OH)_2$ (*s*). Right: Na_2CO_3 solution, producing $ZnCO_3$ (*s*).

NEUTRALIZATION REACTIONS

Neutralization reactions are a specific type of double-displacement reaction in which an acid reacts with a base to produce a salt (and, usually, water). For example, hydrochloric acid and sodium hydroxide will react to form sodium chloride and water:

$$HCl\ (aq) + NaOH\ (aq) \rightarrow NaCl\ (aq) + H_2O\ (l)$$

Bridge

Acids and bases combine in neutralization reactions to produce salts (and, usually, water). Acid–base chemistry is discussed in Chapter 10 of *MCAT General Chemistry Review*.

Reactions between acids and bases are not always visible. The addition of an indicator, as shown in Figure 4.7, can determine when the reaction has occurred.

Figure 4.7. Solutions of Increasing pH, Using Red Cabbage as a pH Indicator

MCAT Concept Check 4.3:

Before you move on, assess your understanding of the material with these questions.

1. Describe in words what occurs when $Zn(NO_3)_2$ is dissolved in $(NH_4)_2S$:

_____

_____

2. Complete and classify the most likely reactions in the table below:

Reactants	Conditions	Products	Reaction Type
$2\ H_2 + O_2$	$\rightarrow$		
$Al(OH)_3 + H_3PO_4$	$\rightarrow$		
$2\ H_2O$	$\xrightarrow{\text{electricity}}$		
$NaNO_3 + CuOH$	$\rightarrow$		
$Zn + AgCl$	$\rightarrow$		

4.4 Balancing Chemical Equations ★★

Because chemical equations express how much and what types of reactants must be used to obtain a given quantity of product, it is of utmost importance that the reaction be balanced so as to reflect the **laws of conservation of mass** and **charge**. The mass of the reactants consumed must equal the mass of products generated. More specifically, one must ensure that the number of atoms of each element on the reactant side equals the number of atoms of that element on the product side. **Stoichiometric coefficients**, which are the numbers placed in front of each compound, are used to indicate the relative number of moles of a given species involved in the reaction. For example, the balanced equation expressing the combustion of nonane is:

$$C_9H_{20}\,(g) + 14\,O_2\,(g) \rightarrow 9\,CO_2\,(g) + 10\,H_2O\,(l)$$

The coefficients indicate that one mole of C_9H_{20} gas must be reacted with fourteen moles of O_2 gas to produce nine moles of carbon dioxide and ten moles of water. In general, stoichiometric coefficients are given as whole numbers.

The steps taken to balance a chemical reaction are necessary to ensure that calculations regarding the reaction are performed correctly. Let's review the steps involved in balancing a chemical equation, using an example.

Example: Balance the following reaction:

$$C_4H_{10}\,(l) + O_2\,(g) \rightarrow CO_2\,(g) + H_2O\,(l)$$

Method One: First, balance the carbons (4 on reactant side) in the products.

$$C_4H_{10}\,(l) + O_2\,(g) \rightarrow \mathbf{4}\,CO_2\,(g) + H_2O\,(l)$$

Then, balance the hydrogens (10 on reactant side) in the products.

$$C_4H_{10}\,(l) + O_2\,(g) \rightarrow 4\,CO_2\,(g) + \mathbf{5}\,H_2O\,(l)$$

Next, balance the oxygens (now 13 on product side) in the reactants.

$$C_4H_{10}\,(l) + \frac{13}{2}\,O_2\,(g) \rightarrow 4\,CO_2\,(g) + 5\,H_2O\,(l)$$

Finally, produce a whole number ratio. In this case, double each coefficient.

$$2\,C_4H_{10}\,(l) + 13\,O_2\,(g) \rightarrow 8\,CO_2\,(g) + 10\,H_2O\,(l)$$

Finally, check that all of the elements and the total charges are balanced correctly. If there is a difference in total charge between the reactants and products, then the charge will also have to be balanced. (Instructions for balancing charge in oxidation–reduction reactions are found in Chapter 11 of *MCAT General Chemistry Review*.)

MCAT Expertise

It is unlikely that you will come across a question that explicitly asks you to balance an equation. However, you will need to recognize unbalanced reactions and quickly add the necessary coefficients. To balance a reaction, look at the number of atoms of each element and the charge on both sides (especially for oxidation–reduction reactions).

Key Concept

When balancing equations, focus on the least represented elements first and work your way to the most represented element of the reaction (usually oxygen or hydrogen). If you're stuck, take a guess for the coefficient of the first reactant and balance the remainder appropriately.

Method Two: First, if in doubt, take a guess. Assume there are 4 of the first reactant and balance the carbons appropriately.

$$\mathbf{4}\ C_4H_{10}\ (l) + O_2\ (g) \rightarrow \mathbf{16}\ CO_2\ (g) + H_2O\ (l)$$

Second, balance the hydrogens (40 on reactant side) in the products.

$$4\ C_4H_{10}\ (l) + O_2\ (g) \rightarrow 16\ CO_2\ (g) + \mathbf{20}\ H_2O\ (l)$$

Third, balance the oxygens (now 52 on product side) in the reactants.

$$4\ C_4H_{10}\ (l) + \mathbf{26}\ O_2\ (g) \rightarrow 16\ CO_2\ (g) + 20\ H_2O\ (l)$$

Fourth, produce the simplest whole number ratio through the greatest common factor. In this case, divide each side by 2.

$$2\ C_4H_{10}\ (l) + 13\ O_2\ (g) \rightarrow 8\ CO_2\ (g) + 10\ H_2O\ (l)$$

Finally, check that all of the elements and the total charges are balanced correctly. Notice that both methods produce a multiple of our final answer. These ratios are not incorrect, but in terms of the stoichiometry one performs on the MCAT, the simpler the numbers are, the easier calculations will become.

MCAT Concept Check 4.4:

Before you move on, assess your understanding of the material with this question.

1. Balance the following reactions:
   - ___ Fe + ___ $Cl_2 \rightarrow$ ___ $FeCl_3$
   - ___ Zn + ___ $HCl \rightarrow$ ___ $ZnCl_2$ + ___ H_2
   - ___ C_5H_{12} + ___ $O_2 \rightarrow$ ___ CO_2 + ___ H_2O
   - ___ $Pb(NO_3)_2$ + ___ $AlCl_3 \rightarrow$ ___ $PbCl_2$ + ___ $Al(NO_3)_3$

4.5 Applications of Stoichiometry ★★

Perhaps the most useful information to glean from a balanced reaction is the mole ratio of reactants consumed to products generated. One can also generate the mole ratio of one reactant to another or one product to another. All of these ratios can be generated using the stoichiometric coefficients. In the formation of water ($2\ H_2 + O_2 \rightarrow 2\ H_2O$), for example, one can determine that, for every one mole of hydrogen gas consumed, one mole of water can be produced; for

every one mole of oxygen gas consumed, two moles of water can be produced. Furthermore, mole-to-mole, hydrogen gas is being consumed at a rate twice that of oxygen gas.

Stoichiometry problems usually involve at least a few unit conversions, so take care when working through these types of problems to ensure that units cancel out appropriately to lead to the desired units of the answer choices. Pay close attention to the following problem, which demonstrates a clear and easy-to-follow method for keeping track of the numbers, calculations, and unit conversions.

Example: How many grams of calcium chloride are needed to prepare 71.7 g of silver chloride according to the following equation?

$$CaCl_2\,(aq) + 2\,AgNO_3\,(aq) \rightarrow Ca(NO_3)_2\,(aq) + 2\,AgCl\,(s)$$

Solution: Noting first that the equation is balanced, 1 mole of $CaCl_2$ yields 2 moles of AgCl when it is reacted with 2 moles of $AgNO_3$. The molar mass of $CaCl_2$ is 111.1 g, and the molar mass of AgCl is 143.4 g. Our given quantity is 71.7 g AgCl.

$$71.7\text{ g AgCl} \times \left[\frac{1\text{ mol AgCl}}{143.4\text{ g AgCl}}\right]\left[\frac{1\text{ mol CaCl}_2}{2\text{ mol AgCl}}\right]\left[\frac{111.1\text{ g CaCl}_2}{1\text{ mol CaCl}_2}\right] \approx 27.8\text{ g CaCl}_2$$

Thus, about 27.8 g $CaCl_2$ are needed to produce 71.7 g AgCl.

LIMITING REAGENT

Rarely are reactants added in the exact stoichiometric proportions shown in the balanced equation of a reaction. As a result, in most reactions, one reactant will be used up or consumed first. This reactant is known as the **limiting reagent** (or reactant) because it limits the amount of product that can be formed in the reaction. The reactants that remain after all the limiting reagent is used up are called **excess reagents** (or reactants).

Figure 4.8 shows a reaction vessel that has significant amounts of reactants A and B, which react in equal amounts to produce product C. On the left, before the reaction, there is more reactant A than B. After the reaction is over, there is more product C but there is reactant A left over. Thus, reactant A is considered in excess, and reactant B is considered limiting.

Key Concept

Stoichiometry, an application of dimensional analysis, is often simplified to a series of three fractions. These fractions demonstrate an underlying three-step process:

- Convert from the given units to moles
- Use the mole ratio
- Convert from moles to the desired units

MCAT Expertise

Common conversions used in stoichiometry include:

- 1 mole of any ideal gas at STP = 22.4 L
- 1 mole of any substance = 6.022×10^{23} particles (Avogadro's number)
- 1 mole of any substance = its molar mass (from the periodic table)

MCAT Expertise

When the quantities of two reactants are given on the MCAT, expect to have to figure out which is the limiting reagent.

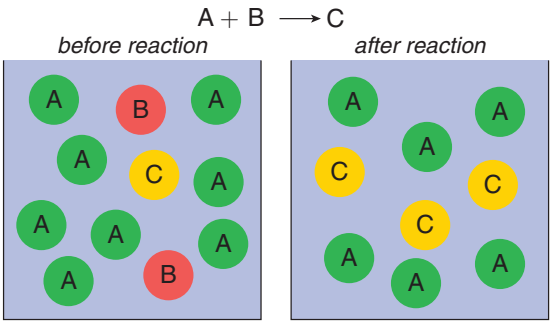

Figure 4.8. Reaction with a Limiting Reagent
A is considered an excess reagent; B is the limiting reagent.

For problems involving the determination of the limiting reagent, keep in mind two principles:

1. All comparisons of reactants must be done in units of moles. Gram-to-gram comparisons will be useless and may even be misleading.
2. It is not the absolute mole quantities of the reactants that determine which reactant is the limiting reagent. Rather, the rate at which the reactants are consumed (the stoichiometric ratios of the reactants), combined with the absolute mole quantities determines which reactant is the limiting reagent.

Example: If 27.9 g of Fe react with 24.1 g of S to produce FeS, what would be the limiting reagent? How many grams of excess reagent would be present in the vessel at the end of the reaction?

The balanced equation is Fe + S → FeS.

Solution: First, determine the number of moles for each reactant.

$$27.9\ \text{g Fe} \times \frac{1\ \text{mol Fe}}{55.8\ \text{g Fe}} = 0.5\ \text{mol Fe}$$

$$24.1\ \text{g S} \times \frac{1\ \text{mol S}}{32.1\ \text{g S}} = 0.75\ \text{mol S}$$

Because 1 mole of Fe is needed to react with 1 mole of S and there are 0.5 moles Fe for the given 0.75 moles S, the limiting reagent is Fe. Thus, 0.5 moles of Fe will react with 0.5 moles of S, leaving an excess of 0.25 moles of S in the vessel. The mass of the excess reagent will be:

$$0.25\ \text{mol} \times \frac{32.1\ \text{g S}}{1\ \text{mol S}} = 8\ \text{g S}$$

YIELD

The **yield** of a reaction can refer to either the amount of product predicted (theoretical yield) or actually obtained (raw or actual yield) when a reaction is carried

out. **Theoretical yield** is the maximum amount of product that can be generated as predicted from the balanced equation, assuming that all of the limiting reactant is consumed, no side reactions have occurred, and the entire product has been collected. Theoretical yield is rarely ever attained through the actual chemical reaction. **Actual yield** is the amount of product one actually obtains during the reaction. The ratio of the actual yield to the theoretical yield, multiplied by 100 percent, gives the **percent yield**:

$$\text{Percent yield} = \frac{\text{Actual yield}}{\text{Theoretical yield}} \times 100\%$$

Equation 4.6

Example: What is the percent yield for a reaction in which 27 g of Cu is produced by reacting 32.7 g of Zn in excess $CuSO_4$ solution?

Solution: The balanced equation is as follows:

$$Zn\,(s) + CuSO_4\,(aq) \rightarrow Cu\,(s) + ZnSO_4\,(aq)$$

Calculate the theoretical yield for Cu.

$$32.7\text{ g Zn} \times \left[\frac{1\text{ mol Zn}}{65.4\text{ g Zn}}\right]\left[\frac{1\text{ mol Cu}}{1\text{ mol Zn}}\right]\left[\frac{63.5\text{ g Cu}}{1\text{ mol Cu}}\right] \approx 31.8\text{ g Cu}$$

This 31.8 g represents the theoretical yield. Finally, determine the percent yield.

$$\frac{27\text{ g}}{31.8\text{ g}} \times 100\% = 85\%$$

MCAT Concept Check 4.5:

Before you move on, assess your understanding of the material with these questions.

Questions 1–3 refer to the following unbalanced equation:

$$Na\,(s) + O_2\,(g) \rightarrow Na_2O\,(s)$$

1. Balance the chemical equation: ___ $Na\,(s)$ + ___ $O_2\,(g)$ → ___ $Na_2O\,(s)$
2. If 50 g Na and 30 g O_2 are provided, find the maximum number of moles of sodium oxide produced.

_____

_____

3. Identify the limiting reagent, and find the mass of the excess reagent left over once the reaction has run to completion.

_____

_____

MCAT Expertise

An experimentally based passage that involves a chemical reaction may include a pseudo-discrete question that involves finding the percent yield.

4. $Be(OH)_2$ is produced when water reacts with BeO. If one starts with 2 kg BeO in excess water, and produces 1.1 kg $Be(OH)_2$, what is the percent yield of this reaction?

_____

_____

_____

4.6 Ions ★★★

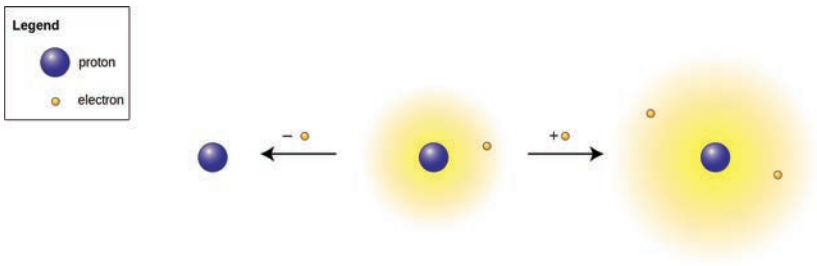
Ionic compounds are of particular interest to chemists because certain important types of chemical reactions—acid–base and oxidation–reduction reactions, for instance—commonly take place in ionic solutions. For stoichiometry problems, the goal with ions is to identify oxidation states. This will allow us to determine electron equivalents, balance equations, and deduce chemical formulas from nomenclature.

Bridge

The magnitude of the electrostatic force in an ionic bond follows the same conventions described for Coulomb's law in Chapter 5 of *MCAT Physics and Math Review*. The distance between nuclei in ionic bonds is inversely proportional to the force. Therefore, ionic compounds with long bond distances are much more weakly held together.

CATIONS AND ANIONS

In Chapter 3 of *MCAT General Chemistry Review*, we discussed how ionic compounds are made up of positively charged **cations**, usually metals, and negatively charged **anions**, usually nonmetals. This rule does not always hold true for elements like hydrogen, which can act like an anion or cation but is still classified as a nonmetal, as shown in Figure 4.9. Ionic compounds are held together by **ionic bonds**, which rely on the force of electrostatic attraction between oppositely charged particles.



No. of protons	1	1	1
No. of electrons	0	1	2
Charge	+1	0	−1
Notation	H^+	H	H^-
Classification	cation	neutral (not an ion)	anion

Figure 4.9. Oxidation States of Hydrogen

The nomenclature of ionic compounds is based on the names of the component ions:

1. For elements (usually metals) that can form more than one positive ion, the charge is indicated by a Roman numeral in parentheses following the name of the element.

Fe^{2+}	Iron(II)	Cu^{+}	Copper(I)
Fe^{3+}	Iron(III)	Cu^{2+}	Copper(II)

2. An older, less commonly used method is to add the endings ***–ous*** or ***–ic*** to the root of the Latin name of the element to represent the ions with lesser and greater charge, respectively.

Fe^{2+}	Ferrous	Cu^{+}	Cuprous
Fe^{3+}	Ferric	Cu^{2+}	Cupric

3. Monatomic anions are named by dropping the ending of the name of the element and adding ***–ide***.

H^{-}	Hydride	S^{2-}	Sulfide
F^{-}	Fluoride	N^{3-}	Nitride
O^{2-}	Oxide	P^{3-}	Phosphide

4. Many polyatomic anions contain oxygen and are therefore called **oxyanions**. When an element forms two oxyanions, the name of the one with less oxygen ends in ***–ite***, and the one with more oxygen ends in ***–ate***.

NO_2^{-}	Nitrite	SO_3^{2-}	Sulfite
NO_3^{-}	Nitrate	SO_4^{2-}	Sulfate

5. In extended series of oxyanions, prefixes are also used. ***Hypo–*** and hyper, written as ***per–***, are used to indicate less oxygen and more oxygen, respectively.

ClO^{-}	Hypochlorite
ClO_2^{-}	Chlorite
ClO_3^{-}	Chlorate
ClO_4^{-}	Perchlorate

6. Polyatomic anions often gain one or more H^{+} ions to form anions of lower charge. The resulting ions are named by adding the word **hydrogen** or **dihydrogen** to the front of the anion's name. An older method uses the prefix ***bi–*** to indicate the addition of a single hydrogen ion.

HCO_3^{-}	Hydrogen carbonate or bicarbonate

MCAT Expertise

It is unlikely that *–ous* or *–ic* endings will be required for most problem-solving. Passages tend to provide reaction schemes that allow you to deduce any unfamiliar compound's formulas. However, it is still important to understand the nomenclature for discrete questions.

Mnemonic

The "**lite**st" anions have the fewest oxygens; the heaviest anions **ate** the most oxygens.

HSO_4^-	Hydrogen sulfate or bisulfate
$H_2PO_4^-$	Dihydrogen phosphate

7. Other common polyatomic ions that may be useful to know are in Table 4.1.

Charge	Formula	Name
+1	NH_4^+	Ammonium
−1	$C_2H_3O_2^-$	Acetate
	CN^-	Cyanide
	MnO_4^-	Permanganate
	SCN^-	Thiocyanate
−2	CrO_4^{2-}	Chromate
	$Cr_2O_7^{2-}$	Dichromate
−3	BO_3^{3-}	Borate

Table 4.1. Other Common Polyatomic Ions

ION CHARGES

Ionic species, by definition, have charge. Cations have positive charge, and anions have negative charge. Some elements are only found naturally in their charged forms, while others may exist naturally in the charged or uncharged state. Some elements can even have several different charges or **oxidation states**, depending on the other atoms in a compound.

Some of the charged atoms or molecules that are on the MCAT include the active metals—the alkali metals (Group IA or Group 1) and the alkaline earth metals (Group IIA or Group 2), which have charges of +1 and +2, respectively, in the natural state.

Bridge

Remember that alkali metals are not typically found in nature in their uncharged state because they are highly reactive with moisture. Instead, they are found as cations in salts (like NaCl).

Nonmetals, which are found on the right side of the periodic table, generally form anions. For example, all the halogens (Group VIIA or Group 17) form monatomic anions with a charge of –1 because they already have 7 electrons and aim to fill an octet.

In summary, all elements in a given group tend to form monatomic ions with the same charge (for example, all Group IA elements have a charge of +1 in their ionic state). Note that there are anionic species that contain metallic elements (for example, MnO_4^- [permanganate] and CrO_4^{2-} [chromate]); even so, the metals have positive oxidation states. Also note that in the oxyanions of the halogens, such as ClO^- and ClO_2^-, the halogen is assigned a positive oxidation state.

Bridge

Oxyanions of transition metals like the MnO_4^- and CrO_4^{2-} ions have an inordinately high oxidation number on the metal. As such, they tend to gain electrons in order to reduce this oxidation number and thus make good oxidizing agents. Good oxidizing and reducing agents are discussed in Chapter 4 of *MCAT Organic Chemistry Review*.

For nonrepresentative elements like many of the transition metals, such as copper, iron, and chromium, there are numerous positively charged states. These states need not be memorized. Qualitatively, the color of a solution can be indicative of the oxidation state of a given element in the solution. The same element in different oxidation states can undergo different electron transitions and therefore absorb different frequencies of light. In Figure 4.10, this phenomenon is shown for various plutonium salts with different oxidation states for plutonium indicated in Roman numerals.

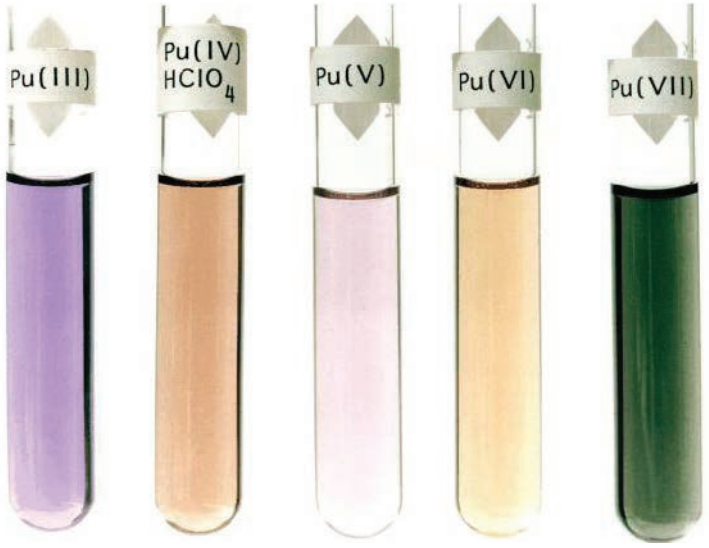


Figure 4.10. Solutions with Various Plutonium Oxidation States

The trends of **ionicity**, as we've described here, are helpful but are complicated by the fact that many elements have intermediate electronegativity and are consequently less likely to form ionic compounds, and by the left-to-right transition from metallic to nonmetallic character on the periodic table.

ELECTROLYTES

In spite of the fact that ionic compounds are composed of ions, solid ionic compounds tend to be poor conductors of electricity because the charged particles are rigidly set in place by the lattice arrangement of the crystalline solid. In aqueous solutions, however, the lattice arrangement is disrupted by the ion–dipole interactions between the ionic components and the water molecules. The cations and anions are now free to move, and as a result, the solution of ions is able to conduct electricity.

Solutes that enable solutions to carry currents are called **electrolytes**. The electrical conductivity of aqueous solutions is governed by the presence and concentration of ions in the solution. Subsequently, the number of electron equivalents being

MCAT Expertise

Ionic compounds make good electrolytes because they dissolve most readily. Nonpolar covalent compounds are the weakest because they do not form current-carrying ions.

transferred in such a system, such as in electrochemical cells, varies. Pure water, which has no ions other than the very few hydrogen ions and hydroxide ions that result from water's low-level autodissociation, is a very poor conductor.

The tendency of an ionic solute to dissolve, or **solvate**, into its constituent ions in water may be high or low. A solute is considered a strong electrolyte if it dissociates completely into its constituent ions. Examples of strong electrolytes include certain ionic compounds, such as NaCl and KI, and molecular compounds with highly polar covalent bonds that dissociate into ions when dissolved, such as HCl in water. An example of solvation of such compounds is shown in Figure 4.11.

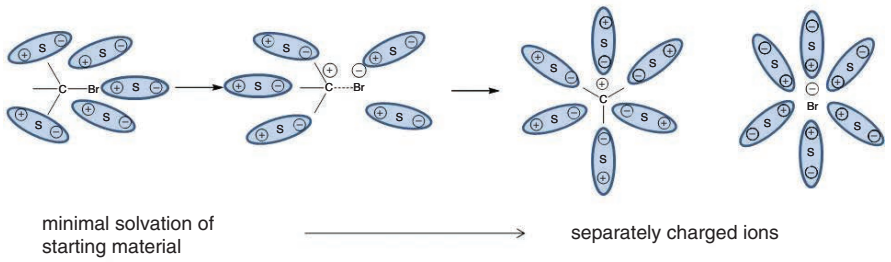

Figure 4.11. Solvation of a Polar Covalent Compound
S indicates a solvent particle.

Bridge

Because electrolytes ionize in solution, they will produce a larger effect on colligative properties, described in Chapter 9 of *MCAT General Chemistry Review*, than one would expect from the given concentration.

A weak electrolyte, on the other hand, ionizes or hydrolyzes incompletely in aqueous solution, and only some of the solute is dissolved into its ionic constituents. Examples include Hg_2I_2 ($K_{sp} = 4.5 \times 10^{-29}$), acetic acid and other weak acids, and ammonia and other weak bases. Many compounds do not ionize at all in water, retaining their molecular structure in solution, which may also limit their solubility. These compounds are called nonelectrolytes and include many nonpolar gases and organic compounds, such as O_2 (g), CO_2 (g), and glucose.

MCAT Concept Check 4.6:
Before you move on, assess your understanding of the material with these questions.

1. Label the following solutions as electrolytes or nonelectrolytes: (Note: Assume these compounds are all in aqueous solution.)
   - HCl Electrolyte Nonelectrolyte
   - Sucrose Electrolyte Nonelectrolyte
   - $MgBr_2$ Electrolyte Nonelectrolyte
   - CH_4 Electrolyte Nonelectrolyte

2. Identify the following ions as cations or anions, and then provide the formula or chemical symbol:

Ion	Cation or Anion	Formula
Phosphate		
Hypochlorite		
Ammonium		
Phosphide		
Bicarbonate		
Nitrite		
Chromium(II)		

Conclusion

We began our consideration of compounds with benzaldehyde. As a compound, it is made from constituent atoms of different elements in a set ratio defined by its empirical or molecular formula. Each molecule of a compound has a defined mass that is measured as its molecular weight. The mass of one mole of any compound is determined from its molar mass in the units of grams per mole. We reviewed the basic classifications of reactions commonly tested on the MCAT: combination, decomposition, combustion, single-displacement, double-displacement, and neutralization reactions. Furthermore, we are now confident in our understanding of the steps necessary to balance any chemical reaction; we are ready to tackle more stoichiometric problems in preparation for Test Day.

Before moving to the next chapters discussing chemical kinetics and thermodynamics, let us offer our congratulations to you. By completing these first four chapters, you have been introduced to the fundamental concepts of chemistry—everything from the structure of the atom and trends of the elements to bonding and the formation of compounds. The understanding you have gained so far will be the foundation for your comprehension of even the most difficult general chemistry concepts tested on the MCAT. Keep moving forward with your review of general chemistry; don't get stuck in the details. Those details will be learned best through the application of the basic principles to MCAT practice passages and questions.

CONCEPT SUMMARY

Molecules and Moles

- **Compounds** are substances composed of two or more elements in a fixed proportion.
- **Molecular weight** is the mass (in amu) of the constituent atoms in a compound as indicated by the molecular formula.
- **Molar mass** is the mass of one mole (**Avogadro's number** or 6.022×10^{23} particles) of a compound; usually measured in grams per mole.
- **Gram equivalent weight** is a measure of the mass of a substance that can donate one equivalent of the species of interest.
- **Normality** is the ratio of equivalents per liter; it is related to **molarity** by multiplying the molarity by the number of equivalents present per mole of compound.
- **Equivalents** are moles of the species of interest; equivalents are most often seen in acid–base chemistry (hydrogen ions or hydroxide ions) and oxidation–reduction reactions (moles of electrons or other ions).

Representation of Compounds

- The **law of constant composition** states that any pure sample of a compound will contain the same elements in the same mass ratio.
- The **empirical formula** is the smallest whole-number ratio of the elements in a compound.
- The **molecular formula** is either the same as or a multiple of the empirical formula; it gives the exact number of atoms of each element in a compound.
- To calculate **percent composition** by mass, determine the mass of the individual element and divide by the molar mass of the compound.

Types of Chemical Reactions

- **Combination reactions** occur when two or more reactants combine to form one product.
- **Decomposition reactions** occur when one reactant is chemically broken down into two or more products.
- **Combustion reactions** occur when a fuel and an oxidant (typically oxygen) react, forming the products water and carbon dioxide (if the fuel is a hydrocarbon).
- **Displacement reactions** occur when one or more atoms or ions of one compound are replaced with one or more atoms or ions of another compound.
    - **Single-displacement reactions** occur when an ion of one compound is replaced with another element.

- **Double-displacement reactions** occur when elements from two different compounds trade places with each other to form two new compounds.

- **Neutralization reactions** are those in which an acid reacts with a base to form a salt (and, usually, water).

Balancing Chemical Equations

- Chemical equations must be balanced to perform stoichiometric calculations.
- **Balanced equations** are determined using the following steps in order:
  - Balancing the least common atoms.
  - Balancing the more common atoms (usually hydrogen and oxygen).
  - Balancing charge, if necessary.

Applications of Stoichiometry

- Balanced equations can be used to determine the **limiting reagent**, which is the reactant that will be consumed first in a chemical reaction.
- The other reactants present are termed **excess reagents**.
- **Theoretical yield** is the amount of product generated if all of the limiting reactant is consumed with no side reactions.
- **Actual yield** is typically lower than theoretical yield.
- **Percent yield** is calculated by dividing actual yield by theoretical yield and converting to a percentage.

Ions

- Like organic chemistry, ions in general chemistry have a system of nomenclature:
  - Roman numerals are used for nonrepresentative elements to denote ionic charge.
  - ***–ous*** endings can also be used to indicate lesser charge, while ***–ic*** endings indicate greater charge.
  - All monatomic anions end in ***–ide***.
  - Oxyanions are given a suffix indicating how oxidized the central atom is. Those that contain a lesser amount of oxygen are given the suffix ***–ite***, and those with a greater amount are given the suffix ***–ate***.
  - Oxyanion series with more than two members are given an additional level of nomenclature. The species with the fewest oxygens is given the prefix ***hypo***–, and the species with the most oxygens is given the prefix ***per***–.
  - Polyatomic ions containing hydrogen denote the number of hydrogens using ***hydrogen*** or ***bi***– to denote one, or ***dihydrogen*** to denote two.

- **Ionic charges** are predictable by group number and type of element (metal or nonmetal) for representative elements, but are generally unpredictable for nonrepresentative elements.
  - Metals form positively charged cations based on group number.
  - Nonmetals form negatively charged anions based on the number of electrons needed to achieve an octet.
- **Electrolytes** contain equivalents of ions from molecules that dissociate in solution. The strength of an electrolyte depends on its degree of dissociation or **solvation**.

ANSWERS TO CONCEPT CHECKS

4.1

1. NaBr: 102.9 $\frac{g}{mol}$; $CuCl_2$: 134.5 $\frac{g}{mol}$; $C_6H_{12}O_6$: 180 $\frac{g}{mol}$
2. NaBr: 0.97 mol; $CuCl_2$: 0.74 mol; $C_6H_{12}O_6$: 0.56 mol
3. Both values equal one mole of the given substance. The number of entities in a mole is always the same (Avogadro's number, 6.022×10^{23} mol^{-1}).
4. 0.25 *M* $H_3PO_4 \times \frac{3 \text{ mol } H^+}{\text{mol } H_3PO_4} = 0.75$ *N* H_3PO_4. 95 g PO_4^{3-} (molar mass = 95 $\frac{g}{mol}$) in 100 mL solution = 950 g PO_4^{3-} per liter solution = 10 *M* $PO_4^{3-} \times \frac{3 \text{ mol } H^+}{\text{mol } PO_4^{3-}} =$ 30 *N* PO_4^{3-}

4.2

1. Both molecular and empirical formulas contain the same elements in the same ratios. They differ in that molecular formulas give the actual number of atoms of each element in the compound; empirical formulas give only the ratio and therefore may or may not give the actual number of atoms.
2. The molar mass of sodium carbonate is 106 $\frac{g}{mol}$. The percent compositions are: Na: $\frac{2 \times \left(23 \frac{g}{mol}\right)}{106 \frac{g}{mol}} = 43.4\%$ Na; C: $\frac{1 \times \left(12 \frac{g}{mol}\right)}{106 \frac{g}{mol}} = 11.3\%$; O: $\frac{3 \times \left(16 \frac{g}{mol}\right)}{106 \frac{g}{mol}} = 45.3\%$
3. Assuming a 100 g compound: 28.5 g Fe, 24.0 g S, and 49.7 g O. Using the atomic weight, there are about 0.5 mol Fe, 0.75 mol S, and 3 mol O. Divide by lowest number of moles to find the Fe:S:O ratio of 1:1.5:6. Multiply by 2 to find the smallest whole number ratio of $Fe_2S_3O_{12}$.

4.3

1. Ammonium cations swap places with (or displace) zinc cations yielding ammonium nitrate and zinc(II) sulfide. Zinc(II) sulfide then precipitates out of solution as a solid salt.
2.

Reactants	Conditions	Products	Reaction Type
$2\ H_2 + O_2$	$\rightarrow$	$2\ H_2O$	Combination
$Al(OH)_3 + H_3PO_4$	$\rightarrow$	$3\ H_2O + AlPO_4$	Neutralization (a type of double-displacement)
$2\ H_2O$	$\xrightarrow{\text{electricity}}$	$2\ H_2 + O_2$	Decomposition
$NaNO_3 + CuOH$	$\rightarrow$	$NaOH + CuNO_3$	Double-displacement (metathesis)
$Zn + AgCl$	$\rightarrow$	$ZnCl + Ag$	Single-displacement

4.4

- $2\ Fe + 3\ Cl_2 \rightarrow 2\ FeCl_3$
- $Zn + 2\ HCl \rightarrow ZnCl_2 + H_2$
- $C_5H_{12} + 8\ O_2 \rightarrow 5\ CO_2 + 6\ H_2O$
- $3\ Pb(NO_3)_2 + 2\ AlCl_3 \rightarrow 3\ PbCl_2 + 2\ Al(NO_3)_3$

4.5

1. $4\ Na\ (s) + O_2\ (g) \rightarrow 2\ Na_2O\ (s)$
2. $50\ g\ Na \times \left[\frac{1\ mol\ Na}{23\ g\ Na}\right] = 2.17\ mol\ Na$; $30\ g\ O_2 \times \left[\frac{1\ mol\ O_2}{32\ g\ O_2}\right] = 0.94\ mol\ O_2$
   Because 4 sodium atoms are needed for every oxygen molecule, sodium will run out first. To determine the amount of Na_2O formed: $2.17\ mol\ Na \times \left[\frac{2\ mol\ Na_2O}{4\ mol\ Na}\right] = 1.09\ mol\ Na_2O$
3. The limiting reagent is Na because 4 sodium atoms are needed for every oxygen molecule. $2.17\ mol\ Na \times \left[\frac{1\ mol\ O_2}{4\ mol\ Na}\right] = 0.54\ mol\ O_2$ will be used, so $0.94 - 0.54\ mol\ O_2 = 0.40\ mol\ O_2$ will remain, representing $0.40\ mol\ O_2 \times \left[\frac{32\ g\ O_2}{1\ mol\ O_2}\right] = 12.8\ g$ excess O_2
4. Reaction: $BeO + H_2O \rightarrow Be(OH)_2$
   Theoretical yield:
   $2000\ g\ BeO \times \left[\frac{1\ mol\ BeO}{25\ g\ BeO}\right]\left[\frac{1\ mol\ Be(OH)_2}{1\ mol\ BeO}\right]\left[\frac{43\ g\ Be(OH)_2}{1\ mol\ Be(OH)_2}\right] = 3440\ g\ Be(OH)_2$
   $\text{Percent yield} = \frac{\text{Actual yield}}{\text{Theoretical yield}} \times 100\% = \frac{1100\ g}{3440\ g} \times 100\% = 32\%$ yield

4.6

1. Electrolytes: HCl, $MgBr_2$; Nonelectrolytes: sucrose, CH_4
2.

Ion	Cation or Anion	Formula
Phosphate	Anion	PO_4^{3-}
Hypochlorite	Anion	ClO^-
Ammonium	Cation	NH_4^+
Phosphide	Anion	P^{3-}
Bicarbonate	Anion	HCO_3^-
Nitrite	Anion	NO_2^-
Chromium(II)	Cation	Cr^{2+}

EQUATIONS TO REMEMBER

(4.1) **Moles from mass:** $\text{Moles} = \dfrac{\text{Mass of a sample}}{\text{Molar mass}}$

(4.2) **Gram equivalent weight:** $\text{GEW} = \dfrac{\text{Molar mass}}{n}$

(4.3) **Equivalents from mass:** $\text{Equivalents} = \dfrac{\text{Mass of compound}}{\text{Gram equivalent weight}}$

(4.4) **Molarity from normality:** $\text{Molarity} = \dfrac{\text{Normality}}{n}$

(4.5) **Percent composition:** $\%\ \text{composition} = \dfrac{\text{Mass of element in formula}}{\text{Molar mass}} \times 100\%$

(4.6) **Percent yield:** $\%\ \text{yield} = \dfrac{\text{Actual yield}}{\text{Theoretical yield}} \times 100\%$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following best describes ionic compounds?

A. Ionic compounds are formed from molecules containing two or more atoms.
B. Ionic compounds are formed of charged particles and are measured by molecular weight.
C. Ionic compounds are formed of charged particles that share electrons equally.
D. Ionic compounds are three-dimensional arrays of charged particles.

2. Which of the following compounds has a formula weight between 74 and 75 grams per mole?

A. KCl
B. $C_4H_{10}O$
C. $MgCl_2$
D. BF_3

3. Which of the following is the gram equivalent weight of H_2SO_4 with respect to protons?

A. 49.1 g
B. 98.1 g
C. 147.1 g
D. 196.2 g

4. Which of the following molecules CANNOT be expressed by the empirical formula CH?

A. Benzene
B. Ethyne
C. D. 
5. In which of the following compounds is the percent composition of carbon by mass closest to 62 percent?

A. Acetone
B. Ethanol
C. C_3H_8
D. Methanol

6. What is the most specific characterization of the reaction shown?

$$Ca(OH)_2\ (aq) + H_2SO_4\ (aq) \rightarrow CaSO_4\ (aq) + H_2O\ (l)$$

A. Single-displacement
B. Neutralization
C. Double-displacement
D. Oxidation–reduction

7. In the reaction shown, if 39.05 g of Na_2S are reacted with 113.3 g of $AgNO_3$, how much of the excess reagent will be left over once the reaction has gone to completion?

$$Na_2S + 2\ AgNO_3 \rightarrow Ag_2S + 2\ NaNO_3$$

A. 13.0 g Na_2S
B. 26.0 g Na_2S
C. 41.4 g $AgNO_3$
D. 74.3 g $AgNO_3$

8. Using a given mass of $KClO_3$, how would one calculate the mass of oxygen produced in the following reaction, assuming it goes to completion?

$$2\ KClO_3 \rightarrow 2\ KCl + 3\ O_2$$

A. $\dfrac{(\text{grams } KClO_3 \text{ consumed})(3 \text{ moles } O_2)(\text{molar mass } O_2)}{(\text{molar mass } KClO_3)(2 \text{ moles } KClO_3)}$

B. $\dfrac{(\text{grams } KClO_3 \text{ consumed})(\text{molar mass } O_2)}{(\text{molar mass } KClO_3)(2 \text{ moles } KClO_3)}$

C. $\frac{(\text{molar mass } KClO_3)(2 \text{ moles } KClO_3)}{(\text{grams } KClO_3 \text{ consumed})(\text{molar mass } O_2)}$

D. $\frac{(\text{grams } KClO_3 \text{ consumed})(3 \text{ moles } O_2)}{(\text{molar mass } KClO_3)(2 \text{ moles } KClO_3)(\text{molar mass } O_2)}$

9. Aluminum metal can be used to remove tarnish from silver when the two solid metals are placed in water, according to the following reaction:

$$3\ AgO + 2\ Al \rightarrow 3\ Ag + Al_2O_3$$

This reaction is a:

I. double-displacement reaction.

II. single-displacement reaction.

III. oxidation–reduction reaction.

IV. combination reaction.

A. II only
B. IV only
C. I and III only
D. II and III only

10. Which of the following types of reactions generally have the same number of reactants and products?

I. Double-displacement reactions

II. Single-displacement reactions

III. Combination reactions

A. I only
B. II only
C. I and II only
D. II and III only

11. A reaction that utilizes oxygen and hydrocarbons as reactants and that produces carbon dioxide and water as products is best characterized as:

A. single-displacement.
B. combustion.
C. metathesis.
D. decomposition.

12. In the process of photosynthesis, carbon dioxide and water combine with energy to form glucose and oxygen, according to the following equation:

$$CO_2 + H_2O \xrightarrow{h\nu} C_6H_{12}O_6 + O_2$$

What is the theoretical yield of glucose if 30 grams of water are reacted with excess carbon dioxide and energy, according to the equation above?

A. 30.0 g
B. 50.0 g
C. 300.1 g
D. 1801 g

13. In the following reaction:

$$Au_2S_3\ (s) + H_2\ (g) \rightarrow Au\ (s) + H_2S\ (g)$$

If 2 moles of Au_2S_3 (s) is reacted with 5 moles of hydrogen gas, what is the limiting reagent?

A. Au_2S_3 (s)
B. H_2 (g)
C. Au (s)
D. H_2S (g)

14. Which of the following would make the strongest electrolytic solution?

A. A nonpolar covalent compound with significant solubility.
B. An ionic compound composed of one cation with +3 charge and three anions with –1 charge.
C. A polar covalent compound with a small dissociation constant.
D. An ionic compound composed of two cations with +1 charge and one anion with –2 charge.

15. What is the molecular formula of a compound with an empirical formula of B_2H_5 and a molar mass of $53.2 \frac{g}{mol}$?

A. B_2H_5
B. B_3H_7
C. B_4H_{10}
D. B_6H_{15}

Explanations to Discrete Practice Questions

1. D

Ionic compounds are composed of atoms held together by ionic bonds. Ionic bonds associate charged particles with large differences in electronegativity. Rather than forming molecules or being measured by molecular weight, as in **choices (A)** and **(B)**, ionic compounds form large arrays of ions in crystalline solids and are measured with formula weights. In ionic bonds, electrons are not really shared but rather are donated from the less electronegative atom to the more electronegative atom, eliminating **choice (C)**.

2. A

Of the compounds listed, both **choices (B)** and **(D)** are covalent compounds and thus are measured in molecular weights, not formula weights. The formula weight of $MgCl_2$ is much too high (24.3 amu + 2 × 35.5 amu = 95.3 amu per formula unit), eliminating **choice (C)**. Only KCl fits the criteria (39.1 amu + 35.5 amu = 74.6 amu).

3. A

First, it is helpful to know the molar mass of one mole of H_2SO_4, which is found by adding the atomic weights of the atoms that constitute the molecule: $2 \times 1.0 \frac{g}{mol} + 32.1 \frac{g}{mol} + 4 \times 16.0 \frac{g}{mol} = 98.1 \frac{g}{mol}$. Gram equivalent weight is the mass (in grams) that would release one mole of protons. Because sulfuric acid has two hydrogens per molecule, the gram equivalent weight is 98.1 g divided by 2, or 49.1 g.

4. C

The definition of an empirical formula is a formula that represents a molecule with the simplest ratio, in whole numbers, of the elements comprising the compound. In this case, given the empirical formula CH, any molecule with carbon and hydrogen atoms in a 1:1 ratio would be accurately represented by this empirical formula. **Choice (C)** has three carbon atoms and four hydrogen atoms. Both its molecular and empirical formulas would be C_3H_4 because this formula represents the smallest whole-number ratio of its constituent elements.

5. A

The percent composition by mass of any given element within a molecule is equal to the mass of that element in the molecule divided by the molar mass of the compound, times 100%. In this case, acetone, C_3H_6O, has $\frac{3 \times 12 \frac{g}{mol}}{3 \times 12 \frac{g}{mol} + 6 \times 1 \frac{g}{mol} + 16 \frac{g}{mol}} = \frac{36 \frac{g}{mol}}{58 \frac{g}{mol}} \approx 62.1\%$ carbon. **Choice (B)**, ethanol, is $\frac{24 \frac{g}{mol}}{46 \frac{g}{mol}} \approx 52.2\%$ carbon. **Choice (C)**, propane, is $\frac{36 \frac{g}{mol}}{44 \frac{g}{mol}} \approx 81.8\%$ carbon. Finally, **choice (D)**, methanol, is $\frac{12 \frac{g}{mol}}{32 \frac{g}{mol}} \approx 37.5\%$ carbon.

6. B

This reaction is a classic example of a neutralization reaction, in which an acid and a base react to form a salt and, usually, water. Although this reaction also fits the criteria for a double-displacement reaction, **choice (C)**, in which two molecules essentially exchange ions with each other, neutralization is a more specific description of the process.

7. A

In this question, you are first given the masses of both reactants used to start the reaction. To figure out what will be left over, we must first determine which species is the

limiting reagent. The formula weight of Na_2S is 78.1 grams per formula unit; the formula weight of $AgNO_3$ is 169.9 grams per formula unit. From this, we can determine that we are given 0.5 mol Na_2S and 0.67 mol $AgNO_3$. Because we need two moles of $AgNO_3$ for every mole of Na_2S, $AgNO_3$ is the limiting reagent, and the correct answer choice will be in grams of Na_2S. If 0.67 mol of $AgNO_3$ are used up, and Na_2S will be consumed at half the rate of $AgNO_3$ (based on their mole ratio), then 0.33 mol Na_2S will be used up. We then have 0.17 mol excess Na_2S, which has a mass of 13.0 g.

8. A

This is a question best answered by dimensional analysis. Keeping in mind that molar mass is measured in grams of a substance per moles of that substance, only **choice (A)** comes out with the units of grams of oxygen. **Choice (B)** has the units of grams per mole of oxygen, not grams of oxygen. **Choice (C)** has the units of moles per gram of oxygen. **Choice (D)** has the units of mol^2 per gram of oxygen.

9. D

In the reaction, there is a single displacement, with the silver in silver oxide being replaced by the aluminum to form aluminum oxide. This single-displacement reaction also necessitates a transfer of electrons in an oxidation–reduction reaction; silver, for example, changes from the +2 oxidation state to neutral. Aluminum changes from neutral to the +3 oxidation state.

10. C

Typically, both single-displacement and double-displacement reactions have two reactants that swap either one or two components between the two species. Combination reactions, on the other hand, have more reactants than products because the reactants combine together to form the product.

11. B

This description characterizes a combustion reaction because a hydrocarbon acts as a fuel when reacting with oxygen. Carbon dioxide (an oxide) and water are the products of such a reaction.

12. B

The equation given is unbalanced. To start, we must balance the equation:

$$6\ CO_2 + 6\ H_2O \xrightarrow{h\nu} C_6H_{12}O_6 + 6\ O_2$$

The theoretical yield is the amount of product synthesized if the limiting reagent is completely used up. This question therefore asks how much glucose is produced if the limiting reagent is 30 grams of water. We can use the three-fraction method discussed in this chapter to solve for the mass of glucose produced:

$$30.0\ g\ H_2O \times \left[\frac{1\ mol\ H_2O}{18\ g\ H_2O}\right]\left[\frac{1\ mol\ C_6H_{12}O_6}{6\ mol\ H_2O}\right]\left[\frac{180\ g\ C_6H_{12}O_6}{1\ mol\ C_6H_{12}O_6}\right]$$

$= 50\ g\ C_6H_{12}O_6$. Thus, 50 grams of glucose are produced.

13. B

A limiting reagent is by definition a reactant. Because Au and H_2S are products, they cannot act as limiting reagents, eliminating **choices (C)** and **(D)**. Next, realize that what you are shown is an unbalanced equation. To answer this question, we must balance the reaction:

$$Au_2S_3\ (s) + 3\ H_2\ (g) \rightarrow 2\ Au\ (s) + 3\ H_2S\ (g)$$

We are given 2 moles of gold(III) sulfide and 5 moles of hydrogen gas. To use up both moles of gold(III) sulfide, we would need 6 moles of hydrogen gas because there is a 1:3 ratio between these reactants. We have only 5 moles of hydrogen gas, so that will have to be the limiting reagent.

14. B

The best electrolytes dissociate readily (have a high dissociation constant) and are ionic compounds with large amounts of cations and anions. This rules out **choices (A)** and **(C)**. **Choice (D)** has fewer total ions with a smaller total magnitude of charge and therefore is not as strong an electrolyte as **choice (B)**.

15. C

The simplest approach is to determine the molar mass of the empirical formula. B_2H_5 has a molar mass of 26.6 $\frac{g}{mol}$. A molecular formula is simply a multiple of the empirical formula; doubling this quantity will result in the molar mass given in the question stem. Therefore, the compound must be B_4H_{10}.

Concept Summary 167

Introduction

The following chapters focus on two primary topics: chemical kinetics and chemical equilibrium. As the term suggests, chemical kinetics is the study of reaction rates, the effects of reaction conditions on these rates, and the mechanisms implied by such observations. We start with kinetics because the molecular basis of reactions provides us with a framework of reaction chemistry. Following this, we will explore the equilibria of these reactions, which are related to—but distinct from—the kinetics of the reaction.

You may already have a fairly good understanding of equilibrium and the differences between spontaneous and nonspontaneous reactions. For instance, the utilization of ATP in the body is a spontaneous reaction that can be used to provide thermochemical energy for other reactions. While the equilibrium tells us that ATP will favor dissociation, it tells us nothing about its rate of dissociation. And, in fact, various conditions in the body can alter the rate at which ATP is synthesized and utilized for energy—primarily temperature. Some of the symptoms of hyper- and hypothermia are related to changes in metabolism caused by changes in temperature and reaction kinetics.

More broadly, we will see how multistep reactions, such as those seen in substrate-level and oxidative phosphorylation in biochemistry, have intermediate steps that have crucial kinetic limitations.

5.1 Chemical Kinetics ★★★★

Reactions can be spontaneous or nonspontaneous; the change in **Gibbs free energy** (ΔG) determines whether or not a reaction will occur by itself without outside assistance. However, even if a reaction is spontaneous, this does not necessarily mean that it will run quickly. In fact, nearly every biochemical reaction

Bridge

Enzymes selectively enhance the rate of certain reactions by a factor of 10^2 to 10^{12} over other thermodynamically feasible reaction pathways. Enzyme function is discussed in Chapter 2 of *MCAT Biochemistry Review*.

that enables life to exist, while perhaps spontaneous, proceeds so slowly that, without the aid of enzymes and other catalysts, measurable reaction progress might not actually occur over the course of an average human lifetime. And enzymes, like many other catalyzed reactions, can be saturated and experience a maximal turnover rate, as shown in Figure 5.1. For now, however, let us review reaction mechanisms, rates, rate laws, and the factors that pertain to simple chemical systems.

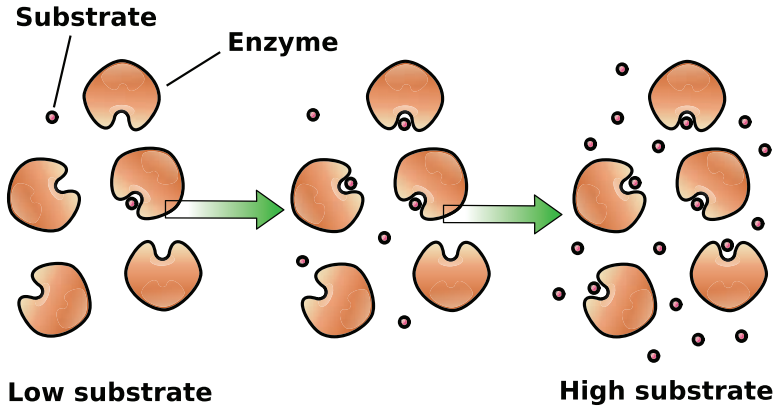

Figure 5.1. Enyzmes, as Biological Catalysts, Can Be Saturated
High substrate conditions saturate the active sites of the enzyme, leading to maximal turnover.

REACTION MECHANISMS

Bridge

Mechanisms are proposed pathways for a reaction that must coincide with rate data information from experimental observation. Reaction mechanisms are a major topic in organic chemistry and metabolism; Chapters 5 through 10 of *MCAT Organic Chemistry Review* and Chapters 9 through 11 of *MCAT Biochemistry Review* focus almost exclusively on reaction mechanisms in specific contexts.

Very rarely is the balanced reaction equation, used for determining limiting reactants and yields, an accurate representation of the actual steps involved in the chemical process from reactants to products. Many reactions proceed by more than one step, the series of which is known as the **mechanism** of a reaction, and the sum of which gives the overall reaction. Knowing the accepted mechanism of a reaction may help explain the reaction's rate, position of equilibrium, and thermodynamic characteristics. Consider this generic reaction:

$$A_2 + 2\,B \rightarrow 2\,AB$$

On its own, this equation seems to imply a mechanism in which two molecules of B collide with one molecule of A_2 to form two molecules of AB. Suppose instead, however, that the reaction actually takes place in two steps:

$$\text{Step 1:} \quad A_2 + B \rightarrow A_2B \qquad \text{(slow)}$$

$$\text{Step 2:} \quad A_2B + B \rightarrow 2\,AB \qquad \text{(fast)}$$

Note that the two steps, taken together, give the overall net reaction. The molecule A_2B, which does not appear in the overall reaction, is called an **intermediate**.

Reaction intermediates are often difficult to detect because they may be consumed almost immediately after they are formed, but a proposed mechanism that includes intermediates can be supported through kinetic experiments. One of the most important points to remember is that the slowest step in any proposed mechanism is called the **rate-determining step** because it acts like a kinetic bottleneck, preventing the overall reaction from proceeding any faster than that slowest step.

Key Concept

The rate of the whole reaction is only as fast as the rate-determining step.

MOLECULAR BASIS OF CHEMICAL REACTIONS

It's one thing to say A_2 *reacts with 2 B to form 2 AB*; it's quite another to be able to describe, as precisely as possible, the actual interactions that occur between A_2 and B to produce AB at some rate. Various theories have been proposed to explain the events that are taking place at the atomic level through the process of a reaction.

Collision Theory of Chemical Kinetics

For a reaction to occur, molecules must collide with each other. The **collision theory of chemical kinetics** states that the rate of a reaction is proportional to the number of collisions per second between the reacting molecules.

The theory suggests, however, that not all collisions result in a chemical reaction. An effective collision (one that leads to the formation of products) occurs only if the molecules collide with each other in the correct orientation and with sufficient energy to break their existing bonds and form new ones. The minimum energy of collision necessary for a reaction to take place is called the **activation energy**, E_a, or the **energy barrier**. Only a fraction of colliding particles have enough kinetic energy to exceed the activation energy. This means that only a fraction of all collisions are effective. The rate of a reaction can therefore be expressed as follows:

$$\text{rate} = Z \times f$$

Equation 5.1

where Z is the total number of collisions occurring per second and f is the fraction of collisions that are effective. A much more quantitatively rigorous analysis of the collision theory can be accomplished through the **Arrhenius equation** which is normally given as:

$$k = Ae^{\frac{-E_a}{RT}}$$

Equation 5.2

where k is the rate constant of a reaction, A is the frequency factor, E_a is the activation energy of the reaction, R is the ideal gas constant, and T is the

temperature in kelvins. The **frequency factor**, also known as the **attempt frequency** of the reaction, is a measure of how often molecules in a certain reaction collide, with the unit s^{-1}. Activation energy is a subject that will be touched upon briefly in the following subsection and more qualitatively in future chapters.

Overall, what is important here in studying the Arrhenius equation is not the actual calculation (because those involving Euler's number, *e*, and natural logs, ln, are not commonly found on the MCAT), but rather the relationships between the variables and the exponent rules that govern the equation.

For example, a simple relationship between *A* and *k* is evident in the equation. As the frequency factor of the reaction increases, the rate constant of the reaction also increases in a direct relationship. More complex relationships can also be seen in this equation. For example, if the temperature (*T*) of a chemical system were to increase to infinity, while all other variables are held constant, the value of the exponent would have a magnitude less than 1. However, before assuming that the rate constant is going to decrease as a result, note the presence of the negative sign. As the magnitude of the exponent gets smaller, it actually moves from a more negative value toward zero. The exponent thus becomes less negative (or more positive), which means that the rate constant actually increases. This should make sense conceptually because the rate of a reaction increases with temperature.

MCAT Expertise

Low activation energy and high temperatures make the negative exponent of the Arrhenius equation smaller in magnitude and thus increase the rate constant *k*.

The frequency factor can be increased by increasing the number of molecules in a vessel. When there are more molecules, the opportunities for collision are increased, as shown in Figure 5.2.

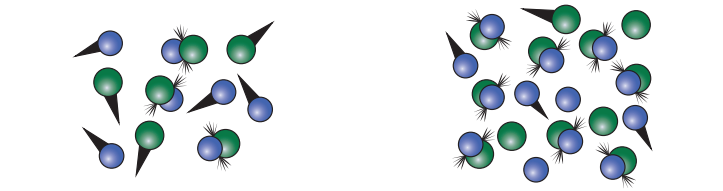

Figure 5.2. Frequency Factor (*A*) Is Increased by Increasing Concentration

Transition State Theory

When molecules collide with energy equal to or greater than the activation energy, they form a transition state in which the old bonds are weakened and the new bonds begin to form. The transition state then dissociates into products, fully

forming the new bonds. For the reaction $A_2 + 2\ B \rightarrow 2\ AB$, the progress along the **reaction coordinate**, which traces the reaction from reactants to products, can be represented as shown in Figure 5.3.

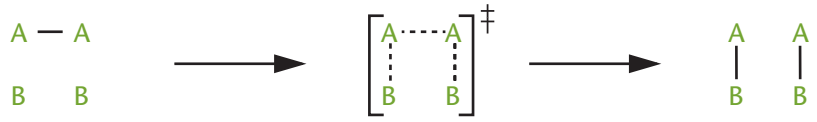

Figure 5.3. The Transition State

The **transition state**, also called the **activated complex**, has greater energy than both the reactants and the products and is denoted by the symbol ‡. The energy required to reach this transition state is the activation energy. Once an activated complex is formed, it can either dissociate into the products or revert to reactants without any additional energy input. Transition states are distinguished from reaction intermediates in that transition states are theoretical constructs that exist at the point of maximum energy, rather than distinct identities with finite lifetimes.

Key Concept

Relative to reactants and products, transition states have the highest energy. They are only theoretical structures and cannot be isolated. Nevertheless, we can still use the proposed structures to better understand the reactions in which they are involved.

A free energy diagram illustrates the relationship between the activation energy, the free energy of the reaction, and the free energy of the system. The most important features to recognize in such diagrams are the relative energies of all of the products and reactants. The **free energy change of the reaction** (ΔG_{rxn}) is the difference between the free energy of the products and the free energy of the reactants. A negative free energy change indicates an **exergonic reaction** (energy is given off), and a positive free energy change indicates an **endergonic reaction** (energy is absorbed). The transition state exists at the peak of the energy diagram. The difference in free energy between the transition state and the reactants is the activation energy of the forward reaction; the difference in free energy between the transition state and the products is the activation energy of the reverse reaction.

Key Concept

$+\Delta G$ = endergonic = energy absorbed
$-\Delta G$ = exergonic = energy given off

For example, consider the formation of HCl from H_2 and Cl_2. The overall reaction is:

$$H_2\ (g) + Cl_2\ (g) \rightleftharpoons 2\ HCl\ (g)$$

Figure 5.4 shows that the reaction is exergonic. The free energy of the products is less than the free energy of the reactants; energy is released, and the free energy change of the reaction is negative.

MCAT Expertise

Kinetics and thermodynamics should be considered separately. Note that the free energy of the product can be raised or lowered, thereby changing the value of ΔG without affecting the value of forward E_a.

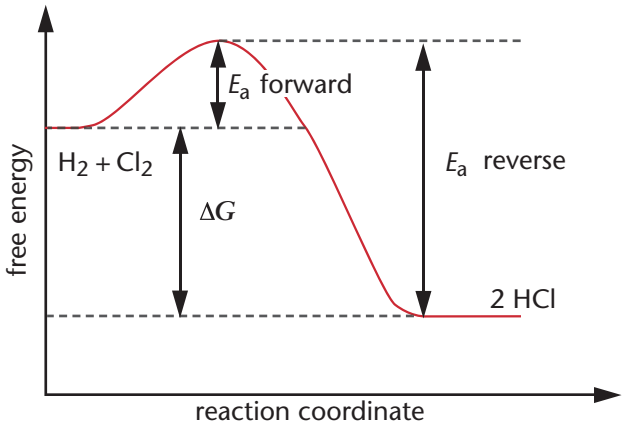

Figure 5.4. Reaction Diagram for the Formation of HCl
On the left are the reactants (H_2 and Cl_2) and on the right are the products (2 HCl); this reaction is exergonic, and forward and reverse activation energies are shown.

FACTORS AFFECTING REACTION RATE

Before we delve into the specifics of rate calculations, it is helpful to understand the conditions that can alter experimental rates.

Reaction Concentrations

The greater the concentrations of the reactants, the greater the number of effective collisions per unit time. Recall that this leads to an increase in the frequency factor (A) of the Arrhenius equation. Therefore, the reaction rate will increase for all but zero-order reactions, which will be discussed shortly. For reactions occurring in the gaseous state, the partial pressures of the gas reactants serve as a measure of concentration, as discussed in Chapter 8 of *MCAT General Chemistry Review*.

Temperature

For nearly all reactions, the reaction rate will increase as the temperature increases. Because the temperature of a substance is a measure of the particles' average kinetic energy, increasing the temperature increases the average kinetic energy of the molecules. Consequently, the proportion of reactants gaining enough energy to surpass E_a (and thus capable of undergoing reaction) increases with higher temperature. All reactions—even the nuclear reactions shown in Figure 5.5—are temperature-dependent and experience an optimal temperature for activity.

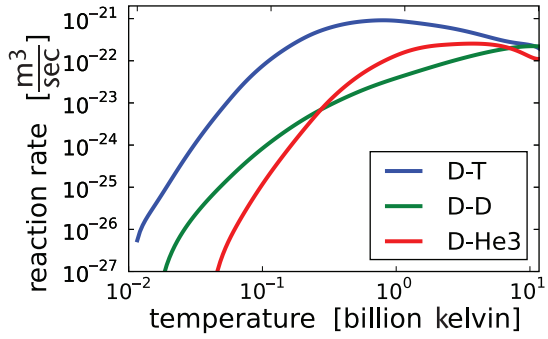

Figure 5.5. All Reactions Are Temperature-Dependent
Examples shown are nuclear fusion reactions; at extreme temperatures, the nucleus itself begins to break down.

You'll often hear that raising the temperature of a system by 10°C will result in an approximate doubling of the reaction rate. Be careful with this approximation because it is *generally* true for biological systems but not so for many other systems. Further, even in biological systems, if the temperature gets too high, a catalyst may denature—and then the reaction rate plummets. Figure 5.6 shows a general curve for an enzymatic reaction that is optimal between 35°C and 40°C (body temperature). Notice that the curve falls sharply after 40°C, at which point denaturation has occurred.

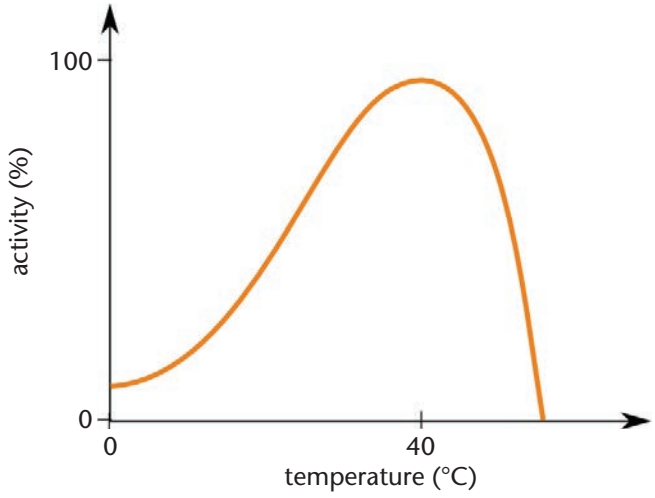

Figure 5.6. An Activity *vs.* Temperature Curve for a Generic Human Enzyme

Medium

The rate at which a reaction takes place may also be affected by the medium in which it takes place. Some molecules are more likely to react with each other

in aqueous environments, while others are more likely to react in nonaqueous solvents, such as in dimethyl sulfoxide (DMSO) or ethanol. Furthermore, the physical state of the medium (liquid, solid, or gas) can also have a significant effect. Generally, polar solvents are preferred because their molecular dipole tends to polarize the bonds of the reactants, thereby lengthening and weakening them, permitting the reaction to occur faster.

Catalysts

Catalysts are substances that increase reaction rate without themselves being consumed in the reaction. Catalysts interact with the reactants, either by adsorption or through the formation of intermediates, and stabilize them so as to reduce the activation energy necessary for the reaction to proceed. While many catalysts, including all enzymes, chemically interact with the reactants, they return to their original chemical state upon formation of the products. They may increase the frequency of collisions between the reactants; change the relative orientation of the reactants, making a higher percentage of the collisions effective; donate electron density to the reactants; or reduce intramolecular bonding within reactant molecules. In **homogeneous catalysis**, the catalyst is in the same phase (solid, liquid, gas) as the reactants. In **heterogeneous catalysis**, the catalyst is in a distinct phase. Figure 5.7 compares the energy profiles of catalyzed and uncatalyzed reactions. Note that, depending on context, reaction profiles can use either Gibbs free energy or enthalpy for the *y*-axis.

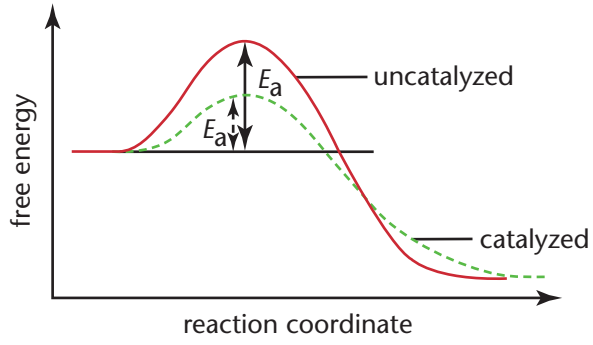

Figure 5.7. Reaction Diagram for a Catalyzed and an Uncatalyzed Reaction

Notice that the only effect of the catalyst is the decrease in the energies of activation, E_a, for both the forward and reverse reactions. The presence of the catalyst has no impact on the free energies of the reactants or the products or the difference between them. This means that catalysts change only the rates of reactions, and in fact, change the forward rate and the reverse rate by the same factor. Consequently, they have no impact whatsoever on the equilibrium position or the measurement of K_{eq}. Remember that, as useful as catalysts are in biological and nonbiological systems, catalysts are not miracle workers: they will not transform a nonspontaneous reaction into a spontaneous one; they only make spontaneous reactions move more quickly toward equilibrium.

Bridge

Equilibrium, like biological homeostasis, is a dynamic process that seeks to find balance in all systems. We can use this concept to our advantage on the MCAT in all seven of the basic sciences. Equilibria are dynamic, meaning that they *do* undergo change but their *net* change will be zero.

MCAT Concept Check 5.1:

Before you move on, assess your understanding of the material with these questions.

1. Describe in words what is occurring in the following two-step mechanism:

$$\text{Step 1: } A_2B + A_2B \rightarrow A_4B_2$$
$$\text{Step 2: } \quad A_4B_2 \rightarrow 2A_2 + B_2$$

_____

_____

2. What does it mean for a step in a mechanism to be the rate-determining step?

_____

_____

3. What is activation energy?

_____

_____

4. How does the transition state theory compare with the collision theory of chemical kinetics?
   - Transition state theory:

     _____
   - Collision theory:

     _____

5.2 Reaction Rates ★★★

Reactions, unfortunately, do not come with handy built-in speedometers. To determine the rate at which a reaction proceeds, we must take measurements of the concentrations of reactants and products and note their change over time.

DEFINITION OF RATE

If we consider a generic reaction, $2\ A + B \rightarrow C$, in which one mole of C can be produced from two moles of A and one mole of B, we can describe the rate of this reaction in terms of either the disappearance of reactants over time or the appearance of products over time. Because the reactants, by definition, are being consumed

in the process of formation of the products, we place a negative sign in front of the rate expression for the reactants. For the above reaction, the rate of the reaction with respect to A is $-\frac{\Delta[A]}{\Delta t}$, with respect to B is $-\frac{\Delta[B]}{\Delta t}$, and with respect to C is $+\frac{\Delta[C]}{\Delta t}$. Notice that the stoichiometric coefficients for the reaction are not equal, which means that the rates of change of concentrations are not equal. Because two moles of A are consumed for every mole of B consumed, $\text{rate}_{-\Delta[A]} = 2 \times \text{rate}_{-\Delta[B]}$. Furthermore, for every two moles of A consumed, only one mole of C is produced; thus, we can say that the $\text{rate}_{-\Delta[A]} = 2 \times \text{rate}_{\Delta[C]}$. Based on the stoichiometry, we can see that the rate of consumption of B is equal to the rate of production of C. To show a standard rate of reaction in which the rates with respect to all reaction species are equal, the rate of concentration change of each species should be divided by the species' stoichiometric coefficients. Thus, for the general reaction $aA + bB \rightarrow cC + dD$,

$$\text{rate} = -\frac{\Delta[A]}{a\Delta t} = -\frac{\Delta[B]}{b\Delta t} = \frac{\Delta[C]}{c\Delta t} = \frac{\Delta[D]}{d\Delta t}$$

Equation 5.3

Rate is expressed in the units of moles per liter per second $\left(\frac{\text{mol}}{\text{L} \bullet \text{s}}\right)$ or molarity per second $\left(\frac{M}{\text{s}}\right)$.

DETERMINATION OF RATE LAW

In the *Chemical and Physical Foundations of Biological Systems* section of the MCAT, it is unlikely that the testmakers will provide a reaction equation that one can merely look at and write the correct rate law. Therefore, on the MCAT, whenever a question asks to determine the rate law for a reaction, the first thing to look for is experimental data.

For nearly all forward, irreversible reactions, the rate is proportional to the concentrations of the reactants, with each concentration raised to some experimentally determined exponent. For the general reaction

$$aA + bB \rightarrow cC + dD$$

the rate is proportional to $[A]^x[B]^y$. By including a proportionality constant, k, we can say that rate is determined according to the following equation:

$$\text{rate} = k[A]^x[B]^y$$

Equation 5.4

where k is the reaction rate coefficient or rate constant and the exponents x and y are the orders of the reaction. This expression is called the **rate law**. Remember that rate is always measured in units of concentration over time; that is, molarity per second. The exponents x and y (or x, y, and z, if there are three reactants) can be used to state

MCAT Expertise

Remember that the stoichiometric coefficients for the overall reaction are often different from those for the rate law and will, therefore, not be the same as the order of the reaction.

the order of the reaction with respect to each reactant or overall: x is the order with respect to reactant A, and y is order with respect to reactant B. The overall order of the reaction is the sum of x and y. These exponents may be integers or fractions and must be determined experimentally. The MCAT will focus almost exclusively on zero-, first-, second-, and third-order reactions. In most cases, the exponents will be integers.

Before we go any further in our consideration of rate laws, we must offer a few warnings about common traps in chemical kinetics. The first—and most common—is the assumption that the orders of a reaction are the same as the stoichiometric coefficients in the balanced overall equation. Pay close attention: *On the MCAT, the values of* x *and* y *are almost never the same as the stoichiometric coefficients*. The orders of a reaction must be determined experimentally. There are only two cases in which the stoichiometric coefficients match the orders of the reaction. The first is when the reaction mechanism is a single step and the balanced overall reaction is reflective of the entire chemical process. The second is when the complete reaction mechanism is given and the rate-determining step is indicated. The stoichiometric coefficients on the reactant side of the rate-determining step are equal to the orders of the reaction. Occasionally, even this can get a little complicated when the rate-determining step involves an intermediate as a reactant, in which case one must derive the intermediate molecule's concentration by the **law of mass action** (that is, the equilibrium constant expression) for the step that produced the intermediate.

MCAT Expertise

Note that the exponents in the rate law are *not* equal to the stoichiometric coefficients, unless the reaction occurs via a single-step mechanism. Note that product concentrations *never* appear in a rate law. Don't fall into the exceedingly common trap of confusing the rate law with an equilibrium expression!

The second common trap is mistaking the equilibrium constant expression (law of mass action) for the rate law. The expressions for both look similar; if you're not alert on Test Day, you may mistake one for the other or use one when you should be using the other. The expression for equilibrium includes the concentrations of all the species in the reaction, both reactants and products. The expression for chemical kinetics—the rate law expression—includes only the reactants. K_{eq} indicates where the reaction's equilibrium position lies. The rate indicates how quickly the reaction will get there.

The third trap regards the rate constant, k. Technically speaking, k is not a constant because its particular value for any specific chemical reaction will depend on the activation energy for that reaction and the temperature at which the reaction takes place. However, for a specific reaction, at a specific temperature, the rate constant is indeed a constant. For a reversible reaction, the K_{eq} is equal to the ratio of the rate constant for the forward reaction, k, divided by the rate constant for the reverse reaction, k_{-1}.

The fourth and final trap is that the notion and principles of equilibrium apply to the system only at the end of the reaction; that is, after the system has already reached equilibrium. On the other hand, while the reaction rate can theoretically be measured

at any time, it is usually measured at or near the beginning of the reaction to minimize the effects of the reverse reaction.

Experimental Determination of Rate Law

This has already been stated a few times, but it bears repeating: The values of k, x, and y in the rate law equation (rate = $k[A]^x[B]^y$) must be determined experimentally for a given reaction at a given temperature. Although rate laws can be quite complex and the orders of the reaction difficult to discern, the MCAT limits its coverage of this topic to fairly straightforward reaction mechanisms, experimental data, and rate laws.

On the MCAT, experimental data for determining rate order is usually provided as a chart that includes the initial concentrations of the reactants and the initial rates of product formation as a function of the reactant concentrations. Often, the data for three or four trials are included in this chart.

To use this data, identify a pair of trials in which the concentration of one of the reactants is changed while the concentrations of all other reactants remain constant. Under these conditions, any change in the rate of product formation from one trial to the other (*if* there is any change) is fully attributable to the change in concentration of that one reactant. Consider a reaction with two reactants, A and B, forming product C. Imagine two trials in which the concentration of A is constant, while the concentration of B doubles. If the rate of the formation of product C has subsequently quadrupled, then the exponent on [B] must be two. Why? Looking at the generic rate law (rate = $k[A]^x[B]^y$), the logic should look something like this: *Doubling [B] has resulted in a quadrupling of the rate, so to determine the order of the reaction, y, with respect to B, I need to calculate the exponent to which the number 2 must be raised to equal 4. Because* $2^y = 4$, $y = 2$.

The next step is to repeat this process for the other reactant, using data from a different pair of trials, making sure that the concentration of only the reactant we are trying to analyze is changed from one trial to the other while the concentrations of all other reactants remain the same. Once the orders of the reaction have been determined with respect to each reactant, we can write the complete rate law, replacing the exponents x and y with actual numbers. To determine the value of the rate constant k, plug in actual values from any one of the trials; pick whichever trial has the most arithmetically convenient numbers.

MCAT Expertise

The testmakers love rate problems. Why? Because solving these questions requires a real understanding of proportionality and variable relationships. With practice, you'll be able to do these quickly in your head with minimal paper-and-pencil calculations. Remember to look for pairs of reaction trials in which the concentration of only one species changes while the others remain constant.

Example: Given the data below, find the rate law for the following reaction at 300 K:

$$A + B \longrightarrow C + D$$

Trial	$[A]_{initial}$ (M)	$[B]_{initial}$ (M)	$rate_{initial}$ $\left(\frac{M}{s}\right)$
1	1.00	1.00	2.0
2	1.00	2.00	8.1
3	2.00	2.00	15.9

Solution: First, look for two trials in which the concentrations of all but one of the substances are held constant.

In Trials 1 and 2, the concentration of A is kept constant, while the concentration of B is doubled. The rate increases by a factor of approximately 4. Considering that k and [A] are constant between the two trials, we have set up a system where rate is proportional to [B] raised to some power (remember that the symbol $\propto$ means "is proportional to"):

$$\text{rate} = k[A]^x[B]^y \xrightarrow{k \text{ and } [A] \text{ are constant}} \text{rate} \propto [B]^y$$

If the rate was multiplied by 4, and [B] was multiplied by 2, this implies the expression $4 = 2^y$. y is therefore equal to 2.

In Trials 2 and 3, the concentration of B is kept constant, while the concentration of A is doubled. The rate increases by a factor of approximately 2. Considering that k and [B] are constant between the two trials, we have set up a system where rate is proportional to [A] raised to some power:

$$\text{rate} = k[A]^x[B]^y \xrightarrow{k \text{ and } [B] \text{ are constant}} \text{rate} \propto [A]^x$$

If the rate was multiplied by 2, and [A] was multiplied by 2, this implies the expression $2 = 2^x$. x is therefore equal to 1.

Therefore, rate = $k[A][B]^2$. The order of the reaction with respect to A is 1 and with respect to B is 2; the overall reaction order is 1 + 2 = 3.

To calculate k, substitute the values from any one of the above trials into the rate law:

$$2.0 \tfrac{M}{s} = k[1.00\ M][1.00\ M]^2$$

$$k = 2.0\ M^{-2}\ s^{-1}$$

Therefore, the rate law is rate = $2.0\ M^{-2}\ s^{-1}\ [A][B]^2$

REACTION ORDERS

We classify chemical reactions as zero-order, first-order, second-order, higher-order, or mixed-order on the basis of kinetics. We will continue to consider the generic reaction $aA + bB \rightarrow cC + dD$ for this discussion.

Zero-Order Reaction

A **zero-order reaction** is one in which the rate of formation of product C is independent of changes in concentrations of any of the reactants, A and B. These reactions have a constant reaction rate equal to the rate constant (rate coefficient), *k*. The rate law for a zero-order reaction is:

$$\text{rate} = k[A]^0[B]^0 = k$$

where *k* has units of $\frac{M}{s}$. Remember that the rate constant itself is dependent on temperature; thus, it is possible to change the rate for a zero-order reaction by changing the temperature. The only other way to change the rate of a zero-order reaction is by the addition of a catalyst, which lowers the activation energy, thereby increasing the value of *k*.

MCAT Expertise

Temperature and the addition of a catalyst are the only factors that can change the rate of a zero-order reaction.

Plotting a zero-order reaction on a concentration *vs.* time curve results in a linear graph, as shown in Figure 5.8. This line shows that the rate of formation of product is independent of the concentration of reactant. The slope of such a line is the opposite of the rate constant, *k*.

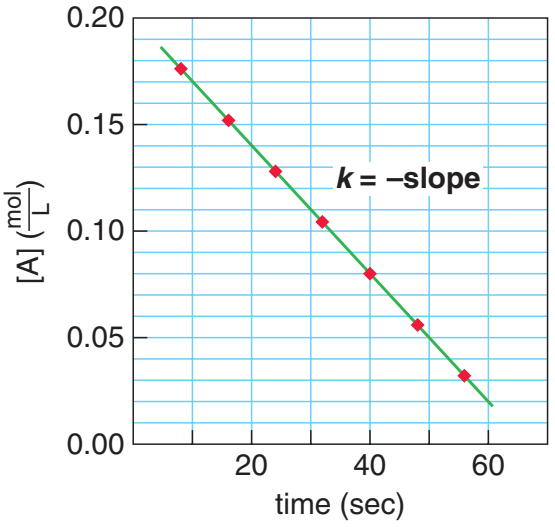

Figure 5.8. Kinetics of a Zero-Order Reaction
Note that the rate of reaction, *k*, is the opposite of the slope.

First-Order Reaction

A **first-order reaction** has a rate that is directly proportional to only one reactant, such that doubling the concentration of that reactant results in a doubling of the rate of formation of the product. The rate law for a first-order reaction is

$$\text{rate} = k[\text{A}]^1 \text{ or rate} = k[\text{B}]^1$$

where k has units of s^{-1}. A classic example of a first-order reaction is the process of radioactive decay. From the rate law, in which the rate of decrease of the amount of a radioactive isotope A is proportional to the amount of A,

$$\text{rate} = -\frac{\Delta[\text{A}]}{\Delta t} = k[\text{A}]$$

The concentration of radioactive substance A at any time t can be expressed mathematically as:

$$[\text{A}]_t = [\text{A}]_0 e^{-kt}$$

Equation 5.5

where $[\text{A}]_t$ is the concentration of A at time t, $[\text{A}]_0$ is the initial concentration of A, k is the rate constant, and t is time. It is important to recognize that a first-order rate law with a single reactant suggests that the reaction begins when the molecule undergoes a chemical change all by itself, without a chemical interaction, and usually without a physical interaction with any other molecule.

Plotting a first-order reaction on a concentration *vs.* time curve results in a nonlinear graph, as shown in Figure 5.9. This curve shows that the rate of formation of product is dependent on the concentration of reactant. Plotting ln [A] *vs.* time reveals a straight line; the slope of such a line is the opposite of the rate constant, k.

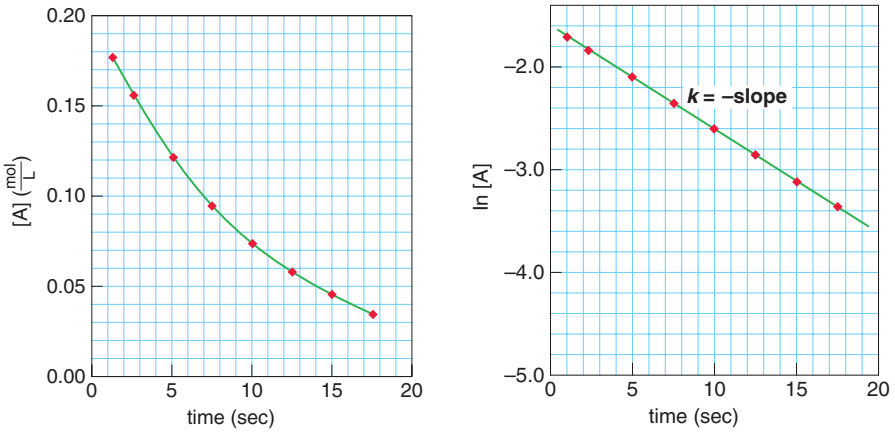

Figure 5.9. Kinetics of a First-Order Reaction
On the left, note that the rate of reaction is dependent on reactant concentration; on the right, note that the rate constant is the opposite of the slope of a graph of ln [A] *vs.* time.

Second-Order Reaction

A **second-order reaction** has a rate that is proportional to either the concentrations of two reactants or to the square of the concentration of a single reactant. The following rate laws all reflect second-order reactions:

$$\text{rate} = k[\text{A}]^1[\text{B}]^1 \text{ or rate} = k[\text{A}]^2 \text{ or rate} = k[\text{B}]^2$$

where k has units of $M^{-1}\,s^{-1}$. It is important to recognize that a second-order rate law often suggests a physical collision between two reactant molecules, especially if the rate law is first-order with respect to each of the two reactants.

Plotting a reaction that is second-order with respect to a single reactant on a concentration *vs.* time curve results in a nonlinear graph, as shown in Figure 5.10. This curve shows that the rate of formation of product is dependent on the concentration of reactant. Plotting $\frac{1}{[\text{A}]}$ *vs.* time reveals a linear curve; the slope of such a curve is equal to the rate constant, k.

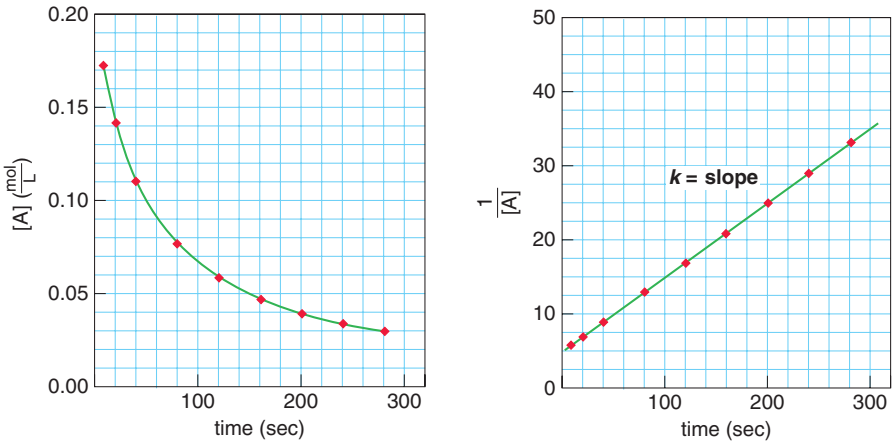

Figure 5.10. Kinetics of a Second-Order Reaction
On the left, note that the rate of reaction is dependent on reactant concentration; on the right, note that the rate constant is equal to the slope of a graph of $\frac{1}{[\text{A}]}$ *vs.* time.

Higher-Order Reactions

Fortunately there are very few noteworthy reactions in which a single reaction step involves a termolecular process; in other words, there are few processes with third-order rates. This is because it is far more rare for three particles to collide simultaneously with the correct orientation and sufficient energy to undergo a reaction.

Mixed-Order Reactions

Mixed-order reactions sometimes refer to non-integer orders (fractions) and in other cases to reactions with rate orders that vary over the course of the reaction. Fractions are more specifically described as **broken-order**. In recent times,

the term mixed-order has come to refer solely to reactions that change order over time. Knowing those two definitions will be sufficient for Test Day.

An example of a mixed-order rate law is given by:

$$\text{rate} = \frac{k_1[\text{C}][\text{A}]^2}{k_2 + k_3[\text{A}]}$$

where A represents a single reactant and C, a catalyst. The overall reaction and its mechanism are beyond the relevance and scope of the MCAT, and the derivation of this rate law is even more unnecessary for Test Day. The result of the large value for [A] at the beginning of the reaction is that $k_3[\text{A}] \gg k_2$, and the reaction will appear to be first-order with respect to A. At the end of the reaction, when [A] is low, $k_2 \gg k_3[\text{A}]$, making the reaction appear second-order with respect to A. While the MCAT will not ask you to derive a rate expression for a mixed-order reaction, you are responsible for being able to recognize how the rate order changes as the reactant concentration changes.

MCAT Concept Check 5.2:

Before you move on, assess your understanding of the material with these questions.

1. Describe the effects the following conditions would have on the initial rate of reaction, given the reaction order: (Examples: rate increased, rate divided by 2, rate unaffected)

Conditions	Zero-Order	First-Order	Second-Order
Temperature lowered			
All reactants' concentrations doubled			
Catalyst added			

2. Determine the rate law and rate order for the following reaction:

$$\text{A} + \text{B} + \text{C} \rightarrow \text{D}$$

Trial	$[\text{A}]_{\text{initial}}$ (M)	$[\text{B}]_{\text{initial}}$ (M)	$[\text{C}]_{\text{initial}}$ (M)	$\text{rate}_{\text{initial}}\left(\frac{M}{\text{s}}\right)$
1	1.00	1.00	1.00	2.0
2	1.00	2.00	1.00	2.1
3	2.00	1.00	1.00	15.9
4	2.00	1.00	2.00	32.2

Conclusion

We began with a consideration of chemical reactions and the mechanisms that illustrate the individual steps necessary to transform reactants into products. We demonstrated the way to derive a reaction's rate law through the analysis of experimental data, and we looked at the factors that can affect the rates of chemical reactions.

After such an overview, you should begin to appreciate that many chemical principles in the human body rely on the principles of chemical kinetics. Why does the body maintain a certain temperature? Primarily to stabilize the enzymes that catalyze the metabolic reactions necessary for life. Why does the body maintain a pH buffer? Altering the concentration of protons affects not only the ability of an enzyme to maintain its secondary, tertiary, and quaternary structure, but can also directly affect the collisions between reactants. You will begin to appreciate these and many other questions from a clinical perspective throughout your medical career. In the next chapter, we will investigate chemical equilibria, which—although related to kinetics—are distinct (and commonly confused!) topics.

CONCEPT SUMMARY

Chemical Kinetics

- The change in **Gibbs free energy** (ΔG) determines whether or not a reaction is spontaneous.
- **Chemical mechanisms** propose a series of steps that make up the overall reaction.
  - **Intermediates** are molecules that exist within the course of a reaction, but are neither reactants nor products overall.
  - The slowest step, also known as the **rate-determining step**, limits the maximum rate at which the reaction can proceed.
- The **collision theory** states that a reaction rate is proportional to the number of effective collisions between the reacting molecules.
  - For a collision to be effective, molecules must be in the proper orientation and have sufficient kinetic energy to exceed the **activation energy**.
  - The **Arrhenius equation** is a mathematical way of representing collision theory.
- The **transition state theory** states that molecules form a **transition state** or **activated complex** during a reaction in which the old bonds are partially dissociated and the new bonds are partially formed.
  - From the transition state, the reaction can proceed toward products or revert back to reactants.
  - The transition state is the highest point on a free energy reaction diagram.
- Reaction rates can be affected by a number of factors.
  - Increasing the concentration of reactant will increase reaction rate (except for zero-order reactions) because there are more effective collisions per time.
  - Increasing the temperature will increase reaction rate because the particles' kinetic energy is increased.
  - Changing the medium can increase or decrease reaction rate, depending on how the reactants interact with the medium.
  - Adding a catalyst increases reaction rate because it lowers the activation energy. **Homogeneous catalysts** are the same phase as the reactants; **heterogeneous catalysts** are a different phase.

Reaction Rates

- Reaction rates are measured in terms of the rate of disappearance of a reactant or appearance of a product.

- **Rate laws** take the form of rate = $k[A]^x[B]^y$.
  - The **rate orders** usually do not match the stoichiometric coefficients.
  - Rate laws must be determined from experimental data.
- The rate order of a reaction is the sum of all individual rate orders in the rate law.
- **Zero-order reactions** have a constant rate that does not depend on the concentration of reactant.
  - The rate of a zero-order reaction can only be affected by changing the temperature or adding a catalyst.
  - A concentration *vs.* time curve of a zero-order reaction is a straight line; the slope of such a line is equal to $-k$.
- **First-order reactions** have a nonconstant rate that depends on the concentration of reactant.
  - A concentration *vs.* time curve of a first-order reaction is nonlinear.
  - The slope of a ln [A] *vs.* time plot is $-k$ for a first-order reaction.
- **Second-order reactions** have a nonconstant rate that depends on the concentration of reactant.
  - A concentration *vs.* time curve of a second-order reaction is nonlinear.
  - The slope of a $\frac{1}{[A]}$ *vs.* time plot is k for a second-order reaction.
- **Broken-order reactions** are those with noninteger orders.
- **Mixed-order reactions** are those that have a rate order that changes over time.

ANSWERS TO CONCEPT CHECKS

5.1

1. Two molecules of A_2B come together in a combination reaction to form an intermediate, A_4B_2, which subsequently decomposes to produce the final products, two molecules of A_2 and one molecule of B_2.
2. The rate-determining step is the slowest step of a reaction. It determines the overall rate of the reaction because the reaction can only proceed as fast as the rate at which this step occurs.
3. The activation energy is the minimum energy needed for a chemical reaction to occur.
4. Both theories require a certain activation energy to be overcome in order for a reaction to occur (therefore not all reactions will occur). The transition state theory focuses on forming a high-energy activated complex that can then proceed forward or backward, forming the products or reverting to the reactants, respectively. The collision theory focuses on the energy and orientation of reactants, and considers each potential reaction to be "all-or-nothing" (either there is enough energy to form the products, or there is not).

5.2

1.

Conditions	Zero-Order	First-Order	Second-Order
Temperature lowered	rate decreased	rate decreased	rate decreased
All reactants' concentrations doubled	rate unaffected	rate doubled	rate multiplied by 4
Catalyst added	rate increased	rate increased	rate increased

2. The rate law is: rate = $k[A]^3[B]^0[C]^1 = k[A]^3[C]$. The rate order is 3 + 0 + 1 = 4.

EQUATIONS TO REMEMBER

(5.1) **Collision theory:** rate = $Z \times f$

(5.2) **Arrhenius equation:** $k = Ae^{\frac{-E_a}{RT}}$

(5.3) **Definition of rate:** rate = $-\frac{\Delta[A]}{a\Delta t} = -\frac{\Delta[B]}{b\Delta t} = \frac{\Delta[C]}{c\Delta t} = \frac{\Delta[D]}{d\Delta t}$

for the general reaction aA + bB $\rightarrow$ cC + dD

(5.4) **Rate law:** rate = $k[A]^x[B]^y$

(5.5) **Radioactive decay:** $[A]_t = [A]_0 e^{-kt}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. In a third-order reaction involving two reactants and two products, doubling the concentration of the first reactant causes the rate to increase by a factor of 2. What will happen to the rate of this reaction if the concentration of the second reactant is cut in half?

A. It will increase by a factor of 2.
B. It will increase by a factor of 4.
C. It will decrease by a factor of 2.
D. It will decrease by a factor of 4.

2. In a certain equilibrium process, the activation energy of the forward reaction is greater than the activation energy of the reverse reaction. This reaction is:

A. endothermic.
B. exothermic.
C. spontaneous.
D. nonspontaneous.

3. A reactant in a second-order reaction at a certain temperature is increased by a factor of 4. By how much is the rate of the reaction altered?

A. It is unchanged.
B. It is increased by a factor of 4.
C. It is increased by a factor of 16.
D. It cannot be determined from the information given.

4. The concentrations of all reactants in a zero-order reaction are increased twofold. What is the new rate of the reaction?

A. It is unchanged.
B. It is decreased by a factor of 2.
C. It is increased by a factor of 2.
D. It cannot be determined from the information given.

5. Which of the following experimental methods should NEVER affect the rate of a reaction?

A. Placing an exothermic reaction in an ice bath.
B. Increasing the pressure of a reactant in a closed container.
C. Putting the reactants into an aqueous solution.
D. Removing the product of an irreversible reaction.

6. What would increasing the concentration of reactants accomplish in a solution containing a saturated catalyst?

A. It would increase the rate constant but not the reaction rate.
B. It would decrease the rate constant but increase the reaction rate.
C. It would increase the rate constant and increase the reaction rate.
D. The reaction rate would be unaffected.

7. A certain chemical reaction has the following rate law:

$$\text{rate} = k[NO_2][Br_2]$$

Which of the following statements necessarily describe(s) the kinetics of this reaction?

I. The reaction is second-order.

II. The amount of NO_2 consumed is equal to the amount of Br_2 consumed.

III. The rate will not be affected by the addition of a compound other than NO_2 and Br_2.

A. I only
B. I and II only
C. II and III only
D. I, II, and III

8. The following data shown in the table were collected for the combustion of the theoretical compound XH_4:

$$XH_4 + 2\ O_2 \rightarrow XO_2 + 2\ H_2O$$

Trial	$[XH_4]_{initial}$ (M)	$[O_2]_{initial}$ (M)	Rate ($\frac{M}{min}$)
1	0.6	0.6	12.4
2	0.6	2.4	49.9
3	1.2	2.4	198.3

What is the rate law for the reaction described here?

A. rate = $k[XH_4][O_2]$
B. rate = $k[XH_4][O_2]^2$
C. rate = $k[XH_4]^2[O_2]$
D. rate = $k[XH_4]^2[O_2]^2$

9. Which of the following best describes the purpose of a catalyst?

A. Catalysts are used up in the reaction, increasing reaction efficiency.
B. Catalysts increase the rate of the reaction by lowering the activation energy.
C. Catalysts alter the thermodynamics of the reaction to facilitate the formation of products or reactants.
D. Catalysts stabilize the transition state by bringing it to a higher energy.

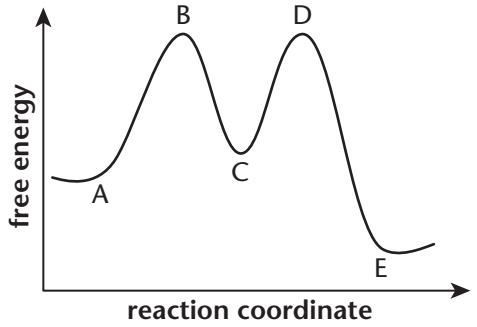
10. If the rate law for a reaction is:

$$\text{rate} = k[A]^0[B]^2[C]^1$$

What is the overall order of the reaction?

A. 0
B. 2
C. 3
D. 4

For questions 11–13, consider the following energy diagram shown below:



11. The overall reaction depicted by this energy diagram is:

A. endergonic, because point B is higher than point A.
B. endergonic, because point C is higher than point A.
C. exergonic, because point D is higher than point E.
D. exergonic, because point A is higher than point E.

12. Which process has the highest activation energy?

A. The first step of the forward reaction
B. The first step of the reverse reaction
C. The second step of the forward reaction
D. The second step of the reverse reaction

13. Point C in this reaction profile refers to the:

A. reactants.
B. products.
C. transition state.
D. intermediates.

14. The following system obeys second-order kinetics.

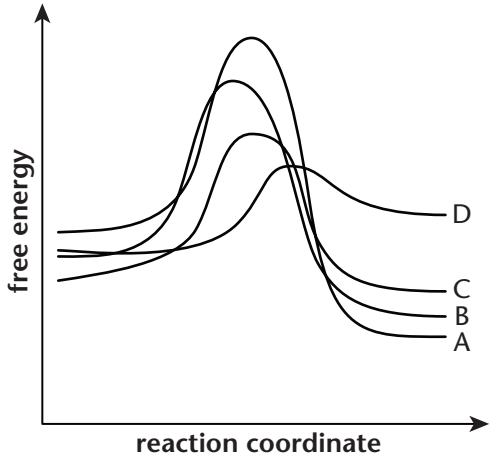
$$2\ NO_2 \rightarrow NO_3 + NO \qquad \text{(slow)}$$

$$NO_3 + CO \rightarrow NO_2 + CO_2 \qquad \text{(fast)}$$

What is the rate law for this reaction?

A. rate = $k[NO_2][CO]$
B. rate = $k[NO_2]^2[CO]$
C. rate = $k[NO_2][NO_3]$
D. rate = $k[NO_2]^2$

15. The potential energy diagram shown represents four different reactions.



Assuming identical conditions, which of the reactions displayed on the energy diagram proceeds the fastest?

A. A
B. B
C. C
D. D

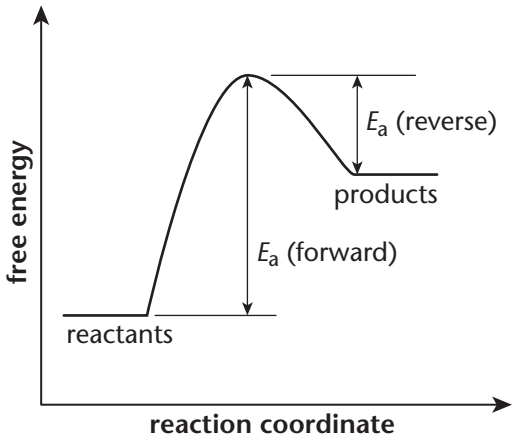
Explanations to Discrete Practice Questions

1. D

Based on the information given in the question, the rate is first-order with respect to the concentration of the first reactant; when the concentration of that reactant doubles, the rate also doubles. Because the reaction is third-order, the sum of the exponents in the rate law must be equal to 3. Therefore, the reaction order with respect to the other reactant must be 3 – 1 = 2. If the concentration of this second reactant is multiplied by $\frac{1}{2}$, the rate will be multiplied by $\left(\frac{1}{2}\right)^2 = \frac{1}{4}$.

2. D

Before you try to answer this question, you should draw a free energy diagram for the system.



If the activation energy of the forward reaction is greater than the activation energy of the reverse reaction, then the products must have a higher free energy than the reactants. The overall energy of the system is higher at the end than it was in the beginning. The net free energy change is positive, indicating an endergonic (nonspontaneous) reaction. The terms endothermic, **choice (A)**, and exothermic, **choice (B)**, are associated with enthalpy. While free energy does depend on enthalpy, it also depends on entropy; there is not enough information in the question stem to reliably determine the sign of the entropy change of the reaction.

3. D

A second-order reaction can be second-order with respect to one reactant, or first-order with respect to two different reactants. In this case, one reactant was increased by a factor of 4. If the reaction is second-order with respect to this reactant, the rate will increase by a factor of 16. If it is first-order with respect to this reactant (and first-order with respect to another reactant), the rate will increase by a factor of 4. We do not know which of these is this correct rate law and, thus, cannot determine the effect on the rate.

4. A

By definition, zero-order reactions are unaffected by the concentrations of any reactants in the reaction. Thus, changing the concentrations of these reactants will not affect the rate.

5. D

The question asks which alteration does NOT affect the rate of the reaction. Temperature directly affects the rate constant (k), making **choice (A)** incorrect. Changing the partial pressure of a gas will affect the number of effective collisions per time. This makes **choice (B)** incorrect—but note that concentration changes will not affect the rate of zero-order reactions. Solvents affect the rate of reactions depending on how the reactants interact with the solvent, making **choice (C)** incorrect. Removing the product of an irreversible reaction, **choice (D)**, should not affect the rate of the reaction because the rate law does not depend on the concentrations of products.

6. D

While increasing the concentration of reactants can alter the reaction rate in first- or higher-order reactions, saturated solutions containing a catalyst have a maximum turnover rate and cannot increase the rate constant or the reaction rate any higher by adding more reactant molecules.

7. A

If the sum of the exponents (orders) of the concentrations of each species in the rate law is equal to 2, then the reaction is second-order. The exponents in the rate law are unrelated to stoichiometric coefficients, so NO_2 and Br_2 could have any stoichiometric coefficients in the original reaction and still be a second-order reaction, invalidating statement II. Statement III is incorrect because the rate can be affected by a wide variety of compounds. A catalyst, for example, could increase the rate.

8. C

In the first two trials, the concentration of XH_4 is held constant while the concentration of O_2 is multiplied by 4. Because the rate of the reaction is also increased by a factor of approximately 4, oxygen must be a first-order reactant. In the last two trials, the concentration of O_2 is held constant while the concentration of XH_4 is doubled. Because the rate of the reaction is increased by a factor of approximately 4 again, XH_4 must be a second-order reactant. Based on this, we can conclude that the experimental rate law is $k[XH_4]^2[O_2]$.

9. B

By definition, a catalyst increases the rate of a reaction by lowering the activation energy, making it easier for both the forward and reverse reactions to overcome this energy barrier. Catalysts are neither used up in the reaction, nor do they alter the equilibrium of a reaction, eliminating **choices (A)** and **(C)**. Finally, catalysts stabilize the transition state by lowering its energy, not raising it, eliminating **choice (D)**.

10. C

The overall order of a reaction is the sum of the individual orders in the reaction. Therefore, the rate order is $0 + 2 + 1 = 3$.

11. D

A system is exergonic if energy is released by the reaction. For exergonic reactions, the net energy change is negative, and the free energy of the final products is lower than the free energy of the initial reactants. Point E, which represents the of the final products, is lower on the energy diagram than point A, which represents the energy of initial reactants. Thus, energy must have been given off, and the reaction is exergonic.

12. B

The activation energy of a reaction is represented by the distance on the *y*-axis from the energy of the reactants to the peak energy prior to formation of products. The activation energy of the first step of the forward reaction, for example, is equal to the distance along the *y*-axis from point A to point B. The largest energy increase on this graph occurs during the progress from point E to point D, which represents the first step of the reverse reaction.

13. D

Intermediates exist at "valleys" in reaction diagrams. Reactants, **choice (A)**, are represented by point A. Products, **choice (B)**, are represented by point E. Transition states, **choice (C)**, are represented by points B and D.

14. D

To answer this question, recall that the slow step of a reaction is the rate-determining step. The rate is always related to the concentrations of the reactants in the rate-determining step (*not* the overall reaction), so NO_2 is the only compound that should be included in the correct answer. The concentration of NO_2 is squared in the rate law because the question stem tells us that the system obeys second-order kinetics.

15. D

The faster a reaction can reach its activation energy, the faster it will proceed to completion. Because this question states that all conditions are equal, the reaction with the lowest activation energy will have the fastest rate. In the diagram, **choice (D)** has the lowest activation energy.

Concept Summary 191

MCAT Expertise

The AAMC has shown that it will only rarely *directly* test the details of equilibrium in this chapter. However, you'll need an excellent conceptual understanding of equilibrium to master many other high-yield topics, such as acid-base chemistry (Chapter 10 of *MCAT General Chemistry Review*) and enzymes (Chapter 2 of *MCAT Biochemistry Review*).

Introduction

You're on the first call of your pediatrics rotation. You get a page from the resident: *Come to the emergency room, now*, she says. *They just brought in a kid with DKA*. DKA, as you know, stands for diabetic ketoacidosis and is a fairly common way for undiagnosed type I diabetes mellitus to present. You remember from your second-year classes about endocrine pathophysiology that ketoacidosis can arise as a result of the body's metabolism of fatty acids when insulin production shuts down. Fatty acids are metabolized into ketone bodies as an alternative energy source to glucose. Some of the ketones produced are ketoacids, and as the diabetic crisis continues and worsens, the concentration of these ketoacids increases (termed metabolic acidosis), resulting in a plasma pH below 7.35.

As you enter the child's room, the examination is already under way; he's young, about ten years old, conscious but agitated, and the most obvious sign—which you notice immediately—is his rapid, shallow breathing. You ask the resident why the boy is hyperventilating, and she takes a piece of paper and writes the following:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

It's Le Châtelier's principle! you realize. *The respiratory system is trying to compensate for the metabolic acidosis; the increased breathing rate allows him to blow off more CO_2, which causes the equilibrium to shift to the left. Hydrogen ions combine with bicarbonate ions to produce carbonic acid, which decomposes into CO_2 gas that's expelled from the lungs. The result is a decrease in the plasma hydrogen ion concentration, which stabilizes the pH and keeps it from getting too low. Wow, chemistry really is essential for medical school!*

Chemical equilibrium is the dynamic state of a chemical reaction in which the concentrations of reactants and products stabilize over time in a low-energy

configuration. Pay particular attention to the concepts of chemical equilibrium because we will return to these topics during our review of solutions, acid–base chemistry, and oxidation–reduction reactions.

6.1 Equilibrium ★★★

In the previous chapter, we danced around the term *equilibrium*. We warned you not to confuse the chemical equilibrium expression for the rate expression. We stressed that catalysts make reactions go faster toward their equilibrium position, but that they can't actually change the equilibrium position or alter the value of K_{eq}. The principles and concepts that are the focus of this chapter will direct our discussion in the upcoming chapters about some of the most important general chemistry topics for the MCAT: solutions, acids and bases, and oxidation–reduction reactions.

DYNAMIC EQUILIBRIA AND REVERSIBILITY

Bridge

Many biochemical reactions can be classified as reversible, and their activation energies are lowered by enzymes. Irreversible biochemical steps are sometimes termed "committed" because they cannot be reversed in their pathways. These steps also tend to be the rate-limiting steps of metabolic pathways, which are discussed in Chapters 9 through 11 of *MCAT Biochemistry Review*.

So far, most of the reactions we've covered are **irreversible**; that is, the reaction proceeds in one direction only, the reaction goes to completion, and the maximum amount of product formed is determined by the amount of limiting reagent initially present. **Reversible** reactions are those in which the reaction can proceed in one of two ways: forward (toward the products or "to the right") and reverse (toward the reactants or "to the left"). Reversible reactions usually do not proceed to completion because the products can react together to reform the reactants. When the reaction system is closed and no reactants or products are added or removed, the system will eventually settle into a state in which the rate of the forward reaction equals the rate of the reverse reaction and the concentrations of the products and reactants remain constant. In this **dynamic equilibrium**, the forward and reverse reactions are still occurring—they haven't stopped, as they do in a **static equilibrium**—but they are going at the same rate; thus, there is no net change in the concentrations of the products or reactants, as shown in Figure 6.1.

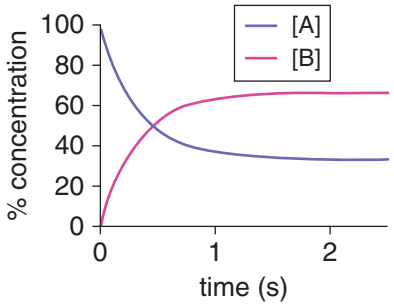

Figure 6.1. Dynamic Equilibrium Occurs when Forward and Reverse Rates Are Equal

Consider the generic reversible reaction illustrated in Figure 6.1:

$$A \rightleftharpoons B$$

At equilibrium, the concentrations of A and B are constant (although not necessarily equal), and the reactions A → B and B → A continue to occur at equal rates.

Equilibrium can be thought of as a balance between the forward and reverse reactions. Better still, equilibrium should be understood on the basis of **entropy**, which is the measure of the distribution of energy throughout a system or between a system and its environment. For a reversible reaction at a given temperature, the reaction will reach equilibrium when the system's entropy—or energy distribution—is at a maximum and the Gibbs free energy of the system is at a minimum.

Bridge

In Chapter 7 of *MCAT General Chemistry Review*, we will explore the more "classic" MCAT definition of entropy—a measure of the disorder of a system. It is important to realize, though, that the units of entropy $\left(\frac{J}{K \cdot mol}\right)$ imply a distribution of energy in a system.

LAW OF MASS ACTION

For a generic reversible reaction $aA + bB \rightleftharpoons cC + dD$, the **law of mass action** states that, if the system is at equilibrium at a constant temperature, then the following ratio is constant:

$$K_{eq} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

Equation 6.1

The law of mass action is actually related to the expressions for the rates of the forward and reverse reactions. Consider the following one-step reversible reaction:

$$2\,A \rightleftharpoons B + C$$

Because the reaction occurs in one step, the rates of the forward and reverse reactions are given by:

$$\text{rate}_f = k_f[A]^2 \text{ and } \text{rate}_r = k_r[B][C]$$

When $\text{rate}_f = \text{rate}_r$, the system is in equilibrium. Because the rates are equal, we can set the rate expressions for the forward and reverse reactions equal to each other:

$$k_f[A]^2 = k_r[B][C] \rightarrow \frac{k_f}{k_r} = \frac{[B][C]}{[A]^2}$$

Because k_f and k_r are both constants, we can define a new constant K_c, where K_c is called the **equilibrium constant** and the subscript c indicates that it is in terms of concentration. When dealing with gases, the equilibrium constant is referred to as K_p, and the subscript p indicates that it is in terms of pressure. For dilute solutions, K_c and K_{eq} are used interchangeably. The new equation can thus be written:

$$K_c = K_{eq} = \frac{[B][C]}{[A]^2}$$

Key Concept

At equilibrium, the rate of the forward reaction equals the rate of the reverse reaction, entropy is at a maximum, and Gibbs free energy is at a minimum. This links the concepts of thermodynamics and kinetics.

Key Concept

For most purposes, you will not need to distinguish between different *K* values. For dilute solutions, $K_{eq} = K_c$ and both are calculated in units of concentration.

While the forward and the reverse reaction rates are equal at equilibrium, the concentrations of the reactants and products are not usually equal. This means that the forward and reverse reaction rate constants, k_f and k_r, respectively, are not usually equal to each other. The ratio of k_f to k_r is K_c:

$$K_c = K_{eq} = \frac{k_f}{k_r}$$

When a reaction occurs in more than one step, the equilibrium constant for the overall reaction is found by multiplying together the equilibrium constants for each step of the reaction. When this is done, the equilibrium constant for the overall reaction is equal to the concentrations of the products divided by the concentrations of the reactants in the overall reaction, with each concentration term raised to the stoichiometric coefficient for the respective species. The forward and reverse rate constants for the nth step are designated k_n and k_{-n}, respectively. For example, if the reaction $aA + bB \rightleftharpoons cC + dD$ occurs in three steps, each with a forward and reverse rate, then:

$$K_c = \frac{k_1 k_2 k_3}{k_{-1} k_{-2} k_{-3}} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

Key Concept

Remember the warning in Chapter 5 of *MCAT General Chemistry Review* about confusing equilibrium expressions and rate laws? In equilibrium expressions, the exponents are equal to the coefficients in the balanced equation. In rate laws, the exponents must be determined experimentally and often do not equal the stoichiometric coefficients.

Example: What is the expression for the equilibrium constant for the following reaction?

$$3\ H_2\ (g) + N_2\ (g) \rightleftharpoons 2\ NH_3\ (g)$$

Solution:

$K_c = K_{eq} = \frac{[NH_3]^2}{[H_2]^3[N_2]}$. The K_p of this reaction would be: $\frac{(P_{NH_3})^2}{(P_{H_2})^3 \times P_{N_2}}$.

REACTION QUOTIENT

The law of mass action defines the position of equilibrium; however, equilibrium is a state that is only achieved through time. Depending on the actual rates of the forward and reverse reactions, equilibrium might be achieved in microseconds or millennia. What can serve as a "timer" to indicate how far the reaction has proceeded toward equilibrium? This role is served by the **reaction quotient**, ***Q***. At any point in time during a reaction, we can measure the concentrations of all of the reactants and products and calculate the reaction quotient according to the following equation:

$$Q_c = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

Equation 6.2

This equation looks identical to the equation for K_{eq}. It is the same form, but the information it provides is quite different. While the concentrations used for the law of mass action are equilibrium (constant) concentrations, the concentrations of the reactants and products are not constant when calculating a value for Q of a reaction. Thus, the utility of Q is not the value itself but rather the comparison that can be made between Q at any given moment in the reaction to the known K_{eq} for the reaction at a particular temperature. Le Châtelier's principle, which will be elaborated upon shortly, will then guide the reaction. For any reaction, if:

- $Q < K_{eq}$, then the forward reaction has not yet reached equilibrium.
    - There is a greater concentration of reactants (and smaller concentration of products) than at equilibrium.
    - The forward rate of reaction is increased to restore equilibrium.
- $Q = K_{eq}$, then the reaction is in dynamic equilibrium.
    - The reactants and products are present in equilibrium proportions.
    - The forward and reverse rates of reaction are equal.
- $Q > K_{eq}$, then the forward reaction has exceeded equilibrium.
    - There is a greater concentration of products (and smaller concentration of reactants) than at equilibrium.
    - The reverse rate of reaction is increased to restore equilibrium.

Any reaction that has not yet reached the equilibrium state, as indicated by $Q < K_{eq}$, will continue spontaneously in the forward direction (consuming reactants to form products) until the equilibrium ratio of reactants and products is reached. Any reaction in the equilibrium state will continue to react in the forward and reverse directions, but the reaction rates for the forward and reverse reactions will be equal, and the concentrations of the reactants and products will be constant, such that $Q = K_{eq}$. A reaction that is beyond the equilibrium state, as indicated by $Q > K_{eq}$, will proceed in the reverse direction (consuming products to form reactants) until the equilibrium ratio of reactants and products is reached again. Once a reaction is at equilibrium, any further movement in either the forward direction (resulting in an increase in products) or in the reverse direction (resulting in the reformation of reactants) will be nonspontaneous. This trend is illustrated in Figure 6.2.

Key Concept

- $Q < K_{eq}$: $\Delta G < 0$, reaction proceeds in forward direction
- $Q = K_{eq}$: $\Delta G = 0$, reaction is in dynamic equilibrium
- $Q > K_{eq}$, $\Delta G > 0$: reaction proceeds in reverse direction

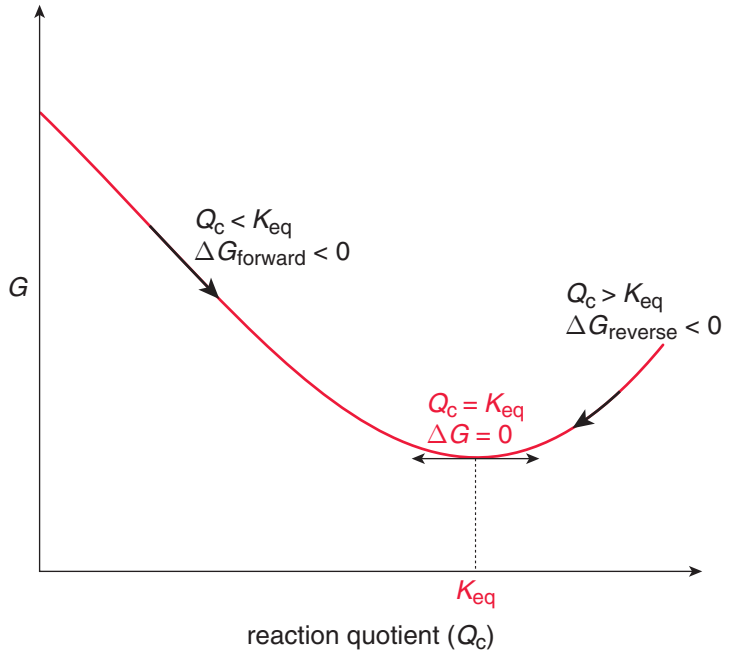

Figure 6.2. Gibbs Free Energy *vs.* Reaction Quotient

In Chapter 7 of *MCAT General Chemistry Review*, we'll further discuss how the spontaneity of these systems is related to enthalpy and entropy.

PROPERTIES OF THE LAW OF MASS ACTION

Make sure to remember the following characteristics of the law of mass action and equilibrium constant expressions:

- The concentrations of pure solids and pure liquids do not appear in the equilibrium constant expression. This is because the equilibrium expression is technically based on the activities of compounds, not concentrations; the activities of pure solids and liquids are defined to be 1. For the purposes of the MCAT, there is a negligible difference between concentration and activity.
- K_{eq} is characteristic of a particular reaction at a given temperature; the equilibrium constant is temperature-dependent.
- The larger the value of K_{eq}, the farther to the right the equilibrium position.
- If the equilibrium constant for a reaction written in one direction is K_{eq}, the equilibrium constant for the reverse reaction is $\frac{1}{K_{eq}}$.

MCAT Concept Check 6.1:

Before you move on, assess your understanding of the material with these questions.

1. Given that [product] = 0.075 *M* and [reactant] = 1.5 *M*, determine the direction of reaction and the sign of the free energy change for reactions with the following K_{eq} values: (Note: Assume that the reaction has only one product and one reactant, and that the stoichiometric coefficient for each is 1.)

K_{eq}	Direction of Reaction	ΔG
5.0×10^{-2}		
5.0×10^{-3}		
5.0×10^{-1}		

2. Write the equilibrium constant expression for the following reactions:
   - $CO\ (g) + 2\ H_2\ (g) \rightleftharpoons CH_3OH\ (g)$:

     _____

   - $H_3PO_4\ (aq) + H_2O\ (l) \rightleftharpoons H_2PO_4^-\ (aq) + H_3O^+\ (aq)$:

     _____

6.2 Le Châtelier's Principle ★★

Le Châtelier's principle states that if a stress is applied to a system, the system shifts to relieve that applied stress. Regardless of the form the stress takes, the reaction is temporarily moved out of its equilibrium state. This is either because the concentrations or partial pressures of the system are no longer in the equilibrium ratio or because the equilibrium ratio itself has changed as a result of a change in the temperature of the system. The reaction then responds by reacting in whichever direction—either forward or reverse—will result in a reestablishment of the equilibrium state.

CHANGES IN CONCENTRATION

When reactants or products are added or removed from a reaction in equilibrium, the reaction is moved from its minimum energy state. With the change in concentration of one or more of the chemical species, the system now has a ratio of products to reactants that is not equal to the equilibrium ratio. In other words, changing the concentration of either a reactant or a product results in $Q_c \neq K_{eq}$. If reactants are added (or products are removed), $Q_c < K_{eq}$, and the reaction will spontaneously react in the forward direction, increasing the value of Q_c until $Q_c = K_{eq}$. If reactants are removed (or products are added), $Q_c > K_{eq}$, and the reaction will spontaneously react in the

MCAT Expertise

Le Châtelier's principle applies to a wide variety of systems and, therefore, appears as a fundamental concept in all three MCAT science sections.

Bridge

The bicarbonate buffer system is a classic example of Le Châtelier's principle applied to physiology:

$$CO_2\ (g) + H_2O\ (l) \rightleftharpoons H_2CO_3\ (aq) \rightleftharpoons H^+\ (aq) + HCO_3^-\ (aq)$$

In the tissues, there is a relatively high concentration of CO_2, and the reaction shifts to the right. In the lungs, CO_2 is lost, and the reaction shifts to the left. Note that blowing off CO_2 (hyperventilation) is used as a mechanism for dealing with acidemia (excess H^+ in the blood). This buffer system plays a key role in the respiratory, circulatory, and excretory systems, discussed in Chapters 6, 7, and 10 of *MCAT Biology Review*, respectively.

reverse direction, thereby decreasing the value of Q_c until once again $Q_c = K_{eq}$. Put simply, the system will always react in the direction away from the added species or toward the removed species.

We often take advantage of Le Châtelier's principle to improve the yield of chemical reactions. For example, in the industrial production of chemicals, products of reversible reactions are removed as they are formed to prevent the reactions from reaching their equilibrium states. The reaction will continue to react in the forward direction, producing more and more products—assuming reactants are continually replaced as they are consumed. One could also drive a reaction forward by starting with high concentrations of reactants. This will lead to an increase in the absolute quantities of products formed, although the reaction will still eventually reach its equilibrium state unless products are removed as they are formed.

CHANGES IN PRESSURE (AND VOLUME)

Because liquids and solids are essentially incompressible, only chemical reactions that involve at least one gaseous species will be affected by changes in the system's pressure and volume. When a system is compressed, its volume decreases and its total pressure increases. This increase in the total pressure is associated with an increase in the partial pressures of each gas in the system, and this results in the system no longer being in the equilibrium state, such that Q_p does not equal K_{eq}. The system will move forward or in reverse, always toward whichever side has the lower total number of moles of gas. This is a consequence of the ideal gas law, which tells us that there is a direct relationship between the number of moles of gas and the pressure of the gas. If one increases the pressure of a system, it will respond by decreasing the total number of gas moles, thereby decreasing the pressure. Note that this scenario assumes that the volume of the system was decreased and then held constant while the system returned to its equilibrium state. When one expands the volume of a system, the total pressure and the partial pressures decrease. The system is no longer in its equilibrium state and will react in the direction of the side with the greater number of moles of gas in order to restore the pressure.

Consider the following reaction:

$$N_2\,(g) + 3\,H_2\,(g) \rightleftharpoons 2\,NH_3\,(g)$$

The left side of the reaction has a total of four moles of gas molecules, while the right side has only two moles. When the pressure of this system is increased, the system will react in the direction that produces fewer moles of gas. In this case, that direction is to the right, and more ammonia will form. However, if the pressure is decreased, the system will react in the direction that produces more moles of gas; thus, the reverse reaction will be favored, and more nitrogen and hydrogen gas will reform.

CHANGES IN TEMPERATURE

Le Châtelier's principle tells us that changing the temperature of a system will also cause the system to react in a particular way to return to its equilibrium state. However, unlike the effect of changing concentrations or pressures, the result of changing temperature is not a change in the reaction quotient, Q_c or Q_p, but a change in K_{eq}. The change in temperature does not cause the concentrations or partial pressures of the reactants and products to change immediately, so Q immediately after the temperature change is the same as before the temperature change. Thus, because K_{eq} is now a different value, Q no longer equals K_{eq}. The system has to move in whichever direction allows it to reach its new equilibrium state at the new temperature. That direction is determined by the enthalpy of the reaction. If a reaction is endothermic ($\Delta H > 0$), heat functions as a reactant; if a reaction is exothermic ($\Delta H < 0$), heat functions as a product. Thinking about heat as a reactant or product allows us to apply the same principles we used with concentration changes to temperature changes.

For example, consider the following endothermic reaction, shown in Figure 6.3:

$$N_2O_4\,(g) \overset{\Delta}{\rightleftharpoons} 2NO_2\,(g)$$

The equilibrium position can be shifted by changing the temperature. When heat is added and the temperature increases, the reaction shifts to the right, and the flask turns reddish-brown due to an increase in [NO_2]. When heat is removed and the temperature decreases, the reaction shifts to the left, and the flask turns more transparent due to an increase in N_2O_4. This demonstrates Le Châtelier's principle because the equilibrium shifts in the direction that consumes energy.

Figure 6.3. Example of a Reversible Endothermic Reaction, $N_2O_4\,(g) \rightleftharpoons 2\,NO_2\,(g)$
Left: As temperature decreases, the equilibrium favors N_2O_4 production, turning the reaction vessel more transparent. Right: As temperature increases, the equilibrium favors NO_2 production, turning the reaction vessel reddish-brown.

Key Concept

The reaction

A (*aq*) + 2 B (*g*) ⇌ C (*g*) + heat

Will shift to the right if . . .	Will shift to the left if . . .
A or B is added	C is added
C is removed	A or B is removed
the pressure is increased or the volume is reduced	the pressure is reduced or the volume is increased
the temperature is reduced	the temperature is increased

MCAT Concept Check 6.2:
Before you move on, assess your understanding of the material with this question.

1. Describe what would happen in the following situations:
   - In the reaction $H_2SO_4\ (aq) \rightleftharpoons H^+\ (aq) + HSO_4^-\ (aq)$, the pH has been increased:

     _____

   - In the reaction $2\ C\ (s) + O_2\ (g) \rightleftharpoons 2\ CO\ (g)$, the pressure of the reaction vessel is decreased:

     _____

   - In the reaction $CH_4\ (g) + 2\ O_2\ (g) \rightleftharpoons CO_2\ (g) + 2\ H_2O\ (l)$ + heat, the reaction vessel is warmed:

     _____

   - In the reaction $H_3PO_4\ (aq) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + H_2PO_4^-\ (aq)$, water is removed (without changing temperature):

     _____

6.3 Kinetic and Thermodynamic Control ★

Having covered the fundamentals of kinetics and thermodynamics, we come upon a topic that bridges all chemical systems: control of a reaction. In particular, biochemical reactions often require regulation in a precise manner to be useful to an organism. The applications of kinetic and thermodynamic control are common on the MCAT and range from metabolic reactions requiring high-energy phosphate molecules such as ATP to the effects of temperature and solvents on enzyme activity.

The examples below consider unimolecular systems through the lens of the transition state theory. Figure 6.4 shows starting materials (reactants) at a certain energy level. These reactants can undergo two different sets of reactions. At lower temperatures (with smaller heat transfer), a **kinetic product** is formed. At higher temperatures (with larger heat transfer), a **thermodynamic product** is formed.

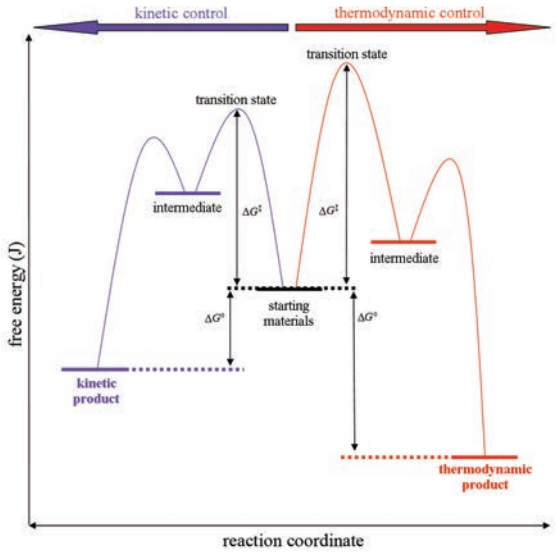

Figure 6.4. Kinetic and Thermodynamic Control of a Reaction
The kinetic pathway requires less free energy to reach the transition state, but results in a higher-energy (less stable) product.

Note that the free energy that must be added for the kinetic pathway is lower than that of the thermodynamic pathway. Therefore, the kinetic products often form faster than the thermodynamic products and are sometimes called "fast" products. On the other hand, the free energy of the thermodynamic product is significantly lower than that of the kinetic product. Thermodynamic products are therefore associated with greater stability, and with a more negative ΔG than kinetic products.

The stability of organic molecules is covered in Chapter 2 of *MCAT Organic Chemistry Review* and is dependent on torsional strain, angle strain, and nonbonded strain. In this example, we consider the conversion of 2-methylcyclohexanone to its thermodynamic product and its kinetic product, as shown in Figure 6.5. Both reactions require a base (B^-) in order to catalyze the conversion, yet two different products are produced.

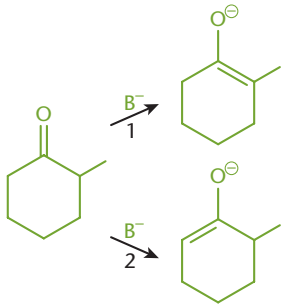

Figure 6.5. Conversion of 2-methylcyclohexanone to (1) Thermodynamic Product and (2) Kinetic Product

For the thermodynamic pathway (**1**), the double bond is located between C-1 and the methyl group. It requires more energy to form the transition state of this reaction because the base must overcome the steric hindrance created by the methyl group. The

base squeezes in to reach the carbon with the methyl group attached to abstract a proton. However, because the double bond is more substituted than the other pathway, the product of this reaction is more stable and less likely to react further.

For the kinetic pathway **(2)**, the double bond is located between C-1 and C-6. This pathway is preferred when there is little heat available because less energy is needed to reach the transition state. The base can more easily reach C-6 to remove a proton, and the resulting enolate can form. This product has a less substituted double bond, which reduces its stability. This lack of stability may leave the ring susceptible to further attack.

MCAT Concept Check 6.3:

Before you move on, assess your understanding of the material with these questions.

1. What conditions favor formation of a kinetic product? A thermodynamic product?
   - Kinetic product:

     _____
   - Thermodynamic product:

     _____
2. On a reaction coordinate diagram, how would the kinetic pathway appear as compared to the thermodynamic pathway?

_____

_____

Conclusion

We've discussed some very important concepts and principles in the past two chapters related to the studies of reaction rates and chemical equilibria. In this chapter, we began with the law of mass action and the significance of the equilibrium state of a chemical reaction. With our understanding of the significance of K_{eq} and Q, we are able to predict the direction that a reaction will go in response to various stresses—concentration, pressure, or temperature changes—that might be applied to a system.

The concept of homeostasis in biology is a direct result of the energy associated with disturbing equilibria in the body. Reactions are often held slightly out of the equilibrium state to generate energy. Many pathologies you will encounter in your future career in medicine will have a fundamental basis in disturbed chemical equilibria—just wait until you start ordering metabolic panels on your patients!

CONCEPT SUMMARY

Equilibrium

- **Reversible** reactions eventually reach a state in which energy is minimized and entropy is maximized.
  - Chemical equilibria are **dynamic**—the reactions are still occurring, just at a constant rate.
  - The concentrations of reactants and products remain constant because the rate of the forward reaction equals the rate of the reverse reaction.
- The **law of mass action** gives the expression for the equilibrium constant, K_{eq}. The reaction quotient, Q, has the same form but can be calculated at any concentrations of reactants and products.
  - Q is a calculated value that relates the reactant and product concentrations at any given time during a reaction.
  - K_{eq} is the ratio of products to reactants at equilibrium, with each species raised to its stoichiometric coefficient. K_{eq} for a reaction is constant at a constant temperature.
  - Pure solids and liquids do not appear in the law of mass action; only gases and aqueous species do.
- Comparison of Q to K_{eq} provides information about where the reaction is with respect to its equilibrium state.
  - If $Q < K_{eq}$, $\Delta G < 0$, and the reaction proceeds in the forward direction.
  - If $Q = K_{eq}$, $\Delta G = 0$, and the reaction is in dynamic equilibrium.
  - If $Q > K_{eq}$, $\Delta G > 0$, and the reaction proceeds in the reverse direction.

Le Châtelier's Principle

- **Le Châtelier's principle** states that when a chemical system experiences a stress, it will react so as to restore equilibrium.
- There are three main types of stresses applied to a system: changes in concentration, pressure and volume, and temperature.
  - Increasing the concentration of reactants or decreasing the concentration of products will shift the reaction to the right. Increasing the concentration of products or decreasing the concentration of reactants will shift the reaction to the left.
  - Increasing pressure on a gaseous system (decreasing its volume) will shift the reaction toward the side with fewer moles of gas. Decreasing pressure on a gaseous system (increasing its volume) will shift the reaction toward the side with more moles of gas.

- Increasing the temperature of an endothermic reaction or decreasing the temperature of an exothermic reaction will shift the reaction to the right. Decreasing the temperature of an endothermic reaction or increasing the temperature of an exothermic reaction will shift the reaction to the left.

Kinetic and Thermodynamic Control

- Reactions may have both kinetic and thermodynamic products that can be regulated by temperature and the presence of a catalyst.
  - **Kinetic products** are higher in free energy than thermodynamic products and can form at lower temperatures. These are sometimes termed "fast" products because they can form more quickly under such conditions.
  - **Thermodynamic products** are lower in free energy than kinetic products and are therefore more stable. Despite proceeding more slowly than the kinetic pathway, the thermodynamic pathway is more spontaneous (more negative ΔG).

ANSWERS TO CONCEPT CHECKS

6.1

1.

K_{eq}	Direction of Reaction	ΔG
$\mathbf{5.0 \times 10^{-2}}$	At equilibrium: no net reaction	0
$\mathbf{5.0 \times 10^{-3}}$	$Q_c > K_{eq}$: proceeds toward reactants (left)	Positive
$\mathbf{5.0 \times 10^{-1}}$	$Q_c < K_{eq}$: proceeds toward products (right)	Negative

2. $$K_p = \frac{P_{CH_3OH}}{P_{CO} \times (P_{H_2})^2}$$

$$K_c = K_a = \frac{[H_2PO_4^-][H_3O^+]}{[H_3PO_4]}$$

6.2

1. • Increasing pH of H_2SO_4 $(aq) \rightleftharpoons H^+$ (aq) + HSO_4^- (aq): $[H^+]$ decreases, shifting reaction to the right.
   • Decreasing pressure of 2 C (s) + O_2 $(g) \rightleftharpoons$ 2 CO (g): Reaction shifts right, favoring the side with more moles of gas.
   • Warming CH_4 (g) + $2O_2$ $(g) \rightleftharpoons CO_2$ (g) + 2 H_2O (l) + heat: Reaction shifts left, using the additional heat energy to produce more reactants.
   • Removing water from H_3PO_4 (aq) + H_2O $(l) \rightleftharpoons H_3O^+$ (aq) + $H_2PO_4^-$ (aq): Reaction shifts left. All concentrations would increase proportionately; because there are more products than reactants (and the stoichiometric coefficient is 1 for each reactant and product), the value of Q will increase.

6.3

1. Kinetic products are favored at low temperatures with low heat transfer. Thermodynamic products are favored at high temperatures with high heat transfer.
2. Kinetic pathways require a smaller gain in free energy to reach the transition state. They also have a higher free energy of the products, with a smaller difference in free energy between the transition state and the products.

EQUATIONS TO REMEMBER

(6.1) **Equilibrium constant:** $K_{eq} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$

(6.2) **Reaction quotient:** $Q_c = \frac{[C]^c[D]^d}{[A]^a[B]^b}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. A reaction is found to stop just before all reactants are converted to products. Which of the following could be true about this reaction?

A. The reaction is irreversible, and the forward rate is greater than the reverse rate.

B. The reaction is irreversible, and the reverse rate is too large for products to form.

C. The reaction is reversible, and the forward rate is equal to the reverse rate.

D. The reaction is reversible, and the reverse rate is greater than the forward rate.

2. What is the equilibrium expression for the reaction $Cu_2SO_4\,(s) \rightleftharpoons 2\,Cu^+\,(aq) + SO_4^{2-}\,(aq)$?

A. $\dfrac{[Cu^+]^2[SO_4^{2-}]}{[Cu_2SO_4]}$

B. $\dfrac{2 \times [Cu^+][SO_4^{2-}]}{[Cu_2SO_4]}$

C. $[Cu^+][SO_4^{2-}]$

D. $[Cu^+]^2[SO_4^{2-}]$

3. Carbonated beverages are produced by dissolving carbon dioxide in water to produce carbonic acid:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq)$$

When a bottle containing carbonated water is opened, the taste of the beverage gradually changes as the carbonation is lost. Which of the following statements best explains this phenomenon?

A. The change in pressure and volume causes the reaction to shift to the left, thereby decreasing the amount of aqueous carbonic acid.

B. The change in pressure and volume causes the reaction to shift to the right, thereby decreasing the amount of gaseous carbon dioxide.

C. Carbonic acid reacts with environmental oxygen and nitrogen.

D. Carbon dioxide reacts with environmental oxygen and nitrogen.

4. What is the proper equilibrium expression for the reaction below?

$$2\,NO_2\,(g) + 4\,H_2\,(g) \rightleftharpoons N_2\,(g) + 4\,H_2O\,(g)$$

A. $K_p = \dfrac{P_{N_2} \times (P_{H_2O})^4}{(P_{NO_2})^2 \times (P_{H_2})^4}$

B. $K_c = \dfrac{P_{N_2} \times (P_{H_2O})^4}{(P_{NO_2})^2 \times (P_{H_2})^4}$

C. $K_p = \dfrac{P_{N_2}}{(P_{NO_2})^2 \times (P_{H_2})^4}$

D. $K_c = \dfrac{P_{N_2}}{(P_{NO_2})^2 \times (P_{H_2})^4}$

5. If $K_c \gg 1$:

A. the equilibrium mixture will favor products over reactants.

B. the equilibrium mixture will favor reactants over products.

C. the equilibrium concentrations of reactants and products are equal.

D. the reaction is essentially irreversible.

6. Acetic acid dissociates in solution according to the following equation:

$$CH_3COOH \rightleftharpoons CH_3COO^- + H^+$$

If sodium acetate is added to a solution of acetic acid in excess water, which of the following effects would be observed in the solution?

A. Decreased pH
B. Increased pH
C. Decreased pK_{eq} (pK_a)
D. Increased pK_{eq} (pK_a)

Questions 7 and 8 refer to the reaction below:

$$FeI\,(aq) + I_2\,(g) \rightarrow FeI_3\,(aq)$$

7. Which of the following would increase the formation of product?

A. Decreasing the volume of the container
B. Decreasing the pressure of the container
C. Increasing the volume of the container
D. Decreasing the volume of the container while maintaining a constant pressure

8. If this reaction were exothermic, what effect would decreasing the temperature have on the equilibrium?

A. The forward reaction rate and the reverse reaction rate both increase.
B. The forward reaction rate decreases while the reverse reaction rate increases.
C. The forward reaction rate increases while the reverse reaction rate decreases.
D. The forward reaction rate and the reverse reaction rate both decrease.

9. Which of the following actions does NOT affect the equilibrium position of a reaction?

A. Adding or removing heat.
B. Adding or removing a catalyst.
C. Increasing or decreasing concentrations of reactants.
D. Increasing or decreasing volumes of reactants.

10. In a sealed 1 L container, 1 mole of nitrogen gas reacts with 3 moles of hydrogen gas to form 0.05 moles of NH_3 at equilibrium. Which of the following is closest to the K_c of the reaction?

A. 0.0001
B. 0.001
C. 0.01
D. 0.1

11. Increasing temperature can alter the K_{eq} of a reaction. Why might increasing temperature indefinitely be unfavorable for changing reaction conditions?

A. The equilibrium constant has a definite limit that cannot be surpassed.
B. The products or reactants can decompose at high temperatures.
C. Increasing temperature would decrease pressure, which may or may not alter reaction conditions.
D. If a reaction is irreversible, its K_{eq} will resist changes in temperature.

12. Which of the following is true of equilibrium reactions?

I. An increase in k_1 results in a decrease in k_{-1}.
II. As the concentration of products increases, the concentrations of reactants decreases.
III. The equilibrium constant is altered by changes in temperature.

A. I only
B. II and III only
C. I and III only
D. I, II, and III

13. Compound A has a K_a (equilibrium constant of acid dissociation) of approximately 10^{-4}. Which of the following compounds is most likely to react with a solution of compound A?

A. HNO_3
B. NO_2
C. NH_3
D. N_2O_5

14. Consider the following two reactions:

$$3\ A + 2\ B \rightleftharpoons 3\ C + 4\ D \text{ (Reaction 1)}$$
$$4\ D + 3\ C \rightleftharpoons 3\ A + 2\ B \text{ (Reaction 2)}$$

If K_{eq} for reaction 1 is equal to 0.1, what is K_{eq} for reaction 2?

A. 0.1
B. 1
C. 10
D. 100

15. Which of the following statements best describes the effect of lowering the temperature of the following reaction?

$$A + B \rightleftharpoons C + D \qquad \Delta H = -1.12\ \frac{kJ}{mol}$$

A. [C] and [D] would increase.
B. [A] and [B] would increase.
C. ΔH would increase.
D. ΔH would decrease.

Explanations to Discrete Practice Questions

1. C

This scenario likely describes a situation in which a reaction has reached equilibrium very far to the right (with high product concentration and low reactant concentration). This reaction must be reversible because the reaction did not proceed all the way to the right. Any reaction in equilibrium has equal forward and reverse rates of reaction.

2. D

Recall that pure solids and liquids do not appear in the equilibrium expression; thus, this K_{eq} has no denominator because the only reactant is a solid, cuprous sulfate. This could also be called K_{sp} because a solid is dissociating into ions in solution. The correct K_{eq} should have $[Cu^+]$ squared because its stoichiometric coefficient is 2.

3. A

Carbon dioxide gas evolves and leaves the bottle, which decreases the total pressure of the reactants. Le Châtelier's principle explains that a decrease in pressure shifts the equilibrium to increase the number of moles of gas present. This particular reaction will shift to the left, which in turn will decrease the amount of carbonic acid and increase the amount of carbon dioxide and water. Oxygen and nitrogen are not highly reactive and are unlikely to combine spontaneously with carbon dioxide or carbonic acid, as in **choices (C)** and **(D)**.

4. A

Recall that equilibrium constants are either based on concentrations (K_c) or partial pressures (K_p). In this case, because all species are in the gas phase, we are using K_p—eliminating **choices (B)** and **(D)**. When water is in the liquid phase, it does not appear in equilibrium expressions, as in **choice (C)**. Here, however, water is in the gaseous phase and thus should appear in the equilibrium expression.

5. A

The larger the value of K_{eq} (whether K_c or K_p), the larger the ratio of products to reactants. Therefore, if $K_c \gg 1$, there are significantly larger concentrations of products than reactants at equilibrium. Even with a large K_{eq}, the reaction will ultimately reach equilibrium far toward the products side and is therefore reversible, eliminating **choice (D)**.

6. B

Adding sodium acetate increases the number of acetate ions present. According to Le Châtelier's principle, this change will push this reaction to the left, resulting in a decrease in the number of free H^+ ions. Because pH is determined by the hydrogen ion concentration, a decrease in the number of free protons will increase the pH. An acid's K_a (which is simply the K_{eq} for acid dissociation) will remain constant under a given temperature and pressure, eliminating **choices (C)** and **(D)**.

7. A

Both increasing the pressure of the container and decreasing the volume would favor the side with fewer moles of gas, which is the product side. This makes **choices (B)** and **(C)** incorrect. **Choice (D)** would not disturb the equilibrium—the significance of decreasing the volume of the container in most equilibria is that there is an increase in pressure; in this case, however, the pressure remains constant despite the change in volume.

8. C

An exothermic reaction produces heat. Decreasing the temperature favors product formation, resulting in an increase in

the forward reaction rate with a concomitant decrease in the reverse reaction rate.

9. B

The equilibrium of a reaction can be changed by several factors. Adding or subtracting heat, **choice (A)**, would shift the equilibrium based on the enthalpy change of the reaction. Increasing reactant concentrations would shift the equilibrium in the direction of the product, and the opposite would occur if reactant concentrations were decreased, eliminating **choice (C)**. Changing the volume of a reactant would affect any reaction with gaseous reactants or products, eliminating **choice (D)**. While adding or removing a catalyst would change the reaction rates, it would not change where the equilibrium lies.

10. A

The first step to answering this question is to write out the balanced equation for the reaction of H_2 and N_2 to produce NH_3: $N_2 + 3\ H_2 \rightleftharpoons 2\ NH_3$. This means that K_c is equal to $\frac{[NH_3]^2}{[N_2][H_2]^3}$. Because the volume is 1 L, the amount of each gas (in moles) is equal to the value of the concentration of each gas (in *M*). If we start with 1 mole N_2 and 3 moles H_2, some amount x of N_2 will react with $3x$ amount of H_2 to form $2x$ amount of ammonia according to their stoichiometric coefficients. The amount of ammonia at equilibrium is given here as 0.05 *M*; thus, $2x = 0.05$ and $x = 0.025$. Thus, the concentration of N_2 at equilibrium is $1 - 0.025 = 0.975$ *M*, and the concentration of H_2 at equilibrium is $3 - 3 \times 0.025 = 2.925$ *M*. Note that these changes are negligible because the answer choices differ by powers of ten. Thus, we can plug into the K_{eq} expression to get $\frac{[NH_3]^2}{[N_2][H_2]^3} \approx \frac{[0.05]^2}{[1][3]^3} = \frac{0.0025}{27} \approx 0.0001$.

11. B

At extremely high temperatures, reactants or products may decompose, which will affect the equilibrium and potentially destroy the desired products. **Choice (A)** implies that reactions have limits, which is true; however, this does not make increasing temperature unfavorable. **Choice (C)** is false because increasing temperature would also increase pressure, assuming constant volume. **Choice (D)** is incorrect because it refers to properties of irreversible reactions which would not be involved in an equilibrium between products and reactants.

12. B

Statement I is false because the addition of a catalyst could increase the rate constants of both the forward and reverse reactions. Statement II is true because—for products to come into existence—reactants must be used up. Statement III is also true: all *K* values are temperature-dependent.

13. C

K_a is equal to the ratio of products to reactants, with each species raised to its stoichiometric coefficient. A compound with a K_a greater than 10^{-7} contains more H^+ cations than HA^- anions at equilibrium, which makes it an acid. This means that the compound in question is likely to react with a compound that is basic. Of the four answer choices, NH_3 is the only base.

14. C

Reaction 2 is simply the reverse of reaction 1. This means that K_{eq} for reaction 2 is the inverse of K_{eq} of reaction 1, so the answer is $(0.1)^{-1} = 10$.

15. A

A negative ΔH value indicates an exothermic reaction, meaning that the forward reaction produces heat. Visualize this as follows:

$$A + B \rightleftharpoons C + D + \text{heat}$$

This means that removing heat by decreasing the temperature is similar to removing any other product of the reaction. To compensate for this loss, the reaction will shift to the right, causing an increase in the concentrations of C and D as well as a decrease in the concentrations of A and B.

Introduction

Styrofoam cups are such good insulators that they can be used as holding containers for certain calorimetry experiments. Coffee-cup calorimetry, which uses Styrofoam cups to measure heats of solution and specific heats of metals and other materials, is low-tech, yet it can produce remarkably accurate results as long as care has been taken to calibrate the calorimeter and to minimize heat loss through the top of the container. The next time you are at your favorite coffee chain, think about what occurs when cold cream is added to hot coffee. If we took the time to measure the masses and temperatures of the hot coffee and the cold cream before mixing them, measured the drink's temperature after it had been stirred, and looked up the specific heats of water and cream, we would have enough information to calculate the amount of heat exchanged between the hot coffee and the cold cream.

This chapter will review the basic principles of thermochemistry, which is the study of the energy changes that accompany chemical and physical processes. Starting with the first law of thermodynamics, which states that energy is never created nor destroyed but—at most—simply changed from one form to another, we will quantify the various exchanges in energy as a system moves from some initial state to a final state. As we go along, we will define what is meant by system and surroundings, state functions, heat, enthalpy, entropy, and Gibbs free energy.

7.1 Systems and Processes

Students often have some anxiety over what constitutes a *system* and what—by exclusion from the system—constitutes the *surroundings* or *environment*. Perhaps the problem isn't so much the definitions themselves but the way in which the boundary between the two can be shifted to suit the needs of the experimenter or observer. Simply put, the **system** is the matter that is being observed—the total amount of reactants and products in a chemical reaction. It could be the amount of solute and solvent used to create a solution. It could be the gas inside a balloon. Then, the **surroundings**, or **environment**, are everything outside of that system. However, the boundary between system and surroundings is not permanently fixed, and can be moved. For example, one might consider the mass of coffee in a coffee cup to be the system and the cup containing it to be part of the environment. This setup would likely be used if someone was interested in determining the amount of heat transferred from the hot coffee to the cooler coffee cup. Alternatively, one might define the system as the hot coffee and the cup together, and the environment as the air surrounding the coffee cup. This setup would likely be used if someone was interested in calculating the heat exchange between the hot coffee and cup system and the cooler surrounding air. The boundary can be extended out farther and farther, until the entire mass of the universe is ultimately included in the system. At this point, there are no surroundings. Again, where the boundary is placed is a decision based on what phenomenon one is interested in studying.

THERMODYNAMIC TERMINOLOGY

Systems can be characterized by whether or not they can exchange heat or matter with the surroundings. A system may be characterized as follows:

- **Isolated**: The system cannot exchange energy (heat and work) or matter with the surroundings; for example, an insulated bomb calorimeter.
- **Closed**: The system can exchange energy (heat and work) but not matter with the surroundings; for example, a steam radiator.
- **Open**: The system can exchange both energy (heat and work) and matter with the surroundings; for example, a pot of boiling water.

When a system experiences a change in one or more of its properties (such as concentrations of reactants or products, temperature, or pressure), it undergoes a **process**.

While processes, by definition, are associated with a change of the state of a system, some processes are uniquely identified by some property that is constant throughout the process. Many of these processes create special conditions because they allow us to simplify the **first law of thermodynamics**:

$$\Delta U = Q - W$$

Equation 7.1

where ΔU is the change in internal energy of the system, Q is the heat added to the system, and W is the work done by the system.

For example, **isothermal** processes occur when the system's temperature is constant. Constant temperature implies that the total internal energy of the system (U) is constant throughout the process. This is because temperature and internal energy are directly proportional. When U is constant, $\Delta U = 0$ and the first law simplifies to $Q = W$ (the heat added to the system equals the work done by the system). An isothermal process appears as a hyperbolic curve on a pressure–volume graph (P–V graph). Work is represented by the area under such a curve, as shown in Figure 7.1.

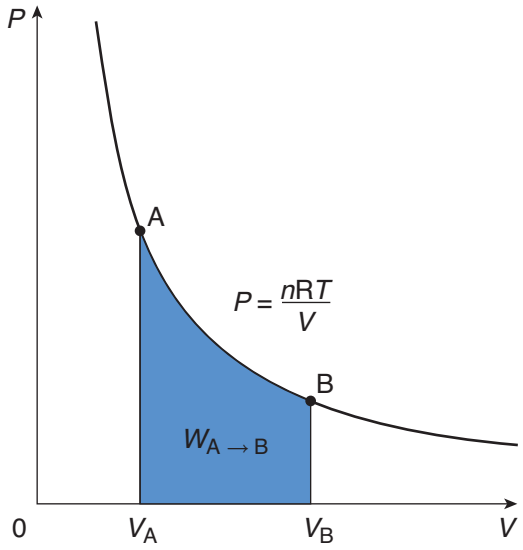

Figure 7.1. Graph of an Isothermal Expansion
Temperature is constant in an isothermal process; thus, the area under the curve represents not only the work performed by the gas, but also the heat that entered the system.

Adiabatic processes occur when no heat is exchanged between the system and the environment; thus, the thermal energy of the system is constant throughout the process. When $Q = 0$, the first law simplifies to $\Delta U = -W$ (the change in internal energy of the system is equal to work done *on* the system [the opposite of work done *by* the system]). An adiabatic process also appears hyperbolic on a P–V graph, as shown in Figure 7.2.

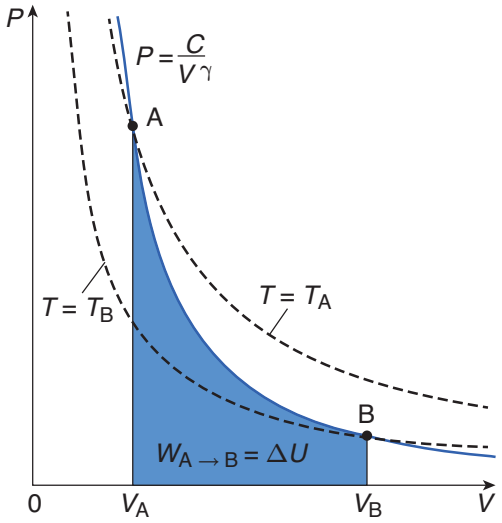

Figure 7.2. Graph of an Adiabatic Expansion
Heat exhange is zero in an adiabatic process; temperature is not constant (as shown by the dotted lines).

Isobaric processes occur when the pressure of the system is constant. Isothermal and isobaric processes are common because it is usually easy to control temperature and pressure. Isobaric processes do not alter the first law, but note that an isobaric process appears as a flat line on a P–V graph, as shown in Figure 7.3.

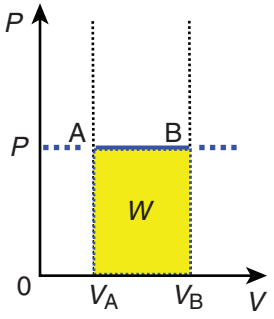

Figure 7.3. Graph of an Isobaric Expansion
Pressure is constant in an isobaric process; the slope of the line is therefore zero.

Finally, **isovolumetric** (**isochoric**) processes experience no change in volume. Because the gas neither expands nor compresses, no work is performed in such a process. Thus, the first law simplifies to $\Delta U = Q$ (the change in internal energy is equal to the heat added to the system). An isovolumetric process is a vertical line on a P–V graph; the area under the curve, which represents the work done by the gas, is zero.

Bridge

The terms isothermal, adiabatic, isobaric, and isovolumetric (isochoric) may seem familiar because they are also discussed in Chapter 3 of *MCAT Physics and Math Review*.

Processes themselves can also be classified as spontaneous or nonspontaneous. A **spontaneous process** is one that can occur by itself without having to be driven by energy from an outside source. Calculating the change in the Gibbs free energy (ΔG) for a process, such as a chemical reaction, allows us to predict whether the process will be spontaneous or nonspontaneous. As discussed later in the chapter, the same quantities that are used to calculate the change in the Gibbs free energy, ΔH and ΔS, can also tell us whether the process will be temperature dependent; that is, spontaneous at some temperatures and nonspontaneous at others.

Spontaneous reactions, as mentioned in Chapters 5 and 6 of *MCAT General Chemistry Review*, will not necessarily happen quickly and may not go to completion. Many spontaneous reactions have very high activation energies and, therefore, rarely take place. For example, when was the last time you saw a match ignite itself? However, providing a quantity of thermal energy (generated by the friction associated with striking the match) that equals or exceeds the activation energy will allow the match to light and burn spontaneously. At this point, the combustion of the chemical components of the match using molecular oxygen in the air will not need any additional external energy once the activation energy has been supplied.

Some spontaneous reactions proceed very slowly. The role of enzymes—biological catalysts—is to selectively enhance the rate of certain spontaneous (but slow) chemical reactions so that the biologically necessary products can be formed at a rate sufficient for sustaining life. As we discussed in Chapter 6 of *MCAT General Chemistry Review*, some reactions do not go to completion but settle into a low-energy state called equilibrium. Spontaneous reactions may go to completion, but many simply reach equilibrium with dynamically stable concentrations of reactants and products. A common method for supplying energy for nonspontaneous reactions is by **coupling** nonspontaneous reactions to spontaneous ones, as shown in Figure 7.4.

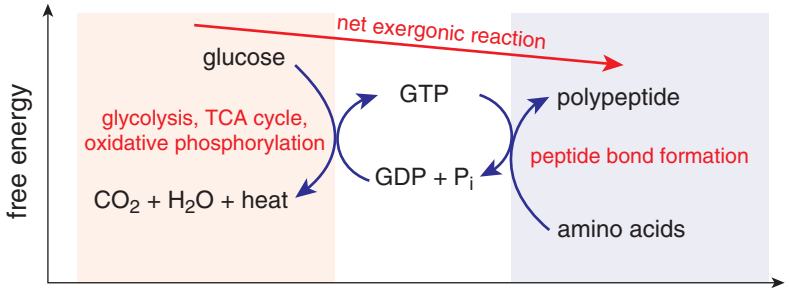

Figure 7.4. Coupling of Reactions
The combustion of glucose is exergonic; the formation of peptide bonds is endergonic. Energy from the combustion of glucose can be stored in the bonds in GTP, which are then lysed to provide the energy for forming peptide bonds.

MCAT Concept Check 7.1:
Before you move on, assess your understanding of the material with these questions.

1. A person snaps an ice pack and places it on his or her leg. In terms of energy transfer, what would be considered the system and what would be the surroundings in this scenario?
   - System:

     _____
   - Surroundings:

     _____

2. What is unique about each of the following types of processes?
   - Isothermal:

     _____
   - Adiabatic:

     _____
   - Isobaric:

     _____
   - Isovolumetric (isochoric):

     _____

7.2 States and State Functions

The state of a system can be described by certain macroscopic properties. These properties, or **state functions**, describe the system in an equilibrium state. They cannot describe the process of the system; that is, how the system got to its current equilibrium. They are useful only for comparing one equilibrium state to another. The pathway taken from one equilibrium state to another is described quantitatively by the **process functions**, the most important of which are work (W) and heat (Q).

Mnemonic

State functions: When I'm under **pressure** and feeling **dense**, all I want to do is watch **TV** and get **HUGS**.
Pressure (P), density (ρ), temperature (T), volume (V), enthalpy (H), internal energy (U), Gibbs free energy (G), and entropy (S).

OVERVIEW

The state functions include pressure (P), density (ρ), temperature (T), volume (V), enthalpy (H), internal energy (U), Gibbs free energy (G), and entropy (S). When the state of a system changes from one equilibrium to another, one or more of these state functions will change. In addition, while state functions are independent of the path

(process) taken, they are not necessarily independent of one another. For example, Gibbs free energy is related to enthalpy, temperature, and entropy.

Because systems can be in different equilibrium states at different temperatures and pressures, a set of **standard conditions** has been defined for measuring the enthalpy, entropy, and Gibbs free energy changes of a reaction. The standard conditions are defined as 25°C (298 K), 1 atm pressure, and 1 *M* concentrations. Don't confuse standard conditions with **standard temperature and pressure** (**STP**), for which the temperature is 0°C (273 K) and pressure is 1 atm. Standard conditions are used for kinetics, equilibrium, and thermodynamics problems; STP is used for ideal gas calculations.

Under standard conditions, the most stable form of a substance is called the **standard state** of that substance. You should recognize the standard states for some elements and compounds commonly encountered on the MCAT. For example, H_2 (*g*), H_2O (*l*), NaCl (*s*), O_2 (*g*), and C (*s*,graphite) are the most stable forms of these substances under standard conditions. Recognizing whether or not a substance is in its standard state is important for thermochemical calculations, such as heats of reactions and—in particular—heats of formation. The changes in enthalpy, entropy, and free energy that occur when a reaction takes place under standard conditions are called the **standard enthalpy**, **standard entropy**, and **standard free energy changes**, respectively, and are symbolized by $\Delta H°$, $\Delta S°$, and $\Delta G°$. The degree sign in these variables represents zero, as the standard state is used as the "zero point" for all thermodynamic calculations.

MCAT Expertise

On the MCAT, be sure that you do not confuse standard conditions in thermodynamics with standard temperature and pressure (STP), which is used in gas law calculations:

- Standard conditions: 25°C (298 K), 1 atm pressure, 1 *M* concentrations
- STP: 0°C (273 K), 1 atm pressure

PHASE CHANGES

Phase diagrams are graphs that show the standard and nonstandard states of matter for a given substance in an isolated system, as determined by temperatures and pressures. **Phase changes** (solid ⇌ liquid ⇌ gas) are reversible, and an equilibrium of phases will eventually be reached at any given combination of temperature and pressure. For example, at 0°C and 1 atm in an isolated system, ice and water exist in an equilibrium. In other words, some of the ice may absorb heat (from the liquid water) and melt, but because that heat is being removed from the liquid water, an equal amount of the liquid water will freeze and form ice. Thus, the relative amounts of ice and water remain constant. Equilibrium between the liquid and gas states of water will be established in a closed container at room temperature and atmospheric pressure, such as a plastic water bottle with the cap screwed on tightly. Most of the water in the bottle will be in the liquid phase, but a small number of molecules at the surface will gain enough kinetic energy to escape into the gas phase; likewise, a small number of gas molecules will lose sufficient kinetic energy to reenter the liquid phase. After a while, equilibrium is established, and the relative amounts of water in the liquid and gas phases become constant—at standard conditions, equilibrium occurs when the air above the water has

Key Concept

As with all equilibria, the rates of the forward and reverse processes will be the same when considering phase changes.

about 3 percent water vapor by mass. Phase equilibria are analogous to the dynamic equilibria of reversible chemical reactions: the concentrations of reactants and products are constant because the rates of the forward and reverse reactions are equal.

Gas–Liquid Equilibrium

The temperature of any substance in any phase is related to the average kinetic energy of the molecules that make up the substance. However, not all of the molecules have exactly the same instantaneous speeds. Therefore, the molecules possess a range of instantaneous kinetic energy values. In the liquid phase, the molecules are relatively free to move around one another. Some of the molecules near the surface of the liquid may have enough kinetic energy to leave the liquid phase and escape into the gaseous phase. This process is known as **evaporation** or **vaporization**. Each time the liquid loses a high-energy particle, the temperature of the remaining liquid decreases. Evaporation is an endothermic process for which the heat source is the liquid water. Of course, the liquid water itself may be receiving thermal energy from some other source, as in the case of a puddle of water drying up under the hot summer sun or a pot of water on the stovetop. Given enough energy, the liquid will completely evaporate.

Boiling is a specific type of vaporization that occurs only under certain conditions. Any liquid will lose some particles to the vapor phase over time; however, boiling is the rapid bubbling of the entire liquid with rapid release of the liquid as gas particles. While evaporation happens in all liquids at all temperatures, boiling can only occur above the boiling point of a liquid and involves vaporization through the entire volume of the liquid.

In a covered or closed container, the escaping molecules are trapped above the solution. These molecules exert a countering pressure, which forces some of the gas back into the liquid phase; this process is called **condensation**. Condensation is facilitated by lower temperature or higher pressure. Atmospheric pressure acts on a liquid in a manner similar to that of an actual physical lid. As evaporation and condensation proceed, the respective rates of the two processes become equal, and equilibrium is reached. The pressure that the gas exerts over the liquid at equilibrium is the vapor pressure of the liquid. Vapor pressure increases as temperature increases because more molecules have sufficient kinetic energy to escape into the gas phase. The temperature at which the vapor pressure of the liquid equals the ambient (also known as external, applied, or incident) pressure is called the **boiling point**.

Liquid–Solid Equilibrium

We've already illustrated the equilibrium that can exist between the liquid and the solid phases of water at 0°C. Even though the atoms or molecules of a solid

are confined to specific locations, each atom or molecule can undergo motions about some equilibrium position. These vibrational motions increase when heat is applied. From our understanding of entropy, we can say that the availability of energy **microstates** increases as the temperature of the solid increases. In basic terms, this means that the molecules have greater freedom of movement, and energy disperses. If atoms or molecules in the solid phase absorb enough energy, the three-dimensional structure of the solid will break down, and the atoms or molecules will escape into the liquid phase. The transition from solid to liquid is called **fusion** or **melting**. The reverse process, from liquid to solid, is called **solidification**, **crystallization**, or **freezing**. The temperature at which these processes occur is called the **melting point** or **freezing point**, depending on the direction of the transition. Whereas pure crystalline solids have distinct, very precise melting points, amorphous solids, such as glass, plastic, chocolate, and candle wax, tend to melt (or solidify) over a larger range of temperatures due to their less-ordered molecular structure.

Gas–Solid Equilibrium

The final phase equilibrium is that which exists between the gaseous and solid phases. When a solid goes directly into the gas phase, the process is called **sublimation**. Dry ice (solid CO_2) sublimes at room temperature and atmospheric pressure; the absence of the liquid phase makes it a convenient dry refrigerant. The reverse transition, from the gaseous to the solid phase, is called **deposition**. In organic chemistry laboratories, a device known as a **cold finger** may be used to purify a product that is heated under reduced pressure, causing it to sublime. The desired product is usually more volatile than the impurities, so the gas is purer than the original product and the impurities are left in the solid state. The gas then deposits onto the cold finger, which has cold water flowing through it, yielding a purified solid product that can be collected.

PHASE DIAGRAMS

Phase diagrams are graphs that show the temperatures and pressures at which a substance will be thermodynamically stable in a particular phase. They also show the temperatures and pressures at which phases will be in equilibrium.

The lines on a phase diagram are called the **lines of equilibrium** or the **phase boundaries** and indicate the temperature and pressure values for the equilibria between phases. The lines of equilibrium divide the diagram into three regions corresponding to the three phases—solid, liquid, and gas—and they themselves represent the phase transformations. The phase diagram for a single compound is shown in Figure 7.5.

MCAT Expertise

On the MCAT, you should be able to identify and understand each area and every line of a phase diagram.

Real World

Because of water's unique properties, ice floats and skates flow smoothly over ice rinks. This all "boils" down to the negative slope of the solid–liquid equilibrium line in its phase diagram. Because the density of ice is less than that of liquid water, an increase in pressure (at a constant temperature) will actually melt ice (the opposite of what is seen for the substance in Figure 7.5).

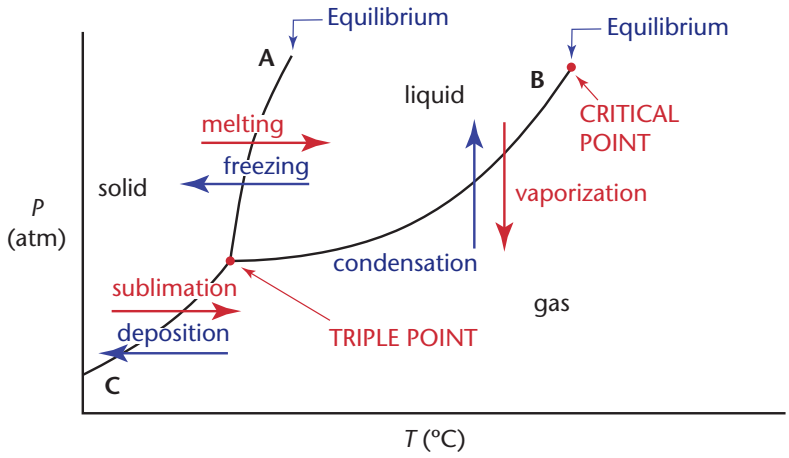

Figure 7.5. Phase Diagram for a Single Compound

Line **A** represents the solid–liquid interface, line **B** the liquid–gas interface, and line **C** the solid–gas interface. In general, the gas phase is found at high temperatures and low pressures, the solid phase is found at low temperatures and high pressures, and the liquid phase is found at moderate temperatures and moderate pressures. The point at which the three phase boundaries meet is called the **triple point**. This is the temperature and pressure at which the three phases exist in equilibrium. The phase boundary that separates the solid and the liquid phases extends indefinitely from the triple point. The phase boundary between the liquid and gas phases, however, terminates at a point called the **critical point**. This is the temperature and pressure above which there is no distinction between the phases. Although this may seem to be an impossibility—after all, it's always possible to distinguish between the liquid and the solid phase—such **supercritical fluids** are perfectly logical. As a liquid is heated in a closed system its density decreases and the density of the vapor sitting above it increases. The critical point is the temperature and pressure at which the two densities become equal and there is no distinction between the two phases. The heat of vaporization at this point and for all temperatures and pressures above the critical point values is zero.

MCAT Concept Check 7.2:

Before you move on, assess your understanding of the material with these questions.

1. What are standard conditions? When are standard conditions used for calculations?

_____

_____

2. What is the definition of a state function? A process function?
   - State function:

     _____
   - Process function:

     _____

3. List at least five common state functions:
   - _____
   - _____
   - _____
   - _____
   - _____

4. What is the definition of the triple point? The critical point?
   - Triple point:

     _____
   - Critical point:

     _____

7.3 Heat

Before we can examine the first of the four state functions that are the focus of this chapter, we must address the topic of heat, which is a source of confusion for many students. Perhaps the greatest barrier to a proper understanding of heat is the semantic conflation of the terms *heat* and *temperature*. Many people use these terms interchangeably in everyday conversation, but this obscures the lexicon of thermodynamics. **Temperature** (***T***) is related to the average kinetic energy of the particles of a substance. Temperature is the way that we scale how hot or cold something is. We are familiar with a few temperature scales: Fahrenheit, Celsius, and Kelvin. The average kinetic energy of the particles in a substance is related to the **thermal energy** (**enthalpy**) of the substance, but because we must also include consideration of how much substance is present to calculate total thermal energy content, the most we can say about temperature is that when a substance's thermal energy increases, its temperature also increases. Nevertheless, we cannot say that something that is hot necessarily has greater thermal energy (in absolute terms) than a substance that is

Key Concept

Remember that heat and temperature are different. Heat is a specific form of energy that can enter or leave a system, while temperature is a measure of the average kinetic energy of the particles in a system.

cold. For example, we might determine that a large amount of lukewarm water has a greater *total* heat content than a very small amount of hot water.

The absolute temperature scale, Kelvin, was determined via the third law of thermodynamics, which elucidated that there is a finite limit to temperature below which nothing can exist. There can be no temperature below 0 K because, by definition, the system is said to be unable to lose any more heat energy. Quantum mechanics describes a state of molecular motions possible below absolute zero, but this is beyond the scope of the MCAT.

OVERVIEW

Heat (***Q***) is the transfer of energy from one substance to another as a result of their differences in temperature. In fact, the **zeroth law of thermodynamics** implies that objects are in thermal equilibrium only when their temperatures are equal. Heat is therefore a process function, not a state function: we can quantify how much thermal energy is transferred between two or more objects as a result of their difference in temperatures by measuring the heat transferred.

Remember that the first law of thermodynamics states that the change in the total internal energy (ΔU) of a system is equal to the amount of heat (Q) transferred to the system minus the amount of work (W) done by the system: $\Delta U = Q - W$.

Because heat and work are measured independently, we can assess the transfer of energy in the form of heat through any process regardless of the amount of work done. Processes in which the system absorbs heat are called **endothermic** ($\Delta Q > 0$), while those processes in which the system releases heat are called **exothermic** ($\Delta Q < 0$). The unit of heat is the unit of energy: joule (J) or calorie (cal), for which 1 cal = 4.184 J. **Enthalpy** ($\boldsymbol{\Delta H}$) is equivalent to heat (Q) under constant pressure, which is an assumption the MCAT usually makes for thermodynamics problems.

When substances of different temperatures are brought into thermal contact with each other—that is, some physical arrangement that allows heat transfer—energy will move from the warmer substance to the cooler substance. When a substance undergoes an endothermic or exothermic reaction, heat energy will be exchanged between the system and the environment.

The process of measuring transferred heat is called **calorimetry**. Two basic types of calorimetry include constant-pressure calorimetry and constant-volume calorimetry. The coffee-cup calorimeter, introduced at the beginning of this chapter, is a low-tech example of a constant-pressure calorimeter, while a bomb calorimeter is an example of a constant-volume calorimeter.

Real World

One of the most important ways that the body works to prevent overheating is through the production of sweat—an exocrine secretion of water, electrolytes, and urea. However, it is not the *production* of sweat that is the cooling mechanism. It's the *evaporation* of the sweat that helps cool the body. Evaporation (vaporization) from the liquid to gas phase is an endothermic process: energy must be absorbed from the body for the particles of the liquid to gain enough kinetic energy to escape into the gas phase. Hot, arid desert air has a lower partial pressure of water vapor than humid, tropical air, so sweat vaporizes more readily in the dry air than it does in the humid air. Accordingly, most people will feel more comfortable in dry heat than in humid heat.

The heat (q) absorbed or released in a given process is calculated via the equation:

$$q = mc\Delta T$$

Equation 7.2

where m is the mass, c is the specific heat of the substance, and ΔT is the change in temperature (in Celsius or kelvins). **Specific heat** is defined as the amount of energy required to raise the temperature of one gram of a substance by one degree Celsius (or one kelvin). Specific heat values will generally be provided on Test Day, but one constant to remember is the specific heat of H_2O (l): $c_{H_2O} = 1\frac{\text{cal}}{\text{g} \bullet \text{K}}$.

It requires less heat to raise the temperature of a glass of water the same amount as a swimming pool. While these two items have the same specific heat, c, they have different **heat capacities**—the product mc (mass times specific heat).

Mnemonic

The equation for heat transfer, given a specific heat, is the same as the test you're studying for! $q = mc\Delta T$ looks a lot like "q equals MCAT."

Real World

When walking barefoot, a blacktop *feels* much hotter than a wooden walkway even when they are the same temperature. This is because they have different specific heats.

CONSTANT-PRESSURE AND CONSTANT-VOLUME CALORIMETRY

To picture the setup of a **constant-pressure calorimeter**, just think of the coffee-cup calorimeter: an insulated container covered with a lid and filled with a solution in which a reaction or some physical process, such as dissolution, is occurring. The incident pressure, which is atmospheric pressure, remains constant throughout the process, and the temperature can be measured as the reaction progresses. There should be sufficient thermal insulation (such as Styrofoam) to ensure that the heat being measured is an accurate representation of the reaction, without gain or loss of heat to the environment. Other commercial applications of these same principles include home insulation, padded clothing, and certain food containers such as thermoses.

Real World

Tests looking at plasma proteins or cancer diagnostics in medicine have utilized differential scanning calorimetry (DSC), which is a constant-pressure device, to identify blood components. Such results have shown that thermal properties of major plasma proteins are altered from early- to late-stage tumors.

The term **bomb calorimeter** may sound rather ominous, but a more accurate descriptive term is **decomposition vessel**. This better reflects what is actually taking place in **constant-volume calorimetry**. As shown in Figure 7.6, a sample of matter, typically a hydrocarbon, is placed in the steel decomposition vessel, which is then filled with almost pure oxygen gas. The decomposition vessel is then placed in an insulated container holding a known mass of water. The contents of the decomposition vessel are ignited by an electric ignition mechanism. The material combusts (burns) in the presence of the oxygen, and the heat that evolves is the heat of the combustion reaction. Because $W = P\Delta V$, no work is done in an isovolumetric process ($\Delta V = 0$), so $W_{\text{calorimeter}} = 0$. Furthermore, because of the insulation, the whole calorimeter can be considered isolated from the rest of the universe, so we can identify the system as the sample plus the oxygen and steel vessel, and the surroundings as the water.

Real World

Bomb calorimeters have helped elucidate the thermodynamic properties of various chemical compounds, including food additives, to determine nutritional value (the caloric content of the additive).

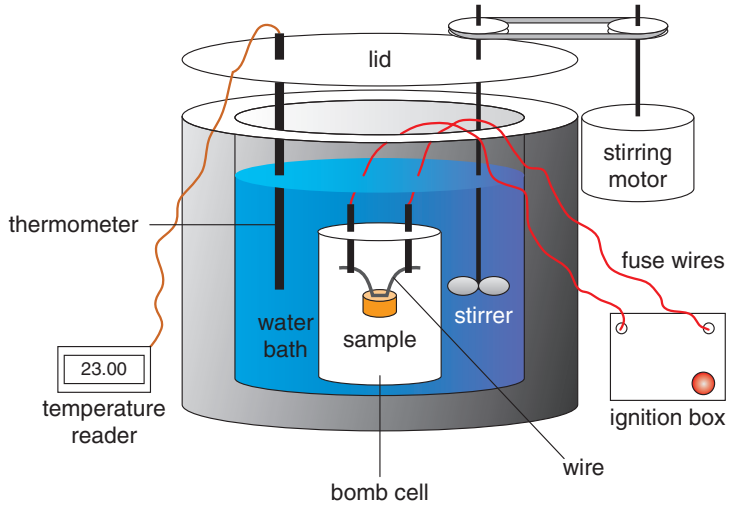

Figure 7.6. Diagram of a Bomb Calorimeter

Because no heat is exchanged between the calorimeter and the rest of the universe, $Q_{calorimeter}$ is 0. So,

$$\Delta U_{system} + \Delta U_{surroundings} = \Delta U_{calorimeter} = Q_{calorimeter} - W_{calorimeter} = 0$$

Therefore,

$$\Delta U_{system} = -\Delta U_{surroundings}$$

and because no work is done,

$$q_{system} = -q_{surroundings}$$

$$m_{steel}c_{steel}\Delta T + m_{oxygen}c_{oxygen}\Delta T = -m_{water}c_{water}\Delta T$$

Note that by using the layer of insulation to isolate the entire calorimeter from the rest of the universe, we've created an adiabatic process. This means that no heat is exchanged between the calorimeter and the rest of the universe, but it *is* exchanged between the steel decomposition vessel and the surrounding water. As the previous derivation shows, heat exchange between the system and its surroundings makes it possible for us to calculate the heat of combustion.

Example: One cup containing 80 grams of water at 300 K is mixed into another cup containing 200 g of water at 450 K. What is the equilibrium temperature of the system? (Note: Assume that the pressure is sufficiently high to avoid boiling.)

Solution: The two liquids undergo thermal exchange; thus, the heat given off by one liquid will be equal to the heat absorbed by the other.

$$q_{cold} = -q_{hot}$$

$$m_{cold}c_{H_2O}\Delta T_{cold} = m_{hot}c_{H_2O}\left(-\Delta T_{hot}\right)$$

MCAT Expertise

Knowing that heat can transfer energy from a system to the surroundings is a key concept tested on calorimetry questions. Whenever asked about equilibrium questions regarding the final temperature of a two-liquid (or liquid–solid) system, remember that the colder object gains thermal energy and the hotter object loses it. You should instinctively realize that a metal bar at 1000 K is hotter than a bath of water at 298 K even though water has a high specific heat. Thus, set up the equation as $q_{cold} = -q_{hot}$. This form of the equation avoids the pesky sign notation issues in the ΔT equation encountered in most general chemistry texts.

Now plug in the values from the question. Because we are solving for final (equilibrium) temperature of a mixture, we can use any value of c so long as we are consistent for both liquids (in this case we have two quantities of water and will use $c_{H_2O} = 1\frac{cal}{g \cdot K}$).

$$m_{cold}c_{H_2O}\Delta T_{cold} = m_{hot}c_{H_2O}(-\Delta T_{hot})$$

$$(80\text{ g})(1\frac{cal}{g \cdot K})(T_f - 300\text{ K}) = (200\text{ g})(1\frac{cal}{g \cdot K})(450\text{ K} - T_f)$$

$$80T_f - 24{,}000\text{ cal} = 90{,}000\text{ cal} - 200T_f$$

$$280T_f = 114{,}000$$

$$T_f = \frac{114{,}000}{280} \approx \frac{120{,}000}{300} = 400\text{ K}$$

This estimated answer is very close to the actual (407.14 K) and is sufficient for Test Day calculations.

HEATING CURVES

When a compound is heated, the temperature rises until the melting or boiling point is reached. Then, the temperature remains constant as the compound is converted to the next phase (liquid or gas, respectively). Once the entire sample is converted, then the temperature begins to rise again. This is depicted in the heating curves in Figure 7.7.

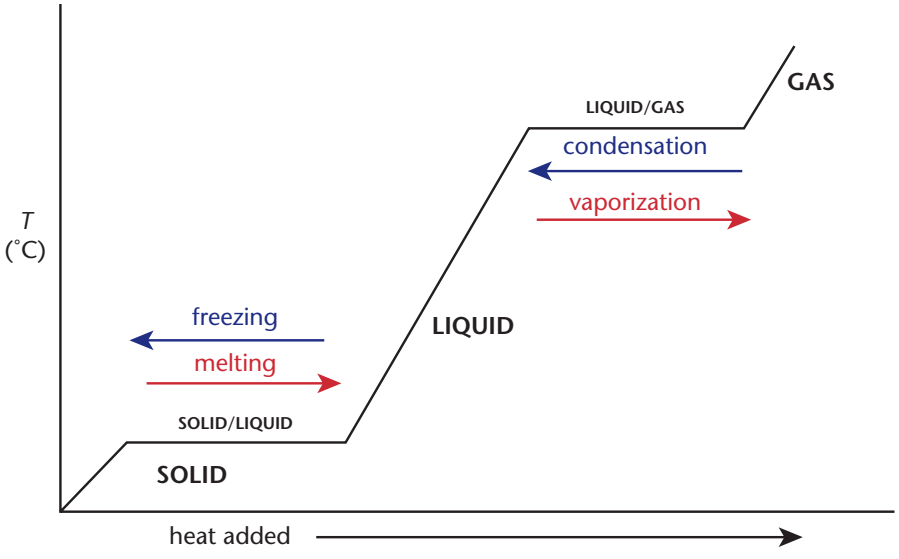

Figure 7.7. Heating Curve for a Single Compound

Heating curves show that phase change reactions do not undergo changes in temperature. For this reason, we cannot use $q = mc\Delta T$ during this interval because $\Delta T = 0$. We know intuitively that heat must continue to be added in order for the whole solid to melt, so where does this heat go? The solid absorbs energy, which allows particles to overcome the attractive forces that hold them in a rigid, three-dimensional arrangement. When melting an ice cube, all of the heat added during the process is used to overcome the intermolecular forces between water molecules in ice, forming liquid water. Once all of the ice has been turned into liquid water, the temperature of the liquid water can then increase again. The converse is also true: removing heat from a liquid at the solid–liquid phase transition temperature will cause the formation of a rigid lattice of water molecules.

During phase changes, we must use values based on enthalpy. When transitioning at the solid–liquid boundary, the **enthalpy** (or **heat**) **of fusion** (ΔH_{fus}) must be used to determine the heat transferred during the phase change. When transitioning from solid to liquid, the change in enthalpy will be positive because heat must be added; when transitioning to a liquid from a solid, the change in enthalpy will be negative because heat must be removed. At the liquid–gas boundary, the **enthalpy** (or **heat**) **of vaporization** (ΔH_{vap}) must be used, and its sign convention also follows a similar pattern. These are utilized in the equation

$$q = mL$$

Equation 7.3

Key Concept

We need a different formula to calculate q during phase changes when $\Delta T = 0$. If we used $q = mc\Delta T$, we'd erroneously think $q = 0$.

where m is the mass and L is the **latent heat**, a general term for the enthalpy of an isothermal process, given in the units $\frac{cal}{g}$.

The total amount of heat needed to cross multiple phase boundaries is simply a summation of the heats for changing the temperature of each of the respective phases and the heats associated with phase changes.

Example: What amount of energy is required to vaporize a 36 cubic centimeter ice cube at −10°C to 110°C? (Note: $c_{H_2O\,(l)} = 4.18\frac{J}{g \cdot K}$, $c_{H_2O\,(s)} = 2.18\frac{J}{g \cdot K}$, $c_{H_2O\,(g)} = 2.00\frac{J}{g \cdot K}$, $\Delta H_{fus} = 6.02\ \frac{kJ}{mol}$, $\Delta H_{vap} = 40.67\ \frac{kJ}{mol}$)

Solution: Recall that 1 cc = 1 mL, and that water at STP has a density of approximately $1\frac{g}{mL}$.

Some of the constants given are in terms of mass (g), and some are in terms of moles, so we should convert the mass (36 g) to moles:

$$n = \frac{36\text{ g } H_2O}{18\ \frac{\text{g}}{\text{mol}}} = 2\text{ mol}$$

Because we are beginning in the ice phase, we must heat the ice cube to the solid–liquid phase transition, which occurs at 0°C. Our first step involves a change in temperature, so we must use a heat formula that contains ΔT and all the pertinent variables for ice (solid water).

$$q_1 = m_{ice}c_{ice}\Delta T_1$$
$$q_1 = (36\text{ g})(2.18\frac{\text{J}}{\text{g}\bullet\text{K}})(10\text{ K}) \approx 36\times 2\times 10 = 720\text{ J} = 0.72\text{ kJ}$$

In step 2, we must convert the ice into liquid form. During this phase change, there will be no temperature change.

$$q_2 = mL = n_{H_2O}\Delta H_{fus}$$
$$q_2 = (2\text{ mol})(6.02\frac{\text{kJ}}{\text{mol}}) \approx 2\times 6 = 12\text{ kJ}$$

In step 3, we heat the water to its liquid–gas phase transition temperature at 100°C.

$$q_3 = m_{water}c_{water}\Delta T_3$$
$$q_3 = (36\text{ g})(4.18\frac{\text{J}}{\text{g}\bullet\text{K}})(100\text{ K}) \approx 36\times 4\times 100 = 14{,}400\text{ J} = 14.4\text{ kJ}$$

In step 4, we vaporize the water. Again, no temperature change will occur during this phase change.

$$q_4 = mL = n_{H_2O}\Delta H_{vap}$$
$$q_4 = (2\text{ mol})(40.67\frac{\text{kJ}}{\text{mol}}) \approx 2\times 40 = 80\text{ kJ}$$

In step 5, we must finally heat the water to the target temperature of 110°C.

$$q_5 = m_{steam}c_{steam}\Delta T_5$$
$$q_5 = (36\text{ g})(2.00\frac{\text{J}}{\text{g}\bullet\text{K}})(10\text{ K}) \approx 36\times 2\times 10 = 720\text{ J} = 0.72\text{ kJ}$$

The total heat required for this whole phase change from beginning to end is:

$$q_{tot} = q_1 + q_2 + q_3 + q_4 + q_5$$
$$q_{tot} = 0.72 + 12 + 14.4 + 80 + 0.72 = 107.84\text{ kJ}$$

MCAT Expertise

It is not in your best interest to memorize all the possible values for c and ΔH for Test Day. The MCAT will provide constants as needed, especially if the system is not water. That being said, practicing with heat calculations for water solutions and gaining familiarity with the heat capacities of water will help on Test Day.

The actual answer without rounding is 109.94 kJ. Such an answer is sufficient for Test Day approximations. Also, a question this involved is unlikely to be seen on the MCAT because many steps must be calculated.

MCAT Concept Check 7.3:

Before you move on, assess your understanding of the material with these questions.

1. Contrast temperature and heat.
   - Temperature:

     _____

   - Heat:

     _____

2. Contrast specific heat and heat capacity.
   - Specific heat:

     _____

   - Heat capacity:

     _____

3. Contrast constant-volume and constant-pressure calorimetry.
   - Constant-volume:

     _____

   - Constant-pressure:

     _____

4. What is the specific heat of water (in calories)?

   _____

7.4 Enthalpy ★★

Most reactions in the lab occur under constant pressure (at 1 atm) in closed thermodynamic systems. To express heat changes at constant pressure, chemists use the term **enthalpy** (***H***). Enthalpy is a state function, so we can calculate the change in enthalpy (ΔH) for a system that has undergone a process—for example, a chemical

reaction—by comparing the enthalpy of the final state to the enthalpy of the initial state, irrespective of the path taken. The change in enthalpy is equal to the heat transferred into or out of the system at constant pressure. To find the enthalpy change of a reaction, ΔH_{rxn}, one must subtract the enthalpy of the reactants from the enthalpy of the products:

$$\Delta H_{rxn} = H_{products} - H_{reactants}$$

Equation 7.4

A positive ΔH_{rxn} corresponds to an endothermic process, and a negative ΔH_{rxn} corresponds to an exothermic process. It is not possible to measure enthalpy directly; only ΔH can be measured, and only for certain fast and spontaneous processes. Thus, several methods have been developed to calculate ΔH for any process.

STANDARD HEAT OF FORMATION

The **standard enthalpy of formation** of a compound, ΔH_f°, is the enthalpy required to produce one mole of a compound from its elements in their standard states. Remember that *standard state* refers to the most stable physical state of an element or compound at 298 K and 1 atm. Note that ΔH_f° of an element in its standard state, by definition, is zero. The ΔH_f° values of most known substances are tabulated. You do not need to memorize these values because they will be provided for you.

STANDARD HEAT OF REACTION

The **standard heat of a reaction**, ΔH_{rxn}°, is the enthalpy change accompanying a reaction being carried out under standard conditions. This can be calculated by taking the difference between the sum of the standard heats of formation for the products and the sum of the standard heats of formation of the reactants:

$$\Delta H_{rxn}^\circ = \sum \Delta H_{f,products}^\circ - \sum \Delta H_{f,reactants}^\circ$$

Equation 7.5

HESS'S LAW

Enthalpy is a state function and is a property of the equilibrium state, so the pathway taken for a process is irrelevant to the change in enthalpy from one equilibrium state to another. As a consequence of this, **Hess's law** states that enthalpy changes of reactions are additive. When thermochemical equations (chemical equations for which energy changes are known) are added to give the net equation for a reaction,

the corresponding heats of reaction are also added to give the net heat of reaction, as shown in Figure 7.8.

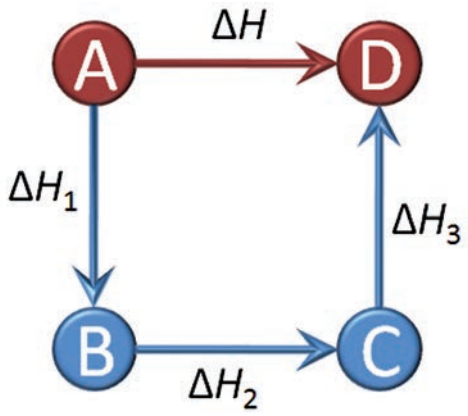

Figure 7.8. Illustration of Hess's Law: Forming Product (D) from Reactant (A)
Because enthalpy is a state function, $\Delta H = \Delta H_1 + \Delta H_2 + \Delta H_3$

Hess's law is embodied in the enthalpy equations we've already introduced. For example, we can describe any reaction as the result of breaking down the reactants into their component elements, then forming the products from these elements. The enthalpy change for the reverse of any reaction has the same magnitude, but the opposite sign, as the enthalpy change for the forward reaction. Therefore,

$$\Delta H_{\text{reactants} \rightarrow \text{elements}} = -\Delta H_{\text{elements} \rightarrow \text{reactants}}$$

The ΔH_{rxn} can be written as:

$$\Delta H_{\text{rxn}} = \Delta H_{\text{reactants} \rightarrow \text{elements}} + \Delta H_{\text{elements} \rightarrow \text{products}}$$

which is another way of writing

$$\Delta H^{\circ}_{\text{rxn}} = \sum \Delta H^{\circ}_{\text{f,products}} - \sum \Delta H^{\circ}_{\text{f,reactants}}$$

Consider the following phase change:

$$\text{Br}_2\,(l) \rightarrow \text{Br}_2\,(g) \qquad\qquad \Delta H^{\circ}_{\text{rxn}} = 31\ \frac{\text{kJ}}{\text{mol}}$$

Key concept
State functions are always path independent.

The enthalpy change for the phase change is called the heat of vaporization $\left(\Delta H^{\circ}_{\text{vap}}\right)$. As long as the initial and final states exist at standard conditions, the $\Delta H^{\circ}_{\text{rxn}}$ will always equal the $\Delta H^{\circ}_{\text{vap}}$, irrespective of the particular pathway that the process takes. For example, it's possible that $\text{Br}_2\,(l)$ could first decompose to Br atoms, which then recombine to form $\text{Br}_2\,(g)$, rather than simply boiling from the liquid to gaseous state. However, because the net reaction is the same, the change in enthalpy will be the same.

Example: Given the following thermochemical equations:

a) $CH_4(g) + 2\,O_2(g) \rightarrow CO_2(g) + 2\,H_2O(l)$ $\quad \Delta H_a = -890.4\ \frac{kJ}{mol}$

b) $C(s, \text{graphite}) + O_2(g) \rightarrow CO_2(g)$ $\quad \Delta H_b = -393.5\ \frac{kJ}{mol}$

c) $H_2(g) + \frac{1}{2}\,O_2(g) \rightarrow H_2O(l)$ $\quad \Delta H_c = -285.8\ \frac{kJ}{mol}$

Calculate ΔH for this reaction:

d) $C(s, \text{graphite}) + 2\,H_2(g) \rightarrow CH_4(g)$

Solution: Equations (a), (b), and (c) must be combined to obtain equation (d). Because equation (d) contains only C, H_2, and CH_4, we must eliminate O_2, CO_2, and H_2O from the first three equations. Equation (a) is reversed to get CH_4 on the product side (equation (e) below). Next, equation (b) is left as is (we will call this equation (f) for consistency below) and (c) is multiplied by 2 (equation (g) below). Then, (d) can be calculated from (e) + (f) + (g):

e) $CO_2(g) + 2\,H_2O(l) \rightarrow CH_4(g) + 2\,O_2(g)$ $\quad \Delta H_e = 890.4\ \frac{kJ}{mol}$

f) $C(s, \text{graphite}) + O_2(g) \rightarrow CO_2(g)$ $\quad \Delta H_f = -393.5\ \frac{kJ}{mol}$

g) $2 \times [H_2(g) + \frac{1}{2}\,O_2(g) \rightarrow H_2O(l)]$ $\quad \Delta H_g = 2 \times -285.8\ \frac{kJ}{mol}$

$C(s, \text{graphite}) + 2\,H_2(g) \rightarrow CH_4(g)$ $\quad \Delta H_d = -74.7\ \frac{kJ}{mol}$

MCAT Expertise

When doing a problem like this on the MCAT, make sure to switch signs when you reverse the equation. Also, make sure to multiply by the correct stoichiometric coefficients when performing your calculations.

It is important to realize that Hess's law applies to *any* state function, including entropy and Gibbs free energy.

BOND DISSOCIATION ENERGY

Hess's law can also be expressed in terms of **bond enthalpies**, also called **bond dissociation energies**. Bond dissociation energy is the average energy that is required to break a particular type of bond between atoms in the gas phase—remember, bond dissociation is an endothermic process. Bond dissociation energy is given in the units $\frac{kJ}{\text{mol of bonds broken}}$ and is often given in tables on the MCAT in a format similar to Table 7.1.

Bond	Enthalpy (ΔH, $\frac{kJ}{mol}$)
O=O	498
C–H	415
H–H	436

Table 7.1. Sample Bond Enthalpies

Key Concept

Because it takes energy to pull two atoms apart, bond breakage is generally endothermic. The reverse process, bond formation, is generally exothermic.

Bond enthalpies are the averages of the bond energies for the same bond in many different compounds. For example, the C–H bond enthalpy (415 $\frac{kJ}{mol}$) is averaged from measurements of the individual C–H bond enthalpies of thousands of different organic compounds. Note that bond formation, the opposite of bond breaking, has the same magnitude of energy but is negative rather than positive; that is, energy is released when bonds are formed. Remember that atoms generally form bonds to become more stable (often by completing an octet). Thus, it makes sense that bond formation is exothermic and bond dissociation is endothermic. The enthalpy change associated with a reaction is given by

$$\Delta H^{\circ}_{rxn} = \sum \Delta H_{\text{bonds broken}} - \sum \Delta H_{\text{bonds formed}} = \text{total energy absorbed} - \text{total energy released}$$

Equation 7.6

Example: Calculate the enthalpy change for the following reaction:

$$C(s) + 2\,H_2(g) \rightarrow CH_4(g) \qquad \Delta H = ?$$

Bond dissociation energies of H–H and C–H bonds are 436 $\frac{kJ}{mol}$ and 415 $\frac{kJ}{mol}$, respectively. The ΔH_f of C (*g*) is 715 $\frac{kJ}{mol}$.

Solution: CH_4 is formed from free elements in their standard states (C in solid state and H_2 in gaseous state). Thus, here $\Delta H_{rxn} = \Delta H_f$. The reaction can be written in three steps:

a) $C(s) \rightarrow C(g)$ $\qquad \Delta H_1$

b) $2\,[H_2(g) \rightarrow 2\,H(g)]$ $\qquad 2 \times \Delta H_2$

c) $C(g) + 4\,H(g) \rightarrow CH_4(g)$ $\qquad \Delta H_3$

with $\Delta H_f = \Delta H_1 + 2 \times \Delta H_2 + \Delta H_3$

$\Delta H_1 = \Delta H_f$ of C (*g*) = 715 $\frac{kJ}{mol}$

ΔH_2 is the energy required to break the H–H bond of one mole of H_2, so ΔH_2 = bond enthalpy of H_2 = 436 $\frac{kJ}{mol}$.

ΔH_3 is the energy released when 4 C–H bonds are formed. Because energy is released when bonds are formed, ΔH_3 is negative.

$\Delta H_3 = -(4 \times \text{bond energy of C–H}) = -(4 \times 415 \frac{\text{kJ}}{\text{mol}}) = -1660 \frac{\text{kJ}}{\text{mol}}$

Therefore,

$$\Delta H_{rxn} = \Delta H_f = 715 \frac{\text{kJ}}{\text{mol}} + 2(436 \frac{\text{kJ}}{\text{mol}}) - 1660 \frac{\text{kJ}}{\text{mol}} = -73 \frac{\text{kJ}}{\text{mol}}$$

STANDARD HEAT OF COMBUSTION

As the name implies, the **standard heat of combustion**, $\boldsymbol{\Delta H^\circ_{comb}}$, is the enthalpy change associated with the combustion of a fuel. Because measurements of enthalpy change require a reaction to be spontaneous and fast, combustion reactions are the ideal processes for such measurements. Most combustion reactions presented on the MCAT occur in the presence of atmospheric oxygen, but keep in mind that there are other combustion reactions in which oxygen is not the oxidant. Diatomic fluorine, for example, can be used as an oxidant. In addition, hydrogen gas will combust with chlorine gas to form gaseous hydrochloric acid and, in the process, will evolve a large amount of heat and light as is characteristic of combustion reactions. The reactions listed in the CH_4 (g) example shown earlier are combustion reactions with O_2 (g) as the oxidant. Therefore, the enthalpy change listed for each of the three reactions is the ΔH_{comb} for each of the reactions.

The glycolytic pathway, described in Chapter 9 of *MCAT Biochemistry Review*, is also a combustion reaction that utilizes a fuel (glucose) mixed with an oxidant (oxygen) to produce carbon dioxide and water.

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$$

The heat of combustion for this reaction is found in a similar fashion to that of Hess's Law. Given the numerous reactions and pathways involved, we can determine the overall enthalpy of the reaction, as shown in Figure 7.9.

Key Concept

The larger the alkane reactant, the more numerous the combustion products.

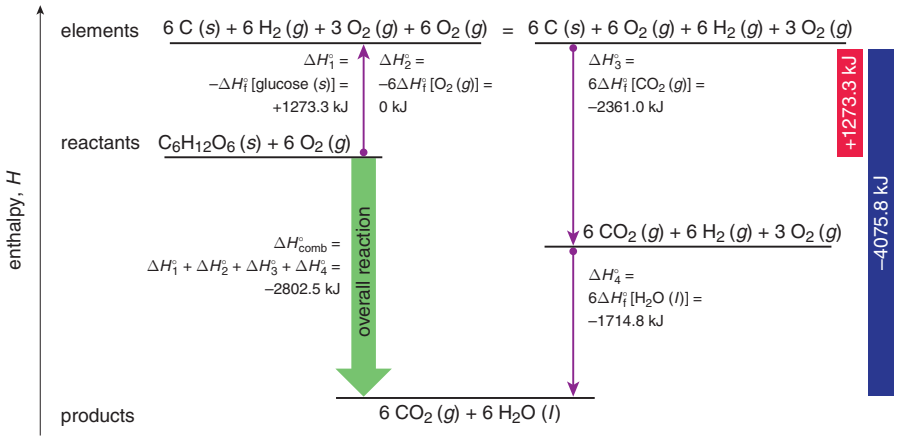

Figure 7.9. Determining the Enthalpy of Glycolysis

MCAT Concept Check 7.4:
Before you move on, assess your understanding of the material with these questions.

1. Define endothermic and exothermic processes.
   - Endothermic:

     _____

   - Exothermic:

     _____

2. Given the following reactions, determine the enthalpy of C (*s*, graphite) + $\frac{1}{2}$ $O_2 \rightarrow CO$.

   C (*s*, graphite) + $O_2 \rightarrow CO_2$ $\quad \Delta H = -393.5 \frac{kJ}{mol}$

   $CO + \frac{1}{2} O_2 \rightarrow CO_2$ $\quad \Delta H = -283 \frac{kJ}{mol}$

   _____

   _____

3. What is the enthalpy of reaction for the reaction 2 H_2O (*g*) $\rightarrow$ 2 H_2 (*g*) + O_2 (*g*), given the following bond enthalpies: H–H = 436 $\frac{kJ}{mol}$, O=O = 498 $\frac{kJ}{mol}$, O–O = 146 $\frac{kJ}{mol}$, and O–H = 463 $\frac{kJ}{mol}$

   _____

   _____

7.5 Entropy ★★

Key concept
Entropy changes that accompany phase changes can be easily estimated, at least qualitatively. For example, freezing is accompanied by a decrease in entropy, as the relatively disordered liquid becomes a well-ordered solid. Meanwhile, boiling is accompanied by a large increase in entropy, as the liquid becomes a much more disordered gas. For any substance, sublimation will be the phase transition with the greatest increase in entropy.

Many students are perplexed by the concept of entropy. Enthalpy makes intuitive sense, especially when the energy change from reactants to products is large, fast, and dramatic (as in combustion reactions involving explosions). Entropy seems to be less intuitive—except that it isn't. Consider, for example, how "normal" each of the following seems: hot tea cools down, frozen drinks melt, iron rusts, buildings crumble, balloons deflate, living things die and decay, and so on.

These examples have a common denominator: in each of them, energy of some form is going from being localized or concentrated to being spread out or dispersed. The thermal energy in the hot tea is spreading out to the cooler air that surrounds it. The thermal energy in the warmer air is spreading out to the cooler frozen

drink. The chemical energy in the bonds of elemental iron and oxygen is released and dispersed as a result of the formation of the more stable, lower-energy bonds of iron oxide (rust). The potential energy of the building is released and dispersed in the form of light, sound, and heat as the building crumbles and falls. The energy of the pressurized air is released to the surrounding atmosphere as the balloon deflates. The chemical energy of all the molecules and atoms in living flesh is released into the environment during the process of death and decay.

The **second law of thermodynamics** states that energy spontaneously disperses from being localized to becoming spread out if it is not hindered from doing so. Pay attention to this: *the usual way of thinking about entropy as "disorder" must not be taken too literally, a trap that many students fall into. Be very careful in thinking about entropy as disorder*. The old analogy between a messy (disordered) room and entropy is deficient and may not only hinder understanding but actually increase confusion.

Entropy is the measure of the spontaneous dispersal of energy at a specific temperature: *how much* energy is spread out, or *how widely* spread out energy becomes, in a process. The equation for calculating the change in entropy is:

$$\Delta S = \frac{Q_{\text{rev}}}{T}$$

Equation 7.7

where ΔS is the change in entropy, Q_{rev} is the heat that is gained or lost in a reversible process, and T is the temperature in kelvin. The units of entropy are usually $\frac{\text{J}}{\text{mol} \bullet \text{K}}$. When energy is distributed into a system at a given temperature, its entropy increases. When energy is distributed out of a system at a given temperature, its entropy decreases.

Notice that the second law states that energy will spontaneously disperse; it does not say that energy can never be localized or concentrated. However, the concentration of energy will rarely happen spontaneously in a closed system. Work usually must be done to concentrate energy. For example, refrigerators work against the direction of spontaneous heat flow (that is, they counteract the flow of heat from the "warm" exterior of the refrigerator to the "cool" interior), thereby "concentrating" energy outside of the system in the surroundings. As a result, refrigerators consume a lot of energy to accomplish this movement of energy against the temperature gradient.

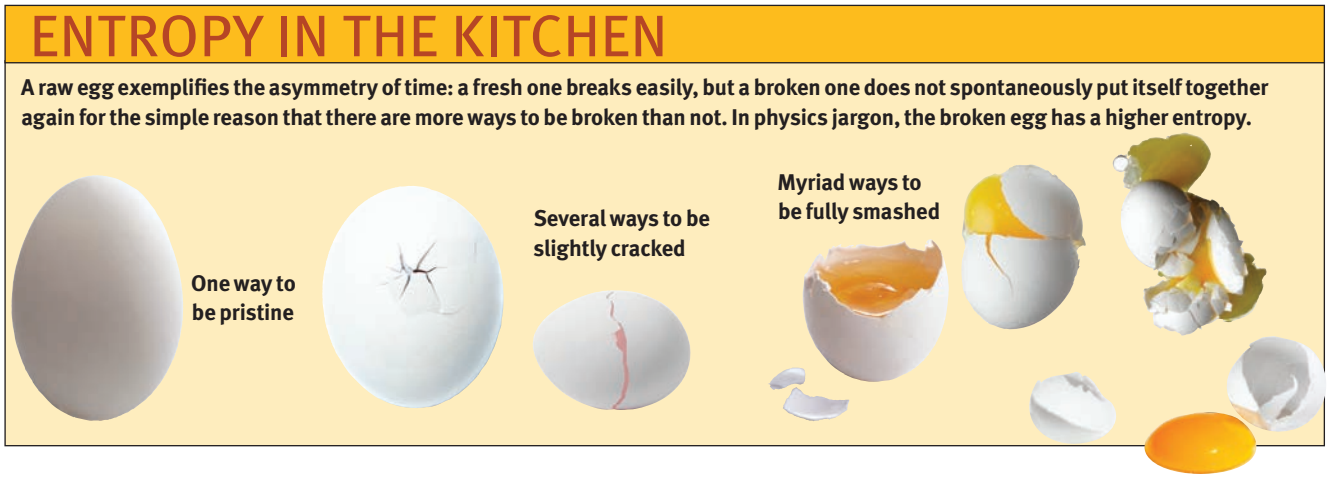

Figure 7.10.

The second law has been described as *time's arrow* because there is a unidirectional limitation on the movement of energy by which we recognize *before and after* or *new and old*, as shown in Figure 7.10. For example, you would instantly recognize whether a video recording of an explosion was running forward or backward. Another way of understanding this is to say that energy in a closed system will spontaneously spread out, and entropy will increase if it is not hindered from doing so. Remember that a system can be variably defined to include the entire universe; in fact, the second law ultimately claims that the entropy of the universe is increasing.

$$\Delta S_{\text{universe}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} > 0$$

Equation 7.8

Entropy is a state function, so a change in entropy from one equilibrium state to another is pathway independent and only depends upon the difference in entropies of the final and initial states. Further, the standard entropy change for a reaction, $\Delta S^\circ_{\text{rxn}}$, can be calculated using the standard entropies of the reactants and products—much like enthalpy:

$$\Delta S^\circ_{\text{rxn}} = \sum \Delta S^\circ_{\text{f,products}} - \sum \Delta S^\circ_{\text{f,reactants}}$$

Equation 7.9

MCAT Concept Check 7.5:
Before you move on, assess your understanding of the material with these questions.

$H_2O\ (l) \rightarrow H_2O\ (s)$	
Dry ice sublimates into carbon dioxide	
$NaCl\ (s) \rightarrow NaCl\ (aq)$	
$N_2\ (g) + 3\ H_2\ (g) \rightarrow 2\ NH_3\ (g)$	
An ice pack is placed on a wound	

7.6 Gibbs Free Energy ★★★★

The final state function that we will examine in this chapter is **Gibbs free energy**, ***G***. This state function is a combination of the three that we've just examined: temperature, enthalpy, and entropy. The change in Gibbs free energy, ΔG, is a measure of the change in the enthalpy and the change in entropy as a system undergoes a process, and it indicates whether a reaction is spontaneous or nonspontaneous. The change in the free energy is the maximum amount of energy released by a process—occurring at constant temperature and pressure—that is available to perform useful work. The change in Gibbs free energy is defined as follows:

$$\Delta G = \Delta H - T\Delta S$$

Equation 7.10

where T is the temperature in kelvins and $T\Delta S$ represents the total amount of energy that is absorbed by a system when its entropy increases reversibly.

Mnemonic

Gibbs free energy: $\Delta G = \Delta H - T\Delta S$
Goldfish **are** (equals sign) **H**orrible **without** (minus sign) **T**artar **S**auce.

OVERVIEW

A helpful visual aid for conceptualizing Gibbs free energy is to think of it as a valley between two hills. Just as a ball would tend to roll down the hill into the valley and eventually come to rest at the lowest point in the valley, any system—including chemical reactions—will move in whichever direction results in a reduction of the free energy of the system. The bottom of the valley represents equilibrium, and the sides of the hill represent the various points in the pathway toward or away from equilibrium. This is shown graphically in Figure 7.11, which was also discussed in the previous chapter.

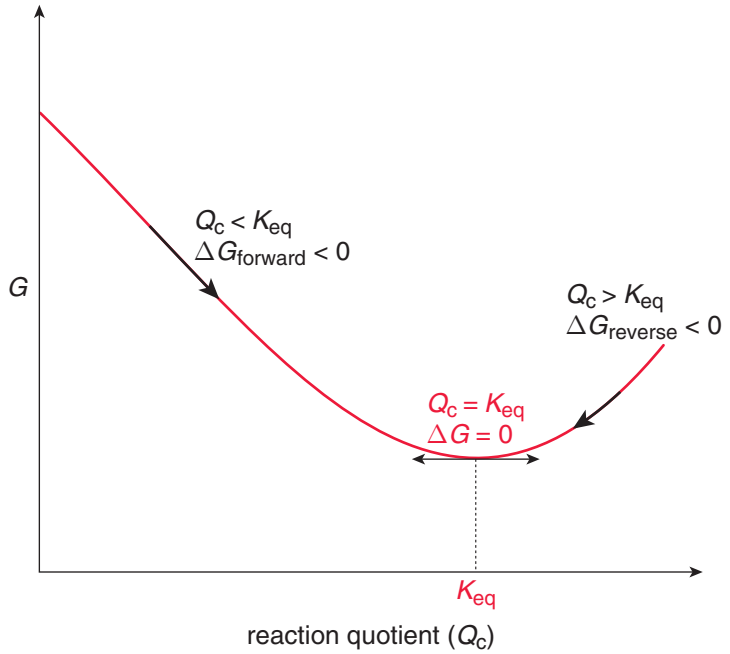

Figure 7.11. Gibbs Free Energy and Spontaneity
A decrease in Gibbs free energy indicates that a reaction is spontaneous. When an equilibrated system is disturbed, it will spontaneously act to restore equilibrium.

MCAT Expertise

Be careful not to confuse endergonic/exergonic (describing Gibbs free energy) with endothermic/exothermic (describing enthalpy).

Movement toward the equilibrium position is associated with a decrease in Gibbs free energy ($\Delta G < 0$) and is spontaneous. When a system releases energy, it is said to be exergonic, as shown in Figure 7.12.

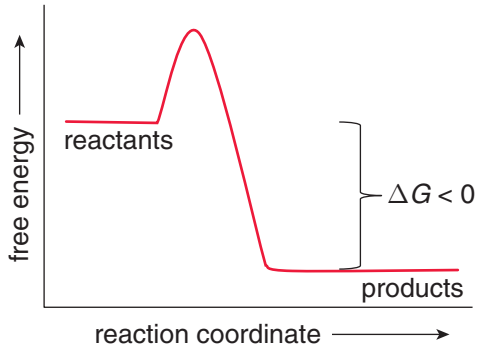

Figure 7.12. Exergonic Reaction Profile
Exergonic reactions release energy and are spontaneous ($\Delta G_{rxn} < 0$).

On the other hand, movement away from the equilibrium position is associated with an increase in Gibbs free energy ($\Delta G > 0$) and is nonspontaneous. Such a reaction is said to be endergonic, as shown in Figure 7.13.

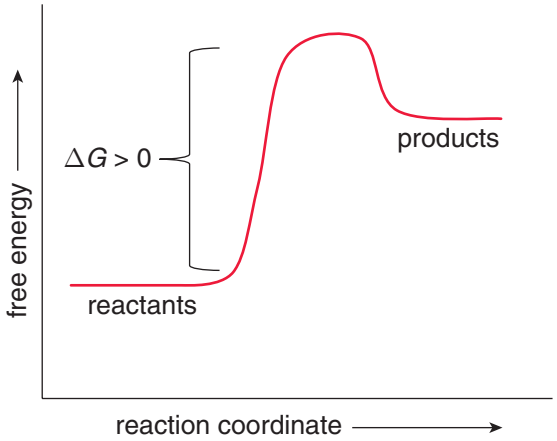

Figure 7.13. Endergonic Reaction Profile
Endergonic reactions absorb energy and are nonspontaneous ($\Delta G_{rxn} > 0$).

Once at the energy minimum state—equilibrium—the system will resist any changes to its state, and the change in free energy is zero. To summarize:

1. If ΔG is negative, the reaction is spontaneous.
2. If ΔG is positive, the reaction is nonspontaneous.
3. If ΔG is zero, the system is in a state of equilibrium; $\Delta H = T\Delta S$.

You should recall that phase equilibria are states in which more than one phase exists. As with all equilibria, the change in Gibbs free energy must be equal to zero ($\Delta G = 0$). For an equilibrium between a gas and a solid,

$$\Delta G = G\,(g) - G\,(s) = 0$$

Therefore,

$$G\,(g) = G\,(s)$$

Because the temperature in Gibbs free energy is in kelvins, it is always positive. Therefore, the effects of the signs of ΔH and ΔS on the spontaneity of a process can be summarized as in Table 7.2.

Key Concept

Recall that thermodynamics and kinetics are separate topics. When a reaction is thermodynamically spontaneous, it has no bearing on how fast it goes. It only means that it will proceed *eventually* without external energy input.

Key Concept

ΔG is temperature dependent when ΔH and ΔS have the same sign.

ΔH	ΔS	Outcome
+	+	Spontaneous at high T
+	–	Nonspontaneous at all T
–	+	Spontaneous at all T
–	–	Spontaneous at low T

Table 7.2. Effects of ΔH, ΔS, and T on Spontaneity

Phase changes are examples of temperature-dependent processes. The phase changes of water should be familiar to you; have you ever wondered why water doesn't boil at, say, 20°C instead of 100°C? When water boils, hydrogen bonds are broken, and the water molecules gain sufficient energy to escape into the gas phase. Thus, boiling is an endothermic process, and ΔH is positive. As thermal energy is transferred to the water molecules, energy is distributed through the molecules entering the gas phase. Thus, entropy is positive and the term $T\Delta S$ is positive. If both ΔH and $T\Delta S$ are positive, the reaction will only be spontaneous if $T\Delta S$ is greater than ΔH, resulting in a negative ΔG. These conditions are met only when the temperature of the system is greater than 373 K (100°C). Below 100°C, the free energy change is positive, and boiling is nonspontaneous; the water remains a liquid. At 100°C, $\Delta H - T\Delta S = 0$, and an equilibrium is established between the liquid and gas phases in such a way that the water's vapor pressure equals the ambient pressure. This is the definition of the boiling point: the temperature at which the vapor pressure equals the ambient pressure.

It is important to remember that the rate of a reaction depends on the activation energy E_a, not ΔG. Spontaneous reactions may be fast or slow. Sometimes a reversible reaction may produce two products that differ both in their stability (as measured by the change in the free energy associated with their production) and in their kinetics (as measured by their respective activation energies). Sometimes, the thermodynamically more stable product will have the slower kinetics due to higher activation energy. In this situation, we talk about kinetic *vs.* thermodynamic reaction control, which is discussed in Chapter 6 of *MCAT General Chemistry Review*. For a period of time after the reaction begins, the major product will be the one that is produced more quickly as a result of its lower activation energy. The reaction can be said to be under kinetic control at this time. Given enough time, however, and assuming a reversible reaction, the dominant product will be the thermodynamically more stable product as a result of its lower free energy value. The reaction can then be said to be under thermodynamic control. Eventually, the reaction will reach equilibrium, as defined by its K_{eq}.

STANDARD GIBBS FREE ENERGY

The free energy change of reactions can be measured under standard state conditions to yield the **standard free energy**, ΔG°_{rxn}. For standard free energy determinations,

the concentrations of any solutions in the reaction are 1 *M*. The standard free energy of formation of a compound, ΔG_f°, is the free energy change that occurs when 1 mole of a compound in its standard state is produced from its respective elements in their standard states under standard state conditions. The standard free energy of formation for any element under standard state conditions is, by definition, zero. The standard free energy of a reaction, ΔG_{rxn}°, is the free energy change that occurs when that reaction is carried out under standard state conditions; that is, when the reactants are converted to the products at standard conditions of temperature (298 K) and pressure (1 atm). Like enthalpy and entropy, the free energy of the reaction can be calculated from the free energies of formation of the reactants and products:

$$\Delta G_{rxn}^\circ = \sum \Delta G_{f,products}^\circ - \sum \Delta G_{f,reactants}^\circ$$

Equation 7.11

FREE ENERGY, K_{eq}, AND Q

We can derive the standard free energy change for a reaction from the equilibrium constant K_{eq} for the reaction using the equation

$$\Delta G_{rxn}^\circ = -RT \ln K_{eq}$$

Equation 7.12

where R is the ideal gas constant, T is the temperature in kelvins, and K_{eq} is the equilibrium constant. This equation allows us to make not only quantitative evaluations of the free energy change of a reaction, but also qualitative assessments of the spontaneity of the reaction. The greater the value of K_{eq}, the more positive the value of its natural logarithm. The more positive the natural logarithm, the more negative the standard free energy change. The more negative the standard free energy change, the more spontaneous the reaction.

Once a reaction begins, however, the standard state conditions (specifically 1 *M* solutions) no longer apply. The value of the equilibrium constant must be replaced with another number that is reflective of where the reaction is in its path toward equilibrium. To determine the free energy change for a reaction that is in progress, we relate ΔG_{rxn} (not ΔG_{rxn}°) to the reaction quotient, Q:

$$\Delta G_{rxn} = \Delta G_{rxn}^\circ + RT \ln Q = RT \ln \frac{Q}{K_{eq}}$$

Equation 7.13

As described in Chapter 6 of *MCAT General Chemistry Review*, if the ratio of $\frac{Q}{K_{eq}}$ is less than one ($Q < K_{eq}$), then the natural logarithm will be negative, and the free energy change will be negative, so the reaction will spontaneously proceed forward until

Key Concept

Note that the right side of this equation is similar to Equation 7.12. The use of the Q indicates that the system is not at equilibrium.

equilibrium is reached. If the ratio of $\frac{Q}{K_{eq}}$ is greater than one ($Q > K_{eq}$), then the natural logarithm will be positive, and the free energy change will be positive. In that case, the reaction will spontaneously move in the reverse direction until equilibrium is reached. Of course, if the ratio is equal to one, the reaction quotient is equal to the equilibrium constant; the reaction is at equilibrium, and the free energy change is zero (ln 1 = 0).

Reaction profiles of free energy can be altered by the presence of catalysts. While the overall free energy change of the reaction is not altered, the activation energy required to accomplish the reaction is reduced significantly in the presence of a catalyst, as shown in Figure 7.14.

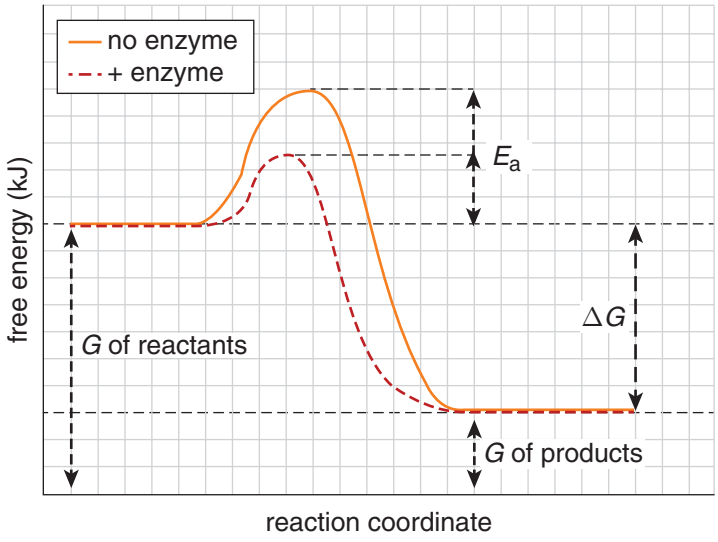

Figure 7.14. Catalysts Alter Kinetics but Not Equilibrium or Free Energy Change

MCAT Concept Check 7.6:

Before you move on, assess your understanding of the material with these questions.

1. The Haber–Bosch process creates ammonia through several reactions, the final step of which is $N_2 + 3\ H_2 \rightarrow 2\ NH_3$ ($\Delta H_{rxn} = -93\ \frac{kJ}{mol}$, $\Delta S_{rxn} = -198\ \frac{J}{mol \cdot K}$). Determine what the Gibbs free energy of this reaction is at standard conditions and at 500 K:

   - At standard conditions:

     _____

   - At 500 K:

     _____

2. At what temperature would the reaction described above be at equilibrium?

_____

_____

3. If you were to suddenly flood the reaction vessel with significant amounts of ammonia, what would occur?

_____

Conclusion

We began our discussion of thermochemistry with a review of different ways in which we characterize systems (open, closed, and isolated) and processes (isothermal, adiabatic, isobaric, and isovolumetric). We then further classified systems according to their state functions—system properties such as pressure, density, temperature, volume, enthalpy, internal energy, Gibbs free energy, and entropy that describe the equilibrium state. We examined the equilibria that exist between the different phases and noted that the change in Gibbs free energy for each phase change in equilibrium is zero, as is the case for all equilibria. We defined enthalpy as the heat content of the system and the change in enthalpy as the change in heat content of the system as it moves from one equilibrium state to another. Enthalpy is defined as the energy found in the intermolecular interactions and bonds of the compounds in the system. We explored the various ways Hess's law can be applied to calculate the total enthalpy change for a series of reactions. Moving on to entropy, we described this property as a measure of the degree to which energy in a system becomes spread out through a process. There is danger in thinking too literally about entropy as "disorder" because a system's entropy may be increasing even if there is no observable change in the system's macroscopic disorder (such as ice warming from –10°C to –5°C). Gibbs free energy combines the effects of temperature, enthalpy, and entropy, and the change in Gibbs free energy determines whether a process will be spontaneous or nonspontaneous. When the change in Gibbs free energy is negative, the process is spontaneous, but when the change in Gibbs free energy is positive, the process is nonspontaneous.

Many reactions in the body must be spontaneous in order for cells to function. While there are some nonspontaneous reactions in our body, we are able to couple them to thermodynamically favorable (exergonic) reactions that allow the cell to perform even more complex functions.

CONCEPT SUMMARY

Systems and Processes

- Systems are classified based on what is or is not exchanged with the surroundings.
  - **Isolated systems** exchange neither matter nor energy with the environment.
  - **Closed systems** can exchange energy but not matter with the environment.
  - **Open systems** can exchange both energy and matter with the environment.
- Processes can be characterized based on a single constant property.
  - **Isothermal** processes occur at a constant temperature.
  - **Adiabatic** processes exchange no heat with the environment.
  - **Isobaric** processes occur at a constant pressure.
  - **Isovolumetric** (**isochoric**) processes occur at a constant volume.

States and State Functions

- **State functions** describe the physical properties of an equilibrium state; they are pathway independent and include pressure, density, temperature, volume, enthalpy, internal energy, Gibbs free energy, and entropy.
- **Standard conditions** are defined as 298 K, 1 atm, and 1 *M* concentrations.
- The **standard state** of an element is its most prevalent form under standard conditions; **standard enthalpy**, **standard entropy**, and **standard free energy** are all calculated under standard conditions.
- **Phase changes** exist at characteristic temperatures and pressures.
  - **Fusion** (**melting**) and **freezing** (**crystallization** or **solidification**) occur at the boundary between the solid and the liquid phases.
  - **Vaporization** (**evaporation** or **boiling**) and **condensation** occur at the boundary between the liquid and the gas phases.
  - **Sublimation** and **deposition** occur at the boundary between the solid and gas phases.
  - At temperatures above the **critical point**, the liquid and gas phases are indistinguishable.
  - At the **triple point**, all three phases of matter exist in equilibrium.
- The **phase diagram** for a system graphs the phases and phase equilibria as a function of temperature and pressure.

Heat

- Temperature and heat are not the same thing.
  - **Temperature** is a scaled measure of the average kinetic energy of a substance.

- **Heat** is the transfer of energy that results from differences of temperature between two substances.

- The heat content of a system undergoing heating, cooling, or phase changes is the sum of all the respective energy changes.

Enthalpy

- **Enthalpy** is a measure of the potential energy of a system found in intermolecular attractions and chemical bonds.
- **Hess's law** states that the total change in potential energy of a system is equal to the changes of potential energies of the individual steps of the process.
- Enthalpy can also be calculated using heats of formation, heats of combustion, or bond dissociation energies.

Entropy

- **Entropy**, while often thought of as disorder, is a measure of the degree to which energy has been spread throughout a system or between a system and its surroundings.
  - Entropy is a ratio of heat transferred per mole per unit kelvin.
  - Entropy is maximized at equilibrium.

Gibbs Free Energy

- **Gibbs free energy** is derived from both enthalpy and entropy values for a given system.
- The change in Gibbs free energy determines whether a process is spontaneous or nonspontaneous.
  - $\Delta G < 0$: reaction proceeds in forward direction (spontaneous)
  - $\Delta G = 0$: reaction is in dynamic equilibrium
  - $\Delta G > 0$: reaction proceeds in reverse direction (nonspontaneous)
- Gibbs free energy depends on temperature; temperature-dependent processes change between spontaneous and nonspontaneous, depending on the temperature.

ANSWERS TO CONCEPT CHECKS

7.1

1. The boundary between system and surroundings could be placed anywhere. Most commonly, the ice pack would be considered the chemical system using up energy, and the person (and the remainder of the universe) constitutes the surroundings that are providing the heat for the ice pack to function.
2. • Isothermal: no change in temperature; $\Delta U = 0$, $Q = W$
   • Adiabatic: no heat exchange; $Q = 0$, $\Delta U = -W$
   • Isobaric: no change in pressure; line appears flat in a P–V graph
   • Isovolumetric (isochoric): no change in volume; $W = 0$, $\Delta U = Q$

7.2

1. Kinetics, equilibrium, and thermodynamics calculations use standard conditions, which are 25°C (298 K), 1 atm pressure, and 1 *M* concentrations.
2. State functions are properties of a system at equilibrium and are independent of the path taken to achieve the equilibrium; they may be dependent on one another. Process functions define the path between equilibrium states and include Q (heat) and W (work).
3. State functions include pressure (P), density (ρ), temperature (T), volume (V), enthalpy (H), internal energy (U), Gibbs free energy (G), and entropy (S).
4. The triple point is the combination of temperature and pressure at which all three phases are in equilibrium. The critical point is the temperature and pressure above which the liquid and gas phases are indistinguishable and the heat of vaporization is zero.

7.3

1. Temperature is an indirect measure of the thermal content of a system that looks at average kinetic energy of particles in a sample. Heat is the thermal energy transferred between objects as a result of differences in their temperatures.
2. Specific heat (c) is the energy required to raise the temperature of one gram of a substance by one degree Celsius. Heat capacity (mc) is the product of mass and specific heat and is the energy required to raise any given amount of a substance one degree Celsius.
3. A constant-pressure calorimeter (coffee cup calorimeter) is exposed to constant (atmospheric) pressure. As the reaction proceeds, the temperature of the contents is measured to determine the heat of the reaction. A constant-volume calorimeter (bomb calorimeter) is one in which heats of certain reactions (like combustion) can be measured indirectly by assessing temperature change in a water bath around the reaction vessel.
4. $c_{H_2O} = 1 \frac{\text{cal}}{\text{g} \bullet \text{K}}$

7.4

1. Endothermic reactions involve an increase in heat content of a system from the surroundings ($\Delta H > 0$), while exothermic reactions involve a release of heat content from a system ($\Delta H < 0$).
2. Reverse the second equation, and then add the enthalpies: $-393.5 \frac{\text{kJ}}{\text{mol}} + 283 \frac{\text{kJ}}{\text{mol}} = -110.5 \frac{\text{kJ}}{\text{mol}}$
3. Enthalpy of reaction = bonds broken – bonds formed. There are four O–H bonds broken, two H–H bonds formed, and one O=O bond formed. Therefore, $\Delta H_{rxn} = 4 \times 463 \frac{\text{kJ}}{\text{mol}} - 2 \times 436 \frac{\text{kJ}}{\text{mol}} - 1 \times 498 \frac{\text{kJ}}{\text{mol}} = 482 \frac{\text{kJ}}{\text{mol}}$

7.5

1. Solids have the lowest entropy, followed by liquids, with gases having the highest entropy.
2. Entropy increases as a system has more disorder or freedom of movement, and energy is dispersed in a spontaneous system. Entropy of the universe can never be decreased spontaneously.

3.

Reaction	ΔS
$\mathbf{H_2O}$ **(*l*)** $\rightarrow$ $\mathbf{H_2O}$ **(*s*)**	Decrease (freezing)
Dry ice sublimates into carbon dioxide	Increase (sublimation)
NaCl (*s*) $\rightarrow$ **NaCl (*aq*)**	Increase (dissolution)
$\mathbf{N_2}$ **(*g*) + 3** $\mathbf{H_2}$ **(*g*)** $\rightarrow$ **2** $\mathbf{NH_3}$ **(*g*)**	Decrease (fewer moles of gas)
An ice pack is placed on a wound	Increase (heat is transferred)

7.6

1. At standard conditions: $\Delta G = \Delta H - T\Delta S = -93{,}000 \frac{\text{J}}{\text{mol}} - (298\,\text{K})(-198 \frac{\text{J}}{\text{mol} \cdot \text{K}}) \approx -90{,}000 + 300 \times 200 = -90{,}000 + 60{,}000 = -30{,}000 \frac{\text{J}}{\text{mol}} = -30 \frac{\text{kJ}}{\text{mol}}$ (actual = $-34.0 \frac{\text{kJ}}{\text{mol}}$)

   At 500 K: $\Delta G = \Delta H - T\Delta S = -93{,}000 \frac{\text{J}}{\text{mol}} - (500\ \text{K})(-198 \frac{\text{J}}{\text{mol} \cdot \text{K}}) \approx -90{,}000 + 500 \times 200 = -90{,}000 + 100{,}000 = 10{,}000 \frac{\text{J}}{\text{mol}} = 10 \frac{\text{kJ}}{\text{mol}}$ (actual = $6 \frac{\text{kJ}}{\text{mol}}$)
2. The system is at equilibrium when $\Delta G = 0$: $0 = -93{,}000 \frac{\text{J}}{\text{mol}} - (T)(-198 \frac{\text{J}}{\text{mol} \cdot \text{K}}) \rightarrow 93{,}000 = 200T$; $T = 465$ K (actual = 470 K).
3. The value of Q would increase significantly, causing the system to shift left, forming more reactants until the system again reached equilibrium.

EQUATIONS TO REMEMBER

(7.1) **First law of thermodynamics:** $\Delta U = Q - W$

(7.2) **Heat transfer (no phase change):** $q = mc\Delta T$

(7.3) **Heat transfer (during phase change):** $q = mL$

(7.4) **Generalized enthalpy of reaction:** $\Delta H_{rxn} = H_{products} - H_{reactants}$

(7.5) **Standard enthalpy of reaction:** $\Delta H^{\circ}_{rxn} = \sum \Delta H^{\circ}_{f,products} - \sum \Delta H^{\circ}_{f,reactants}$

(7.6) **Bond enthalpy:** $\Delta H^{\circ}_{rxn} = \sum \Delta H_{bonds\ broken} - \sum \Delta H_{bonds\ formed}$
= total energy absorbed – total energy released

(7.7) **Entropy:** $\Delta S = \frac{Q_{rev}}{T}$

(7.8) **Second law of thermodynamics:** $\Delta S_{universe} = \Delta S_{system} + \Delta S_{surroundings} > 0$

(7.9) **Standard entropy of reaction:** $\Delta S^{\circ}_{rxn} = \sum \Delta S^{\circ}_{f,products} - \sum \Delta S^{\circ}_{f,reactants}$

(7.10) **Gibbs free energy:** $\Delta G = \Delta H - T\Delta S$

(7.11) **Standard Gibbs free energy of reaction:**
$\Delta G^{\circ}_{rxn} = \sum \Delta G^{\circ}_{f,products} - \sum \Delta G^{\circ}_{f,reactants}$

(7.12) **Standard Gibbs free energy from equilibrium constant:**
$\Delta G^{\circ}_{rxn} = -RT \ln K_{eq}$

(7.13) **Gibbs free energy from reaction quotient:** $\Delta G_{rxn} = \Delta G^{\circ}_{rxn} + RT \ln Q = RT \ln \frac{Q}{K_{eq}}$

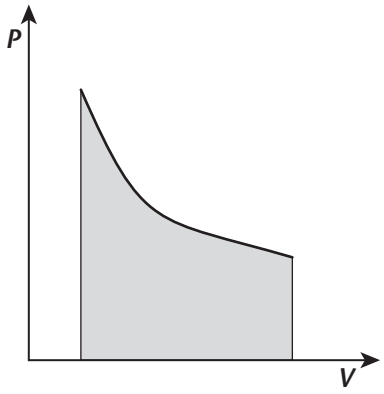
Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Consider the cooling of an ideal gas in a closed system. This process is illustrated in the pressure–volume graph shown in the following figure.



Based on this information, the process may be:

A. adiabatic.
B. isobaric.
C. isothermal.
D. isochoric.

2. A reaction has a positive entropy and enthalpy. What can be inferred about the progress of this reaction from this information?

A. The reaction is spontaneous.
B. The reaction is nonspontaneous.
C. The reaction is at equilibrium.
D. There is not enough information to determine whether the reaction is spontaneous or not.

3. Pure sodium metal spontaneously combusts upon contact with room temperature water. What is true about the equilibrium constant of this combustion reaction at 25°C?

A. $K_{eq} < 0$
B. $0 < K_{eq} < 1$
C. $K_{eq} = 1$
D. $K_{eq} > 1$

4. Which of the following processes has the most exothermic standard heat of combustion?

A. Combustion of ethane
B. Combustion of propane
C. Combustion of *n*-butane
D. Combustion of *n*-pentane

5. Methanol reacts with acetic acid to form methyl acetate and water.

Type of Bond	Bond Dissociation Energy ($\frac{kJ}{mol}$)
C — C	348
C — H	415
C = O	805
O — H	463
C — O	360

Based on the values in the table above, what is the heat of reaction in $\frac{kJ}{mol}$?

A. 0
B. 464
C. 824
D. 1288

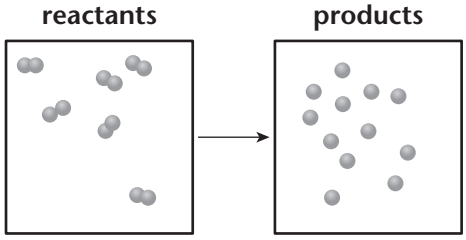
6. At standard temperature and pressure, a chemical process is at equilibrium. What is the free energy of reaction (ΔG) for this process?

A. $\Delta G > 0$
B. $\Delta G < 0$
C. $\Delta G = 0$
D. There is not enough information to determine the free energy of the reaction.

7. For a certain chemical process, $\Delta G° = -4.955 \frac{\text{kJ}}{\text{mol}}$. What is the equilibrium constant K_{eq} for this reaction? (Note: $R = 8.314 \frac{\text{J}}{\text{mol} \bullet \text{K}}$)

A. $K_{eq} = 1.0$
B. $K_{eq} = 7.4$
C. $K_{eq} = 8.9$
D. $K_{eq} = 10$

8. Consider the chemical reaction in the vessel depicted in the following diagram.



A. The reaction is spontaneous.
B. The reaction is nonspontaneous.
C. The reaction is at equilibrium.
D. There is not enough information to determine if the reaction is spontaneous.

9. Suppose $\Delta G^{\circ}_{rxn} = -2000 \frac{\text{kJ}}{\text{mol}}$ for a chemical reaction. At 300 K, what is the change in Gibbs free energy in $\frac{\text{kJ}}{\text{mol}}$?

A. $\Delta G = -2000 + (300\text{ K})(8.314)(\ln Q)$
B. $\Delta G = -2000 - (300\text{ K})(8.314)(\ln Q)$
C. $\Delta G = -2000 + (300\text{ K})(8.314)(\log Q)$
D. $\Delta G = -2000 - (300\text{ K})(8.314)(\log Q)$

10. A chemical reaction has a negative enthalpy and a negative entropy. Which of the following terms necessarily describes this reaction?

A. Exothermic
B. Endothermic
C. Exergonic
D. Endergonic

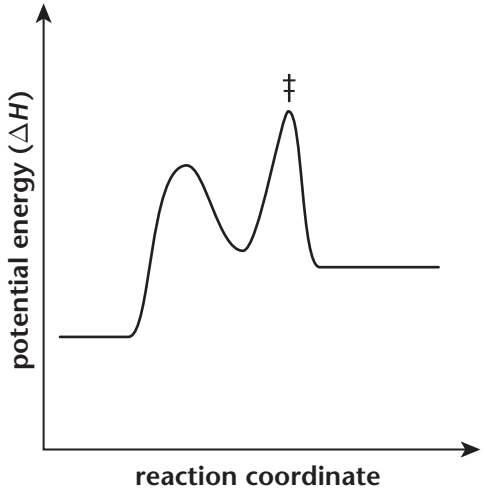
11. Which of the following statements is true of a process that is spontaneous in the forward direction?

A. $\Delta G > 0$ and $K_{eq} > Q$
B. $\Delta G > 0$ and $K_{eq} < Q$
C. $\Delta G < 0$ and $K_{eq} > Q$
D. $\Delta G < 0$ and $K_{eq} < Q$

12. Which of the following devices would be the most appropriate to use to measure the heat capacity of a liquid?

A. Thermometer
B. Calorimeter
C. Barometer
D. Volumetric flask

13. A reaction coordinate for a chemical reaction is displayed in the graph below.



Which of the following terms describes the energy of this reaction?

A. Endothermic
B. Exothermic
C. Endergonic
D. Exergonic

14. Which of the following phase changes is associated with the largest decrease in entropy?

A. Fusion
B. Solidification
C. Deposition
D. Sublimation

15. Explosions are necessarily characterized by:

A. $\Delta G < 0$.
B. $\Delta H > 0$.
C. $\Delta S < 0$.
D. $T < 0$.

Explanations to Discrete Practice Questions

1. A

This process may be adiabatic. Given that the gas was cooled, it did not maintain constant temperature, eliminating **choice (C)**. Isobaric and isovolumetric processes appear as horizontal and vertical lines in pressure–volume graphs, respectively, eliminating **choices (B)** and **(D)**. Adiabatic processes appear hyperbolic on pressure–volume graphs, as illustrated here.

2. D

There is not enough information in the problem to determine whether or not the reaction is spontaneous. If the signs of enthalpy and entropy are the same, the reaction is temperature dependent according to $\Delta G = \Delta H - T\Delta S$. Without the temperature, we cannot determine if this reaction is spontaneous, nonspontaneous, or at equilibrium.

3. D

Solve this question using the equation $\Delta G^\circ_{rxn} = -RT \ln K_{eq}$. ΔG°_{rxn} is negative (as it must be for a spontaneous reaction), and R and T are always positive. Therefore, $\ln K_{eq}$ must also be positive for the sign convention to work out correctly. If $\ln K_{eq} > 0$, then $e^{\ln K_{eq}} > e^0 \rightarrow K_{eq} > 1$.

4. D

Combustion often involves the reaction of a hydrocarbon with oxygen to produce carbon dioxide and water. Longer hydrocarbon chains yield greater amounts of combustion products and release more heat in the process—that is, the reaction is more exothermic. Of the hydrocarbons listed here, *n*-pentane is the longest chain.

5. A

At first glance, this might seem like a math-heavy problem, but it really doesn't require any calculations at all. We just have to keep track of which bonds are broken and which bonds are formed. Remember, breaking bonds requires energy, while forming bonds releases energy. Two bonds are broken: a C–O bond between the carbonyl and oxygen of acetic acid, and an O–H bond between the hydroxyl oxygen and hydrogen of methanol. Two bonds are also formed: a C–O bond between the carbonyl and the oxygen of methanol, and an O–H bond between the hydroxyl group and a hydrogen to form water. Given that the same two bonds are broken and formed in this reaction, the energy change must be $0 \frac{kJ}{mol}$.

6. C

Standard temperature and pressure indicates 0°C and 1 atm. Gibbs free energy is temperature dependent, but if a reaction is at equilibrium, $\Delta G = 0$.

7. B

Solve this question using the equation $\Delta G^\circ_{rxn} = -RT \ln K_{eq}$. ΔG°_{rxn} is $-4.955 \frac{kJ}{mol}$, R is $8.314 \frac{J}{mol \cdot K}$, and $T = 298$ K because the reaction is occurring under standard conditions. Because ΔG°_{rxn} uses kilojoules in its units and R uses joules, one will have to be converted. Plugging into the equation, we get:

$$-4955 \frac{J}{mol} = -\left(8.314 \frac{J}{mol \cdot K}\right)(298 \text{ K})(\ln K_{eq}) \rightarrow$$

$$\ln K_{eq} = \frac{4955 \frac{J}{mol}}{\left(8.314 \frac{J}{mol \cdot K}\right)(298 \text{ K})} \approx \frac{5000}{8 \times 300} = \frac{5000}{2400} \approx 2$$

If ln K_{eq} = 2, then $K_{eq} = e^2$. e is approximately 2.7, so we're looking for a number between 4 (2^2) and 9 (3^2). Both **choices (B)** and **(C)** fit these criteria; however, 8.9 is very close to 9, so we can assume that its square root is very, very close to 3. The answer choice should be a bit smaller, so **choice (B)**, 7.4, is correct.

8. D

There is not enough information available to determine the free energy of this reaction. While the entropy is clearly increasing (there are more particles in the system), it is unclear what the enthalpy change is. Because bonds are breaking, the reaction should be endothermic, meaning that both ΔS and ΔH are positive. In this case, it is a temperature-dependent process, and—without a temperature given—we cannot determine the sign on ΔG.

9. A

This problem asks for the free energy of a reaction at nonstandard conditions, which can be determined with the equation $\Delta G = \Delta G^\circ + RT\ln Q$.

10. A

A reaction with a negative enthalpy is, by definition, exothermic. Because both enthalpy and entropy are negative, this is a temperature-dependent process, and the reaction will be both endergonic and exergonic—but only at particular temperatures, eliminating **choices (C)** and **(D)**.

11. C

For a process to progress forward spontaneously, Q must be less than K_{eq} and will therefore have a tendency to move in the direction toward equilibrium. A spontaneous reaction's free energy is negative by convention.

12. B

A calorimeter measures heat transfer. Although calorimeters often incorporate thermometers, the thermometer itself only tracks temperature, not the heat transfer itself, so **choice (A)** is incorrect. **Choice (C)** is irrelevant; barometers measure changes in pressure. **Choice (D)** is also incorrect because volumetric flasks measure quantities of liquid, not the heat capacity of the liquid.

13. A

Eliminate **choices (C)** and **(D)**, which describe the free energy of reaction and cannot be determined from this graph. While most reaction coordinate graphs we've explored in this book use free energy for the y-axis, this one uses potential energy (enthalpy). If the heat of formation of the products is greater than that of the reactants, the reaction is endothermic. We can determine this information from their relative positions on the graph: because the products are higher than the reactants, this is an endothermic reaction.

14. C

Gases have the highest entropy, and solids have the lowest. Therefore, a phase change from a gas to a solid—deposition—would have the largest decrease in entropy of any phase change process.

15. A

In an explosion, a significant amount of heat energy is released, meaning that the reaction is exothermic ($\Delta H < 0$), eliminating **choice (B)**. The entropy change associated with an explosion is positive because energy is dispersed over a much larger area, eliminating **choice (C)**. If this is true, the expression $\Delta H - T\Delta S$ must be negative, indicating that this is an exergonic process ($\Delta G < 0$). Absolute temperature can never be negative, eliminating **choice (D)**.

Introduction

The next time you're leaving a birthday party, snag a helium balloon on your way out. Tie the helium balloon to the gearshift lever between the front seats, making sure that the balloon is floating freely. Once you're on an open road, accelerate the car abruptly, and as you do, watch the balloon—safely! What do you predict will happen to the balloon as the car accelerates? What do you observe? You might think, based on how you feel when you are sitting in a car accelerating forward, that the balloon will be pushed toward the back of the car due to its inertia. However, the balloon's movement isn't what we might predict: the balloon shifts forward as the car accelerates because the balloon is filled with helium. The molar mass of helium is 4 $\frac{\text{g}}{\text{mol}}$, while that of air, which is mostly nitrogen and oxygen, is about 29 $\frac{\text{g}}{\text{mol}}$. This means that air is about seven times denser than helium. Because the air in which the balloon is floating is more dense than the balloon itself, the air will have greater inertia. In fact, we can approximate the balloon's inertia as practically non-existent. Therefore, as the car accelerates forward, everything that has significant mass, including the air in the car, resists the forward motion (has inertia) and shifts toward the back of the car (even though, of course, everything in the car is accelerating forward, just not as quickly as the car itself). As the air shifts toward the back, a pressure gradient builds up such that there is greater air pressure in the back of the car than in the front, and this pressure difference results in a pushing force against the balloon that is directed from the back toward the front. Responding to this force, the balloon shifts forward in the direction of the car's acceleration. Who would have thought that general chemistry and physics could be so much fun?

In this chapter, we will discuss some MCAT favorites—the gas phase and the ideal gas laws. We will begin our discussion with ideal gases and the laws that govern their behavior. We will then examine the kinetic molecular theory that describes ideal gases and conclude with an evaluation of the ways in which the behavior of real gases deviates from that predicted by the ideal gas law.

8.1 The Gas Phase

Matter can exist in three different physical forms, called **phases** or **states**: gas, liquid, and solid. We have discussed liquids in the context of intermolecular forces and solids in the context of organized crystals in Chapter 3 of *MCAT General Chemistry Review*. The gaseous phase may be the simplest to understand because all gases display similar behavior and follow similar laws regardless of their particular chemical identities. Like liquids, gases are classified as fluids because they can flow and take on the shapes of their containers. However, the atoms or molecules in a gaseous sample move rapidly and are far apart from each other. In addition, only very weak intermolecular forces exist between gas particles; this results in certain characteristic physical properties, such as the ability to expand to fill any volume. Gases are also easily—although not infinitely—compressible, which distinguishes them from liquids.

VARIABLES

We can define the state of a gaseous sample by four variables: **pressure** (***P***), **volume** (***V***), **temperature** (***T***), and number of **moles** (***n***).

Gas pressures are usually expressed in units of **atmospheres** (**atm**) or in **millimeters of mercury** (**mmHg**), which are equivalent to **torr**. The SI unit for pressure, however, is the **pascal** (**Pa**). The mathematical relationships among all of these units are as follows:

$$1 \text{ atm} = 760 \text{ mmHg} \equiv 760 \text{ torr} = 101.325 \text{ kPa}$$

Medical devices that measure blood pressure are termed **sphygmomanometers**, and the most clinically relevant unit of measurement for them is mmHg. In fact many medical devices utilize the same conceptual design of a **barometer**, shown in Figure 8.1, to continuously monitor blood pressure.

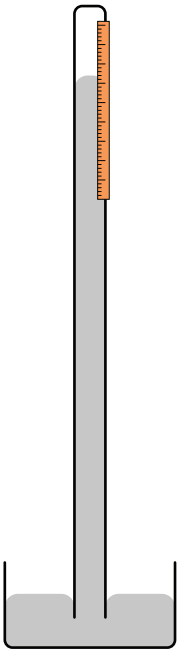

Figure 8.1. Schematic of a Simple Mercury Barometer

In order to explain why the mercury rises in a barometer, we must summarize the forces at play here. **Atmospheric pressure** creates a downward force on the pool of mercury at the base of the barometer while the mercury in the column exerts an opposing force (its weight) based on its density. The weight of the mercury creates a vacuum in the top of the tube. When the external air exerts a higher force than the weight of the mercury in the column, the column rises. When the external air exerts a lower force than the weight of the mercury, the column falls. Thus, a reading can be obtained by measuring the height of the mercury column (in mm), which will be directly proportional to the atmospheric pressure being applied.

It is important to mention here that atmospheric pressure is not the only external pressure that can exert this force. For instance, a clinical blood pressure cuff creates a force that is opposed by the person's systolic and diastolic arterial blood pressure.

The volume of a gas is generally expressed in liters (L) or milliliters (mL). Temperature is usually given in kelvins (K), although Celsius (°C) may be used instead. Many processes involving gases take place under **standard temperature and pressure** (**STP**), which refers to conditions of 273 K (0°C) and 1 atm.

A note of caution: **STP conditions** are not identical to **standard state conditions**. The two standards involve different temperatures and are used for different purposes. STP (273 K and 1 atm) is generally used for gas law calculations; standard state conditions (298 K, 1 atm, 1 *M* concentrations) are used when measuring standard enthalpy, entropy, free energy changes, and electrochemical cell voltage.

Bridge

Fluid dynamics is an important concept discussed in Chapter 4 of *MCAT Physics and Math Review* that applies to multiple aspects of the gas laws covered here, including the functionality of a mercury barometer.

Real World

Blood pressure is measured by a sphygmomanometer, which uses units of mmHg. A normal adult blood pressure is considered less than 120 mmHg systolic and 80 mmHg diastolic (< 120/80). Hypertension (high blood pressure) is defined as having at least two blood pressure readings > 140 mmHg systolic or > 90 mmHg diastolic.

MCAT Expertise

On the MCAT, remember that STP is different from standard state. Temperature at STP is 0°C (273 K). Temperature at standard state is 25°C (298 K).

MCAT Concept Check 8.1:
Before you move on, assess your understanding of the material with these questions.

1. Name some characteristics that make the gas phase unique:

_____

_____

_____

2. A mercury barometer is primarily affected by atmospheric pressure. What would happen to the level of the mercury in the column if:
   - the barometer was moved to the top of a mountain?

     _____
   - the barometer was placed ten meters under water?

     _____

3. What are the conditions for STP?

_____

4. What are the standard conditions?

_____

8.2 Ideal Gases

★★★★

Key Concept

An ideal gas follows the gas laws we will discuss at all pressures and temperatures. A real gas deviates from these laws at high pressures (low volumes) and low temperatures because of intermolecular forces or volume effects.

When we examine the behavior of gases under varying conditions of temperature and pressure, we assume that the gases are ideal. An **ideal gas** represents a hypothetical gas with molecules that have no **intermolecular forces** and occupy no volume. Although **real gases** deviate from this ideal behavior at high pressures (low volumes) and low temperatures, many compressed real gases demonstrate behavior that is close to ideal.

IDEAL GAS LAW

The ideal gas law was first stated in 1834 by Benoît Paul Émile Clapeyron, more than 170 years after Sir Robert Boyle performed his experimental studies on the relationship between pressure and volume in the gas state. In fact, by the time the ideal gas law found its expression, Boyle's law, Charles's law, and Dalton's law had already

been well-established. Historical considerations aside, it will benefit us to examine the ideal gas law first so that we can then understand the other laws, which had been identified earlier, to be only special cases of the ideal gas law.

The ideal gas law shows the relationship among four variables that define a sample of gas:

$$PV = nRT$$

Equation 8.1

where P is the pressure, V is the volume, n is the number of moles, and T is the temperature. R represents the **ideal gas constant**, which has a value of 8.21×10^{-2} $\frac{\text{L} \bullet \text{atm}}{\text{mol} \bullet \text{K}}$. Be aware that the gas constant can be expressed in other units. On the MCAT, you may also encounter R given as 8.314 $\frac{\text{J}}{\text{K} \bullet \text{mol}}$, which is derived when SI units of pascal (for pressure) and cubic meters (for volume) are substituted into the ideal gas law. Although the relevant values for R will be provided on Test Day if needed, it is important to recognize the appropriate value for R based on the units of the variables given in a passage or question stem.

The ideal gas law is used to determine the missing term when given all of the others. It can also be used to calculate the change in a term while holding two of the others constant. It is most commonly used to solve for volume or pressure at any given temperature and number of moles; Figure 8.2 shows graphs of P–V relationships at increasing temperatures.

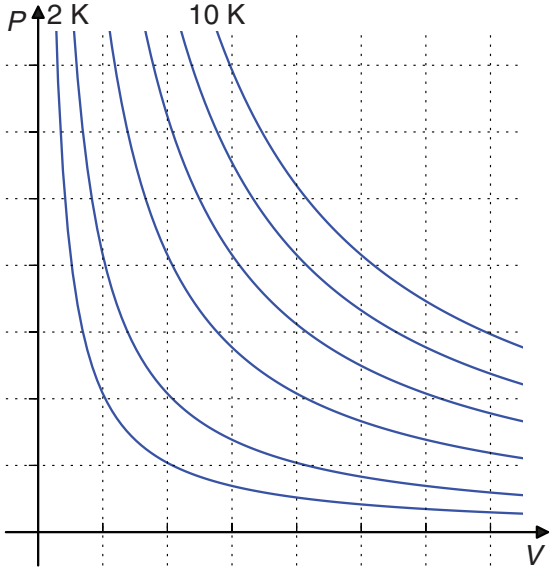

Figure 8.2. Ideal Gas Isothermal Curves
When n, R, and T are held constant, one can easily analyze the relationship between pressure and volume.

Example: What volume would 12 g of helium occupy at 27°C and a pressure of 380 mmHg?

Solution: The ideal gas law can be used, but first, all of the variables must be converted to units that will correspond to the expression of the gas constant as $8.21 \times 10^{-2} \frac{\text{L} \cdot \text{atm}}{\text{mol} \cdot \text{K}}$.

$$P = 380 \text{ mmHg}\left[\frac{1 \text{ atm}}{760 \text{ mmHg}}\right] = 0.5 \text{ atm}$$

$$T = 27^{\circ}\text{C} + 273 = 300 \text{ K}$$

$$n = 12 \text{ g He}\left[\frac{1 \text{ mol}}{4.0 \text{ g}}\right] = 3 \text{ mol He}$$

$$PV = nRT$$

$$(0.5 \text{ atm})(V) = (3 \text{ mol He})\left(0.0821 \frac{\text{L} \cdot \text{atm}}{\text{mol} \cdot \text{K}}\right)(300 \text{ K})$$

$$0.5V \approx 3 \times 8 \times 3$$

$$V = 144 \text{ L} \ (\text{actual} = 148 \text{ L})$$

Bridge

Round numbers to speed up your arithmetic on Test Day. For instance, constants such as 0.0821 can be rounded to 0.08. Choices will be sufficiently different so that your estimated answer will be nearly identical to the true answer choice. Arithmetic and math strategies are discussed in Chapter 10 of *MCAT Physics and Math Review*.

The ideal gas law is useful not only for standard calculations of pressure, volume, or temperature of a gas under a given set of conditions, but also for determinations of gas density and molar mass.

Density

We define **density** (ρ) as the ratio of the mass per unit volume of a substance. The densities of gases are usually expressed in units of grams per liter. The ideal gas law contains variables for volume and number of moles, so we can rearrange the law to calculate the density of any gas:

$$PV = nRT$$

$$\text{where } n = \frac{m \text{ (mass)}}{M \text{ (molar mass)}}$$

$$\text{Therefore, } PV = \frac{m}{M}RT$$

$$\text{and } \rho = \frac{m}{V} = \frac{PM}{RT}$$

Equation 8.2

A different approach could start with the fact that a mole of an ideal gas at STP occupies 22.4 L. We can then calculate the effect of changes in pressure and temperature when they differ from STP conditions, predicting the volume of the gas. Finally, we'll calculate the density by dividing the mass by the predicted volume. The following equation, the **combined gas law**, is an amalgam of some of the special cases we will discuss in the following section. It can be used to relate changes in temperature, volume, and pressure of a gas:

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

Equation 8.3

where the subscripts 1 and 2 refer to the two states of the gas (at STP and at the conditions of actual temperature and pressure, for example). This equation assumes the number of moles stays constant.

To calculate a change in volume, the equation is rearranged as follows:

$$V_2 = V_1\left[\frac{P_1}{P_2}\right]\left[\frac{T_2}{T_1}\right]$$

V_2 is then used to find the density of the gas under nonstandard conditions:

$$\rho = \frac{m}{V_2}$$

On Test Day, it may be helpful to visualize how the changes in pressure and temperature affect the volume of the gas, and this can serve as a check to avoid accidentally switching the values of pressure and temperature in the numerator and denominator. For example, one could predict that doubling the temperature of a gas would result in doubling its volume, and doubling the pressure of a gas would result in halving the volume, so doubling both the temperature and pressure at the same time results in a final volume that is equal to the original volume.

Example: What is the density of CO_2 gas at 2 atm and 273°C?

Solution: At STP, a mole of gas occupies 22.4 L. Because the increase in pressure to 2 atm decreases volume, 22.4 L must be multiplied by $\frac{1\,\text{atm}}{2\,\text{atm}}$. Because the increase in temperature increases volume, the temperature factor will be $\frac{546\,\text{K}}{273\,\text{K}}$.

$$V_2 = \left[\frac{22.4\,\text{L}}{\text{mol}}\right]\left[\frac{1\,\text{atm}}{2\,\text{atm}}\right]\left[\frac{546\,\text{K}}{273\,\text{K}}\right] = 22.4\,\frac{\text{L}}{\text{mol}}$$

$$\rho = \frac{44\,\frac{\text{g}}{\text{mol}}}{22.4\,\frac{\text{L}}{\text{mol}}} = 1.96\,\frac{\text{g}}{\text{L}}.$$

Molar Mass

Sometimes the identity of a gas is unknown, and the molar mass, discussed in Chapter 4 of *MCAT General Chemistry Review*, can be determined in order to identify it. Using the equation for density derived from the ideal gas law, we can calculate the molar mass of a gas experimentally in the following way:

The pressure and temperature of a gas contained in a bulb of a given volume are measured, and the mass of the bulb with the sample is measured. Then, the bulb is evacuated—the gas is removed—and the mass of the empty bulb is determined. The mass of the bulb with the sample minus the mass of the evacuated bulb gives the mass of the sample. Finally, the density of the sample is determined by dividing the mass of the sample by the volume of the bulb. This gives the density at the given temperature and pressure.

Using $V_2 = V_1\left[\frac{P_1}{P_2}\right]\left[\frac{T_2}{T_1}\right]$, we then calculate the volume of the gas at STP, substituting 273 K for T_2 and 1 atm for P_2. The ratio of the sample mass divided by V_2 gives the density of the gas at STP. The molar mass can then be calculated as the product of the gas's density at STP and the STP volume of one mole of gas, 22.4 $\frac{\text{L}}{\text{mol}}$:

$$M = (\rho_{\text{STP}})(22.4\ \frac{\text{L}}{\text{mol}})$$

Example: What is the molar mass of a 22.4 L sample of gas that has a mass of 336 g at a temperature of 546°C and a pressure of 10 atm?

Solution:

$$\rho = \frac{336\,\text{g}}{22.4\,\text{L}} \text{ at } 546^{\circ}\text{C and } 10\text{ atm}$$

$$V_{\text{STP}} = V_1\left[\frac{P_1}{P_{\text{STP}}}\right]\left[\frac{T_{\text{STP}}}{T_1}\right] = 22.4\,\text{L}\left[\frac{10\text{ atm}}{1\text{ atm}}\right]\left[\frac{273\,\text{K}}{819\,\text{K}}\right] = 22.4\times 10\times\frac{1}{3}\approx 75\,\text{L}$$

$$\frac{336\,\text{g}}{75\,\text{L}}\approx 4.5\,\frac{\text{g}}{\text{L}} \text{ at STP}$$

$$M = 4.5\,\frac{\text{g}}{\text{L}}\left[\frac{22.4\,\text{L}}{\text{mol}}\right]\approx 100\,\frac{\text{g}}{\text{mol}}$$

SPECIAL CASES

Now that we have considered the ideal gas law as the mathematical relationship between four variables that define the state of a gas (pressure, volume, temperature, and moles of gas), we can examine the other laws that preceded its discovery. Even though the following laws were developed before the ideal gas law, it is conceptually helpful to think of them as special cases of the more general ideal gas law.

Avogadro's Principle

One important discovery that preceded Clapeyron's formulation of the ideal gas law was **Avogadro's principle**, which states that all gases at a constant temperature and pressure occupy volumes that are directly proportional to the number of moles of gas present. Equal amounts of all gases at the same temperature and

pressure will occupy equal volumes. As discussed above, one mole of any gas, irrespective of its chemical identity, will occupy 22.4 liters at STP.

$$\frac{n}{V} = k \text{ or } \frac{n_1}{V_1} = \frac{n_2}{V_2}$$

Equation 8.4

where k is a constant, n_1 and n_2 are the number of moles of gas 1 and gas 2, respectively, and V_1 and V_2 are the volumes of the gases, respectively. This can be summarized in the following statement: *as the number of moles of gas increases, the volume increases in direct proportion*.

Example: A 2.0 L sample at 100°C and 20 atm contains 5 moles of a gas. If an additional 25 moles of gas at the same pressure and temperature are added, what is the final volume of the gas?

Solution: If pressure and temperature are held constant, the ideal gas law reduces to Avogadro's principle:

$$\frac{n_1}{V_1} = \frac{n_2}{V_2}$$

$$\frac{5\,\text{mol}}{2.0\,\text{L}} = \frac{5\,\text{mol} + 25\,\text{mol}}{V_2}$$

$$V_2 = \frac{30\,\text{mol} \times 2.0\,\text{L}}{5\,\text{mol}} = 12.0\,\text{L}$$

Boyle's Law

Robert Boyle conducted a series of experimental studies in 1660 that led to his formulation of a law that now bears his name: **Boyle's law**. His work showed that, for a given gaseous sample held at constant temperature (isothermal conditions), the volume of the gas is inversely proportional to its pressure:

$$PV = k \text{ or } P_1V_1 = P_2V_2$$

Equation 8.5

where k is a constant, and the subscripts 1 and 2 represent two different sets of pressure and volume conditions. Careful examination of Boyle's law shows that it is, indeed, simply the special case of the ideal gas law in which n and T are constant.

A plot of volume *vs*. pressure for a gas—the inverse of the curves in Figure 8.2—is shown in Figure 8.3.

Key Concept

Boyle's law is a derivation of the ideal gas law and states that pressure and volume are inversely related: when one increases, the other decreases.

MCAT Expertise

Sometimes it is easier to remember the shape of the graph to help you recall the variables' relationship on Test Day. Here we can see that, as pressure increases, the volume decreases, and vice-versa. These ratios and relationships will often allow you to answer questions on the MCAT without having to do much math.

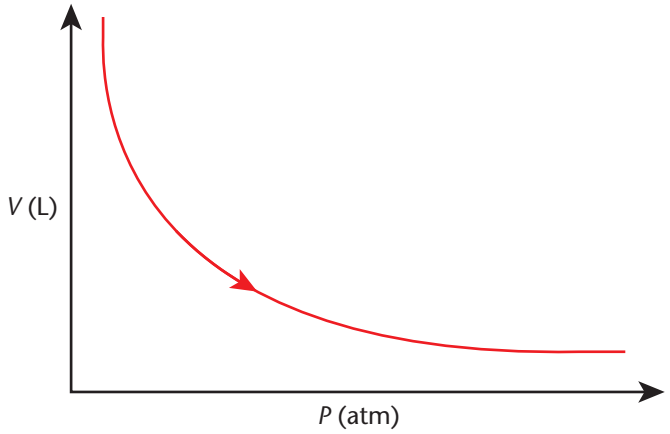

Figure 8.3. Boyle's Law (Isothermal Compression)
As pressure increases, volume decreases.

Example: What would be the volume of a 1 L sample of helium if its pressure is changed from 12 atm to 4 atm under isothermal conditions?

Solution: If the number of moles of gas and temperature are held constant, the ideal gas law reduces to Boyle's law:

$$P_1V_1 = P_2V_2$$
$$(12\,\text{atm})(1\,\text{L}) = (4\,\text{atm})(V_2)$$
$$V_2 = \frac{12\,\text{atm} \times 1\,\text{L}}{4\,\text{atm}} = 3\ \text{L}$$

Charles's Law

In the early 19th century, Joseph Louis Gay-Lussac published findings based, in part, on earlier unpublished work by Jacques Charles; hence, the law of Charles and Gay-Lussac is more commonly known simply as **Charles's law**. The law states that, at constant pressure, the volume of a gas is proportional to its absolute temperature, expressed in kelvins. Expressed mathematically, Charles's law is

$$\frac{V}{T} = k \text{ or } \frac{V_1}{T_1} = \frac{V_2}{T_2}$$

Equation 8.6

where, again, k is a proportionality constant and the subscripts 1 and 2 represent two different sets of temperature and volume conditions. Careful examination of Charles's law shows that it is another special case of the ideal gas law in which n and P are constant.

Key Concept

Charles's law is also a derivation of the ideal gas law and states that volume and temperature are directly proportional: when one increases, the other increases in direct proportion.

A plot of temperature *vs.* volume is shown in Figure 8.4. Note that if one extrapolates the *V vs. T* plot for a gas back to where $T = 0$ (absolute zero), we find that $V = 0$!

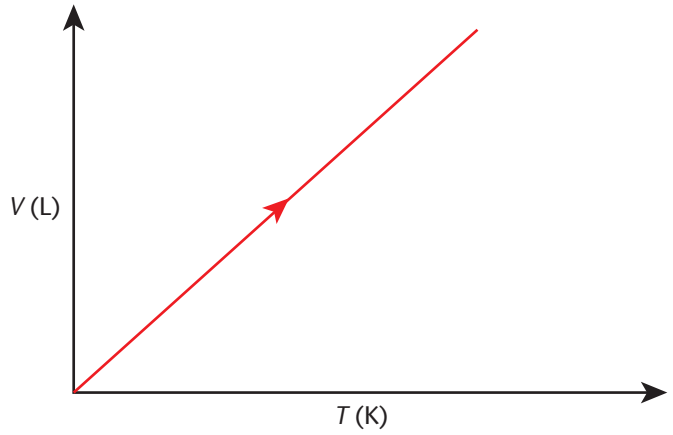

Figure 8.4. Charles's Law (Isobaric Expansion)
As temperature increases, volume increases.

Example: If the temperature of 2 L of gas at constant pressure is changed from 283 K to 566 K, what would be its final volume?

Solution: If the number of moles of gas and pressure are held constant, the ideal gas law reduces to Charles's law:

$$\frac{V_1}{T_1} = \frac{V_2}{T_2}$$

$$\frac{2\,\text{L}}{283\,\text{K}} = \frac{V_2}{566\,\text{K}}$$

$$V_2 = \frac{2\,\text{L} \times 566\,\text{K}}{283\,\text{K}} = 4\,\text{L}$$

Gay-Lussac's Law

Gay-Lussac's law is complementary to Charles's Law. It utilizes the same derivation from the ideal gas law, but it relates pressure to temperature instead. Expressed mathematically, Gay-Lussac's law is

$$\frac{P}{T} = k \text{ or } \frac{P_1}{T_1} = \frac{P_2}{T_2}$$

Equation 8.7

where, again, k is a proportionality constant, and the subscripts 1 and 2 represent two different sets of temperature and pressure conditions. Careful examination of Gay-Lussac's law shows that it is another special case of the ideal gas law in which n and V are constant.

Real World

While the temperature of 0 K cannot be physically attained, curves such as Charles's law were originally used to figure out its value.

Figure 8.5 graphs this concept, which is nearly identical to Charles's law. Again, an increase in temperature will increase the pressure in direct proportion.

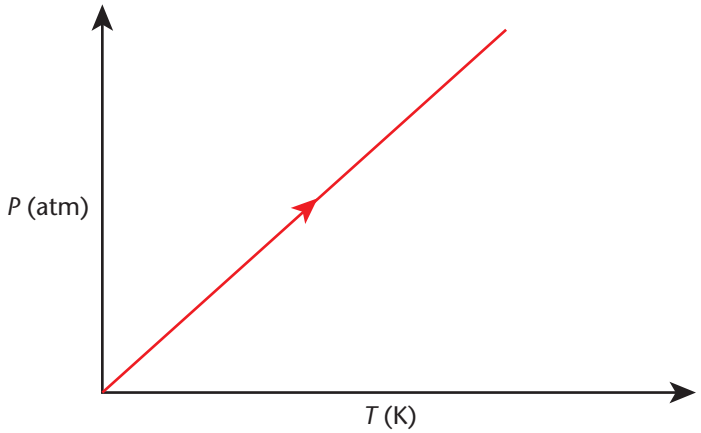

Figure 8.5. Gay-Lussac's Law (Isovolumetric Heating)
As temperature increases, pressure increases.

Example: If the pressure of a sample of gas with a temperature of 273 K changes from 2 atm to 5 atm during heating, what would be the final temperature if volume is held constant?

Solution: If the number of moles of gas and volume are held constant, the ideal gas law reduces to Gay-Lussac's law:

$$\frac{P_1}{T_1} = \frac{P_2}{T_2}$$

$$\frac{2\,\text{atm}}{273\,\text{K}} = \frac{5\,\text{atm}}{T_2}$$

$$T_2 = \frac{5\,\text{atm} \times 273\,\text{K}}{2\,\text{atm}} = 682.5\,\text{K}$$

Combined Gas Law

As discussed earlier, the **combined gas law** (Equation 8.3) was a combination of many of the preceding laws. This law relates pressure and volume (Boyle's law) in the numerator, and relates the variations in temperature to both volume (Charles's law) and pressure (Gay-Lussac's law) simultaneously. When using this equation, take care to place all of the variables in the right place.

MCAT Expertise

Understanding how the combined gas law functions helps avoid the need to memorize every other special case of the ideal gas law. Read the question stem or passage with an eye toward the quantities that remain constant to know when assumptions can be made.

DALTON'S LAW OF PARTIAL PRESSURES

When two or more gases that do not chemically interact are found in one vessel, each gas will behave independently of the others. That is, each gas will behave as if it were the only gas in the container. Therefore, the pressure exerted by each gas in the mixture will be equal to the pressure that the gas would exert if it were the only

one in the container. The pressure exerted by each individual gas is called the **partial pressure** of that gas. In 1801, John Dalton derived an expression, now known as **Dalton's law of partial pressures**, which states that the total pressure of a gaseous mixture is equal to the sum of the partial pressures of the individual components. The equation for Dalton's law is

$$P_T = P_A + P_B + P_C + \ldots$$

Equation 8.8

where P_T is the total pressure in the container, and P_A, P_B, and P_C are the partial pressures of gases A, B, and C, respectively.

The partial pressure of a gas is related to its mole fraction and can be determined using the following equation:

$$P_A = X_A P_T$$

$$\text{where } X_A = \frac{\text{moles of gas A}}{\text{total moles of gas}}$$

Equation 8.9

Example: A vessel contains 0.75 mol of nitrogen, 0.20 mol of hydrogen, and 0.05 mol of fluorine at a total pressure of 2.5 atm. What is the partial pressure of each gas?

Solution: First calculate the mole fraction of each gas.

$$X_{N_2} = \frac{0.75\text{ mol}}{1.00\text{ mol}} = 0.75 \quad X_{H_2} = \frac{0.20\text{ mol}}{1.00\text{ mol}} = 0.20 \quad X_{F_2} = \frac{0.05\text{ mol}}{1.00\text{ mol}} = 0.05$$

Then calculate the partial pressure.

$$P_A = X_A P_T$$
$$P_{N_2} = (0.75)(2.5\text{ atm}) = 1.875\text{ atm}$$
$$P_{H_2} = (0.20)(2.5\text{ atm}) = 0.5\text{ atm}$$
$$P_{F_2} = (0.05)(2.5\text{ atm}) = 0.125\text{ atm}$$

Key Concept

When more than one gas is in a container, each contributes to the whole as if it were the only gas present. Add up all of the pressures of the individual gases and you get the whole pressure of the system.

HENRY'S LAW

The difference in gas solubility between fluids was explained by William Henry in 1803. What Henry noticed was that, at various applied pressures, the concentration of a gas in a liquid increased or decreased. This was a characteristic of a gas's vapor pressure. **Vapor pressure** is the pressure exerted by evaporated particles above the surface of a liquid. Evaporation, as discussed in Chapter 7 of *MCAT General Chemistry Review*, is a dynamic process that requires the molecules at the surface of a liquid to gain enough energy to escape into the gas phase.

Key Concept

The solubility of a gas will increase with increasing partial pressure of the gas.

Vapor pressure from the evaporated molecules forces some of the gas back into the liquid phase, and equilibrium is reached between evaporation and condensation. Mathematically, this is expressed as

$$[A] = k_H \times P_A \text{ or } \frac{[A]_1}{P_1} = \frac{[A]_2}{P_2} = k_H$$

Equation 8.10

where [A] is the concentration of A in solution, k_H is Henry's constant, and P_A is the partial pressure of A. The value of Henry's constant depends on the identity of the gas.

According to this relationship, solubility (concentration) and pressure are directly related. In biology, this is a critically important relationship for gas and nutrient exchange. As discussed in Chapter 6 of *MCAT Biology Review*, lung tissue—at the microscopic level—is organized into grapelike clusters of sacs called alveoli. These sacs are perfused by capillaries that allow for the exchange of carbon dioxide and oxygen, as shown in Figure 8.6. If the atmospheric pressure changes, as it does from sea level to high altitude, then the partial pressure of oxygen in the atmosphere also changes (as explained by Dalton's law), and the amount of gas exchanged is altered accordingly; if the partial pressure of a particular gas is elevated, such as when giving hyperbaric oxygen, the amount of that gas dissolved in the blood is also elevated.

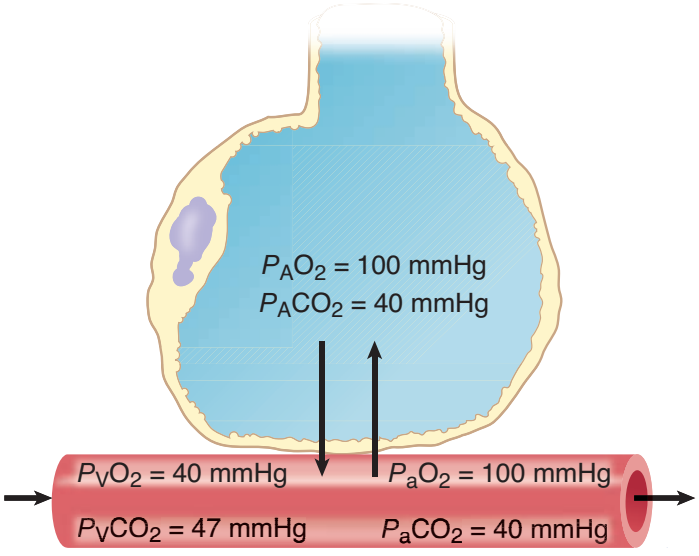

Figure 8.6. Alveolar Capillary Gas Exchange
In medicine, *A* represents alveolar concentrations, *V* represents venous concentrations, and *a* represents arterial concentrations.

Example: If 4×10^{-4} moles of gas are dissolved in 2 L of solution under an ambient pressure of 2 atm, what will be the molar concentration of the gas under 10 atm?

Solution: Start by determining the initial concentration of the gas in solution.

$$[A]_1 = \frac{4 \times 10^{-4} \text{ mol}}{2 \text{ L}} = 2 \times 10^{-4} M$$

Next, utilize the direct relationship between solubility and pressure according to Henry's law.

$$\frac{[A]_1}{P_1} = \frac{[A]_2}{P_2}$$

$$\frac{2 \times 10^{-4} M}{2 \text{ atm}} = \frac{[A]_2}{10 \text{ atm}}$$

$$[A]_2 = \frac{(2 \times 10^{-4} M)(10 \text{ atm})}{2 \text{ atm}} = 10^{-3} M$$

MCAT Concept Check 8.2:

Before you move on, assess your understanding of the material with these questions.

1. A container with 4 moles of a gas at a pressure of 6 atm has a volume of 12 liters. What is its temperature? (Note: $R = 8.21 \times 10^{-2} \frac{\text{L} \bullet \text{atm}}{\text{mol} \bullet \text{K}}$)

_____

2. What is the density of argon gas at 4 atm and 136.5°C?

_____

3. A 20 L sample at 300°C and 5 atm of pressure contains 2 moles of a gas. If an additional 3 moles of gas at the same pressure and temperature are added, what is the final total volume of the gas?

_____

_____

4. What would be the volume of a 2 L sample of neon if its pressure is changed from 1 atm to 40 atm under isothermal conditions?

_____

_____

5. If the temperature of 7.5 L of gas at constant pressure is changed from –136.5°C to 136.5°C, what would be its final volume?

_____

_____

6. If the pressure of a sample of gas with a temperature of 273°C is changed from 5 atm to 2 atm during cooling, what would be the final temperature?

_____

_____

7. A vessel contains 8 mol O_2, 3 mol CH_4, and 1 mol CO_2 at a total pressure of 240 atm. What is the partial pressure of each gas?

_____

_____

8. How can the concentration of carbon dioxide in sodas or other carbonated beverages be so much higher than that of atmospheric carbon dioxide?

_____

_____

8.3 Kinetic Molecular Theory ★★★

The **kinetic molecular theory** was developed in the second half of the 19th century, well after the laws describing gas behavior had been developed. The kinetic molecular theory was used to *explain* the behavior of gases, which the other laws merely *described*. The gas laws demonstrate that all gases show similar physical characteristics and behavior irrespective of their particular chemical identity. The behavior of real gases deviates from the ideal behavior predicted under the assumptions of this theory, but these deviations can be corrected for in calculations. The combined efforts of James Maxwell, Ludwig Boltzmann, and others led to a simple explanation of gaseous molecular behavior based on the motion of individual molecules. Like the gas laws, the kinetic molecular theory was developed in reference to ideal gases, although it can be applied with reasonable accuracy to real gases as well.

ASSUMPTIONS

To simplify the model proposed by the kinetic molecular theory, certain assumptions are made:

1. Gases are made up of particles with volumes that are negligible compared to the container volume.
2. Gas atoms or molecules exhibit no intermolecular attractions or repulsions.
3. Gas particles are in continuous, random motion, undergoing collisions with other particles and the container walls.
4. Collisions between any two gas particles (or between particles and the container walls) are elastic, meaning that there is conservation of both momentum and kinetic energy.
5. The average kinetic energy of gas particles is proportional to the absolute temperature of the gas (in kelvins), and it is the same for all gases at a given temperature, irrespective of chemical identity or atomic mass.

APPLICATIONS

It is fairly straightforward to imagine gas particles as little rubber balls bouncing off each other and off the walls of the container. Of course, rubber balls, like real gas particles, have measurable mass and volume, and not even the bounciest rubber balls will collide in a completely elastic manner. Still, this provides an apt visualization of the behaviors described by the kinetic molecular theory.

Average Molecular Speeds

According to the kinetic molecular theory of gases, the average kinetic energy of a gas particle is proportional to the absolute temperature of the gas:

$$KE = \frac{1}{2}mv^2 = \frac{3}{2}k_B T$$

Equation 8.11

where k_B is the **Boltzmann constant** (1.38×10^{-23} $\frac{\text{J}}{\text{K}}$), which serves as a bridge between the macroscopic and microscopic behaviors of gases (that is, as a bridge between the behavior of the gas as a whole and the individual gas molecules). This equation shows that the speed of a gas particle is related to its absolute temperature. However, because of the large number of rapidly and randomly moving gas particles, which may travel only nanometers before colliding with another particle or the container wall, the speed of an individual gas molecule is nearly impossible to define. Therefore, the speeds of gases are defined in terms of their average molecular speed. One way to define an average speed is to determine the average kinetic energy per particle and then calculate the speed to which this corresponds. The resultant quantity, known as the **root-mean-square speed** ($\boldsymbol{u}_{rms}$), is given by the following equation:

MCAT Expertise

Understanding concepts will be much more fruitful on Test Day than memorizing all of the facts. The higher the temperature, the faster the molecules move. The larger the molecules, they slower they move.

$$u_{rms} = \sqrt{\frac{3RT}{M}}$$

Equation 8.12

where R is the ideal gas constant, T is the temperature, and M is the molar mass.

A **Maxwell–Boltzmann distribution curve** shows the distribution of gas particle speeds at a given temperature. Figure 8.7 shows a distribution curve of molecular speeds at two temperatures, T_1 and T_2, where T_2 is greater than T_1. Notice that the bell-shaped curve flattens and shifts to the right as the temperature increases, indicating that at higher temperatures, more molecules are moving at higher speeds.

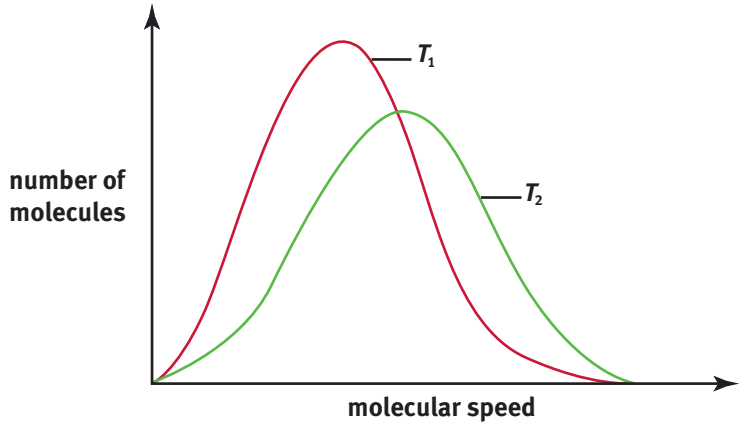

Figure 8.7. Maxwell–Boltzmann Distribution Curves of Molecular Speeds at Two Different Temperatures

Example: What is the average speed of xenon difluoride molecules at 20°C?

Solution: The ideal gas constant R = 8.314 $\frac{J}{K \cdot mol}$ should be used, and the molar mass of xenon difluoride is 169.3 $\frac{g}{mol}$. M must be expressed in $\frac{kg}{mol}$ because joules are also derived from kilograms.

$$u_{rms} = \sqrt{\frac{3RT}{M}}$$

$$u_{rms} = \sqrt{\frac{3\left(8.314 \frac{J}{K \cdot mol}\right)(293K)}{0.17 \frac{kg}{mol}}} \approx \sqrt{\frac{(3)(8)(300)}{0.18}} = \sqrt{\frac{7200}{0.18}} = \sqrt{40{,}000}$$

$$u_{rms} \approx 200 \frac{m}{s} \left(\text{actual} = 208 \frac{m}{s}\right)$$

Graham's Law of Diffusion and Effusion

The movement of molecules from high concentration to low concentration through a medium (such as air or water) is called **diffusion**, as shown in Figure 8.8.

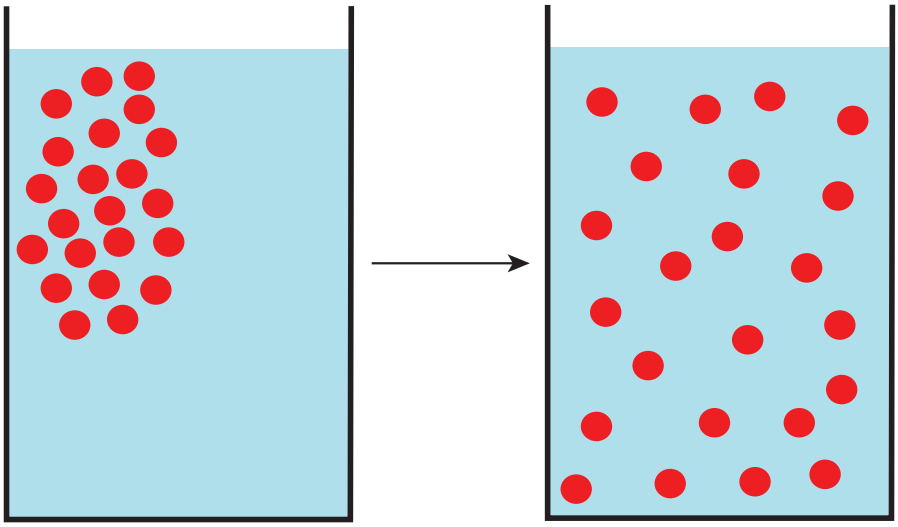

Figure 8.8. Diffusion of Solutes in a Solvent

The kinetic molecular theory of gases predicts that heavier gases diffuse more slowly than lighter ones because of their differing average speeds, as shown in Figure 8.9. Because all gas particles have the same average kinetic energy at the same temperature, it must be true that particles with greater mass travel at a slower average speed.

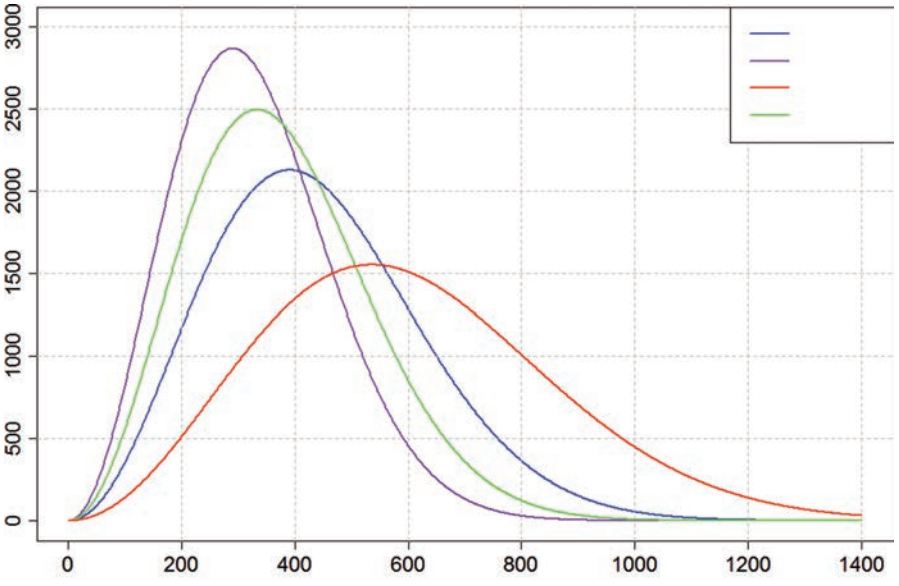

Figure 8.9. Maxwell–Boltzmann Distribution Curves of Molecular Speeds for Gases with Different Molar Masses
The more massive the gas particles, the slower their average speed.

In 1832, Thomas Graham showed mathematically that, under isothermal and isobaric conditions, the rates at which two gases diffuse are inversely proportional to the square roots of their molar masses. This is called **Graham's law**, which is written mathematically as

$$\frac{r_1}{r_2} = \sqrt{\frac{M_2}{M_1}}$$

Equation 8.13

where r_1 and r_2 are the diffusion rates of gas 1 and gas 2, respectively, and M_1 and M_2 are the molar masses of gas 1 and gas 2, respectively. From this equation, we can see that a gas that has a molar mass four times that of another gas will travel half as fast as the lighter gas.

Effusion is the flow of gas particles under pressure from one compartment to another through a small opening, as shown in Figure 8.10. Graham used the kinetic molecular theory of gases to show that, for two gases at the same temperature, the rates of effusion are proportional to the average speeds. He then expressed the rates of effusion in terms of molar mass and found that the relationship is the same as that for diffusion.

Real World

In the clinics, a pleural effusion is a condition in which fluid enters the intrapleural space through small openings in the capillaries or lymphatic vessels. This causes a pressure buildup around the lungs that hinders breathing.

Key Concept

Diffusion—When gases mix with one another.
Effusion—When a gas moves through a small hole under pressure.
Both will be slower for larger molecules.
Both conditions use the same equation.

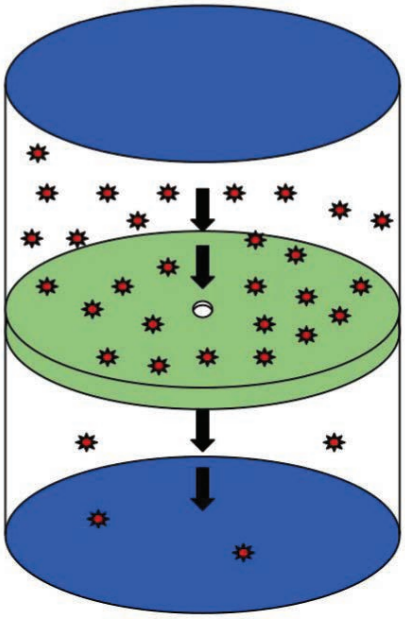

Figure 8.10. Effusion of Gas Particles
Effusion is the flow of gas particles under pressure from one compartment to another through a small opening.

Example: Oxygen molecules travel at an average speed of approximately 482 $\frac{m}{s}$ at room temperature. Calculate the average speed of hydrogen molecules at the same temperature.

Solution: Oxygen's molar mass is 32 $\frac{g}{mol}$. Hydrogen's molar mass is 2 $\frac{g}{mol}$. Plugging into Graham's law, we get:

$$\frac{r_1}{r_2} = \sqrt{\frac{M_2}{M_1}} \rightarrow r_2 = r_1\sqrt{\frac{M_1}{M_2}}$$

$$r_2 = 482\,\frac{m}{s}\sqrt{\frac{32\,\frac{g}{mol}}{2\,\frac{g}{mol}}} = 482\,\frac{m}{s} \times 4 = 1928\,\frac{m}{s}$$

MCAT Concept Check 8.3:

Before you move on, assess your understanding of the material with these questions.

1. What are the assumptions made by the kinetic molecular theory?

_____

_____

_____

2. What is the average speed of helium atoms at –173°C?

_____

_____

3. If neon gas travels at 400 $\frac{m}{s}$ at a given temperature, calculate the average speed of krypton at the same temperature.

_____

_____

4. Hydrogen sulfide (H_2S) has a very strong rotten egg odor. Methyl salicylate (C_8H_8O) has a wintergreen odor, and benzaldehyde (C_7H_6O) has a pleasant almond odor. If the vapors for these three substances were released at the same time from across a room, in which order would one smell the odors? Explain your answer.

_____

_____

8.4 Real Gases ★★

MCAT Expertise

At high temperature and low pressure (high volume), deviations from ideality are usually small; good approximations can still be made from the ideal gas law.

Throughout our discussions of the laws and theory that describe and explain the behaviors of gases, we have stressed that the fundamental assumption is a gas that behaves ideally. However, our world is not one of ideal gases but rather real ones. Real gases have particles that occupy nonnegligible volumes and that interact with each other in measurable ways. In general, the ideal gas law is a good approximation of the behavior of real gases, but all real gases deviate from ideal gas behavior to some extent, particularly when the gas atoms or molecules are forced into close proximity under high pressure (at low volume) or at low temperature. These effects are implied by Figure 8.11, which shows isothermal lines on a pressure–volume graph for a real gas. Compare these lines to the ideal isotherms in Figure 8.2. Under these nonideal conditions, the intermolecular forces and the particles' volumes become significant.

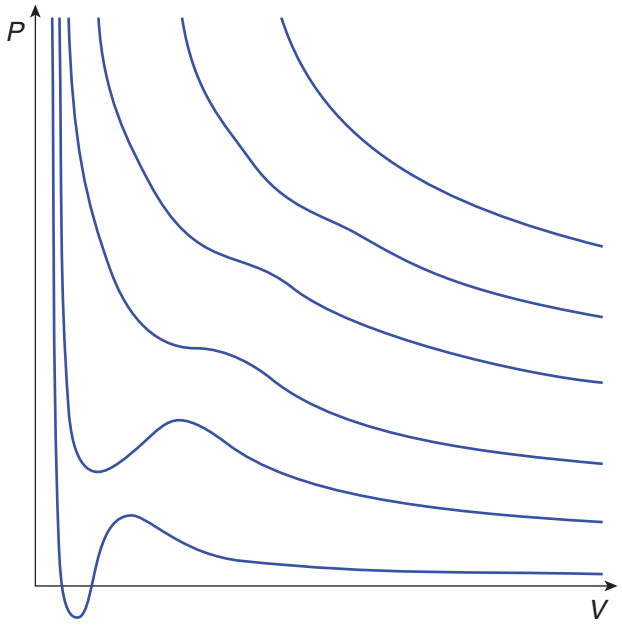

Figure 8.11. Real Gas Isothermal Curves
Compare these lines to the ideal gas isotherms in Figure 8.2.

DEVIATIONS DUE TO PRESSURE

MCAT Expertise

On the MCAT, an understanding of nonideal conditions will help with determining how gases' behaviors may deviate.

As the pressure of a gas increases, the particles are pushed closer and closer together. As the condensation pressure for a given temperature is approached, intermolecular attraction forces become more and more significant, until the gas condenses into a liquid.

At moderately high pressure (a few hundred atmospheres), a gas's volume is less than would be predicted by the ideal gas law due to intermolecular attraction. At

extremely high pressures, however, the size of the particles becomes relatively large compared to the distance between them, and this causes the gas to take up a larger volume than would be predicted by the ideal gas law. That is, while the ideal gas law assumes that a gas can be compressed to take up zero volume, this is not actually physically possible—the gas particles themselves will take up space.

DEVIATIONS DUE TO TEMPERATURE

As the temperature of a gas is decreased, the average speed of the gas molecules decreases and the attractive intermolecular forces become increasingly significant. As the condensation temperature is approached for a given pressure, intermolecular attractions eventually cause the gas to condense to a liquid state.

Like deviations due to pressure, as the temperature of a gas is reduced toward its condensation point (which is the same as its boiling point), intermolecular attraction causes the gas to have a smaller volume than that which would be predicted by the ideal gas law. The closer a gas is to its boiling point, the less ideally it acts. At extremely low temperatures, gases will again occupy more space than predicted by the ideal gas law because the particles cannot be compressed to zero volume.

VAN DER WAALS EQUATION OF STATE

There are several gas equations that attempt to correct for the deviations from ideality that occur when a gas does not closely follow the ideal gas law. The van der Waals equation of state is one such equation:

$$\left(P + \frac{n^2 a}{V^2}\right)(V - nb) = n\mathrm{R}T$$

Equation 8.14

where a and b are physical constants experimentally determined for each gas. The a term corrects for the attractive forces between molecules and, as such, will be smaller for gases that are small and less polarizable (such as helium), larger for gases that are larger and more polarizable (such as Xe or N_2), and largest for polar molecules such as HCl and NH_3. The b term corrects for the volume of the molecules themselves. Larger molecules thus have larger values of b. Numerical values for a are generally much larger than those for b.

Key Concept

Note that if a and b are both zero, the van der Waals equation of state reduces to the ideal gas law.

Mnemonic

a is the van der Waals term for the **a**ttractive forces.
b is the van der Waals term for ***b***ig particles.

MCAT Expertise

Be familiar with the concepts embodied by this equation but do not bother memorizing it; if the testmakers want you to apply the equation, it will be provided in a passage or question stem.

Example: By what percentage does the real pressure of 1 mole of ammonia in a 1 liter flask at 0°C deviate from its ideal pressure? (Note: R = 0.0821 $\frac{\text{L} \cdot \text{atm}}{\text{mol} \cdot \text{K}}$; for NH_3, $a = 4.2$, $b = 0.037$)

Solution: According to the ideal gas law,

$$P = \frac{nRT}{V} = \frac{(1\,\text{mol})\left(0.0821\,\frac{\text{L} \cdot \text{atm}}{\text{mol} \cdot \text{K}}\right)(273\,\text{K})}{1\,\text{L}} = 22.4\ \text{atm}$$

According to the van der Waals equation of state,

$$P = \frac{nRT}{V - nb} - \frac{n^2 a}{V^2} = \frac{(1\,\text{mol})\left(0.0821\,\frac{\text{L} \cdot \text{atm}}{\text{mol} \cdot \text{K}}\right)(273\,\text{K})}{1\,\text{L} - (1\,\text{mol})(0.037)} - \frac{(1\,\text{mol})^2(4.2)}{(1\,\text{L})^2}$$

$$P = \frac{22.4}{0.963} - 4.2 = 19.1\ \text{atm}$$

The pressure is thus 3.3 atm less than would be predicted from the ideal gas law, representing an error of $\frac{3.3\ \text{atm}}{22.4\ \text{atm}} \times 100\% = 15$ percent.

MCAT Concept Check 8.4:

Before you move on, assess your understanding of the material with these questions.

1. In what ways do real gases differ from ideal gases?

_____

_____

2. If the attractive forces between gas molecules were to increase while the actual volumes of the molecules remained negligible, what would occur?

_____

_____

3. If the volumes of gas molecules were to increase while the attractive forces between the molecules remained negligible, what would occur?

_____

_____

Conclusion

In this chapter, we reviewed the basic characteristics and behaviors of gases. The ideal gas law shows the mathematical relationship among four variables associated with gases: pressure, volume, temperature, and number of moles. We examined special cases of the ideal gas law in which temperature (Boyle's law), pressure (Charles's law), or volume (Gay-Lussac's law) is held constant. Henry's law helped explain the principles behind dissolution of gases in liquids and gas exchange in biological systems. We also examined Dalton's law, which relates the partial pressure of a gas to its mole fraction and the sum of the partial pressures of all the gases in a system to the total pressure of the system. The kinetic molecular theory of gases provided the explanation for the behaviors of ideal gases as described by the ideal gas law. Finally, we examined the ways in which real gases deviate from the predicted behaviors of ideal gases. The van der Waals equation of state is a useful equation for correcting deviations caused by molecular interactions and volumes.

From helium-filled balloons to the bubbles of carbon dioxide in a glass of soda, from the pressurized gases used for scuba diving to the air we breathe on land, gases are all around us. And yet, all the different gases that bubble, flow, and settle in and through our daily living experiences behave in remarkably similar ways. Human life is dependent on the exchange of two gases: oxygen and carbon dioxide—to that end, expect that the MCAT will frequently test gases because of their importance in our everyday lives.

CONCEPT SUMMARY

The Gas Phase

- Gases are the least dense phase of matter.
- Gases are fluids and therefore conform to the shapes of their containers.
- Gases are easily compressible.
- Gas systems are described by the variables **temperature** (***T***), **pressure** (***P***), **volume** (***V***), and **number of moles** (***n***).
- Important pressure equivalencies include 1 atm = 760 mmHg ≡ 760 torr = 101.325 kPa.
- A **simple mercury barometer** measures incident (usually atmospheric) pressure. As pressure increases, more mercury is forced into the column, increasing its height. As pressure decreases, mercury flows out of the column under its own weight, decreasing its height.

Ideal Gases

- **Standard temperature and pressure** (**STP**) is 273 K (0°C) and 1 atm.
- Equations for ideal gases assume negligible mass and volume of gas molecules.
- Regardless of the identity of the gas, equimolar amounts of two gases will occupy the same volume at the same temperature and pressure. At STP, one mole of an ideal gas occupies 22.4 L.
- The **ideal gas law** describes the relationship between the four variables of the gas state for an ideal gas.
- **Avogadro's principle** is a special case of the ideal gas law for which the pressure and temperature are held constant; it shows a direct relationship between the number of moles of gas and volume.
- **Boyle's law** is a special case of the ideal gas law for which temperature and number of moles are held constant; it shows an inverse relationship between pressure and volume.
- **Charles's law** is a special case of the ideal gas law for which pressure and number of moles are held constant; it shows a direct relationship between temperature and volume.
- **Gay-Lussac's law** is a special case of the ideal gas law for which volume and number of moles are held constant; it shows a direct relationship between temperature and pressure.
- The **combined gas law** is a combination of Boyle's, Charles's, and Gay-Lussac's laws; it shows an inverse relationship between pressure and volume along with direct relationships between pressure and volume with temperature.

- **Dalton's law of partial pressures** states that individual gas components of a mixture of gases will exert individual pressures in proportion to their **mole fractions**. The total pressure of a mixture of gases is equal to the sum of the partial pressures of the component gases.
- **Henry's law** states that the amount of gas dissolved in solution is directly proportional to the partial pressure of that gas at the surface of a solution.

Kinetic Molecular Theory

- The **kinetic molecular theory** attempts to explain the behavior of gas particles. It makes a number of assumptions about the gas particles:
  - Gas particles have negligible volume.
  - Gas particles do not have intermolecular attractions or repulsions.
  - Gas particles undergo random collisions with each other and the walls of the container.
  - Collisions between gas particles (and with the walls of the container) are elastic.
  - The average kinetic energy of the gas particles is directly proportional to temperature.
- **Graham's law** describes the behavior of gas diffusion or effusion, stating that gases with lower molar masses will diffuse or effuse faster than gases with higher molar masses at the same temperature.
  - **Diffusion** is the spreading out of particles from high to low concentration.
  - **Effusion** is the movement of gas from one compartment to another through a small opening under pressure.

Real Gases

- **Real gases** deviate from ideal behavior under high pressure (low volume) and low temperature conditions.
  - At moderately high pressures, low volumes, or low temperatures, real gases will occupy less volume than predicted by the ideal gas law because the particles have intermolecular attractions.
  - At extremely high pressures, low volumes, or low temperatures, real gases will occupy more volume than predicted by the ideal gas law because the particles occupy physical space.
  - The **van der Waals equation of state** is used to correct the ideal gas law for intermolecular attractions (a) and molecular volume (b).

ANSWERS TO CONCEPT CHECKS

8.1

1. Gases are compressible fluids with rapid molecular motion, large intermolecular distances, and weak intermolecular forces.
2. At the top of the mountain, atmospheric pressure is lower, causing the column to fall. Under water, hydrostatic pressure is exerted on the barometer in addition to atmospheric pressure, causing the column to rise.
3. STP: $T = 273$ K (0°C), $P = 1$ atm
4. Standard conditions: $T = 298$ K (25°C), $P = 1$ atm, concentrations = 1 M

8.2

1. $PV = nRT \rightarrow T = \frac{PV}{nR} = \frac{(6\text{ atm})(12\text{ L})}{(4\text{ mol})\left(0.0821\frac{\text{L}\bullet\text{atm}}{\text{mol}\bullet\text{K}}\right)} \approx 225\text{ K}$ (actual = 219 K)

2. $\rho = \frac{m}{V} = \frac{PM}{RT} = \frac{(4\text{ atm})\left(39.9\frac{\text{g}}{\text{mol}}\right)}{\left(0.0821\frac{\text{L}\bullet\text{atm}}{\text{mol}\bullet\text{K}}\right)(409.5\text{ K})} \approx 5\frac{\text{g}}{\text{L}}$ (actual = 4.7 $\frac{\text{g}}{\text{L}}$)

3. $\frac{n_1}{V_1} = \frac{n_2}{V_2} \rightarrow V_2 = \frac{n_2 \times V_1}{n_1} = \frac{(2+3\text{ mol})(20\text{ L})}{2\text{ mol}} = 50\text{ L}$

4. $P_1V_1 = P_2V_2 \rightarrow V_2 = \frac{P_1V_1}{P_2} = \frac{(1\text{ atm})(2\text{ L})}{40\text{ atm}} = 0.05\text{ L}$

5. $\frac{V_1}{T_1} = \frac{V_2}{T_2} \rightarrow V_2 = \frac{V_1 \times T_2}{T_1} = \frac{(7.5\text{ L})(409.5\text{ K})}{136.5\text{ K}} = 22.5\text{ L}$

6. $\frac{P_1}{T_1} = \frac{P_2}{T_2} \rightarrow T_2 = \frac{P_2 \times T_1}{P_1} = \frac{(2\text{ atm})(546\text{ K})}{5\text{ atm}} = 218.4\text{ K}$

7. There are twelve total moles of gas, so the mole fractions of each gas are: $X_{O_2} = \frac{8\text{ mol }O_2}{12\text{ mol}} = 0.67$; $X_{CH_4} = \frac{3\text{ mol }CH_4}{12\text{ mol}} = 0.25$; $X_{CO_2} = \frac{1\text{ mol }CO_2}{12\text{ mol}} = 0.083$
   Then multiply each mole fraction by the total pressure to get the partial pressures:
   $P_{O_2} = 0.67(240\text{ atm}) = 160\text{ atm}$; $P_{CH_4} = 0.25(240\text{ atm}) = 60\text{ atm}$;
   $P_{CO_2} = 0.083(240\text{ atm}) = 20\text{ atm}$
8. High pressures of carbon dioxide gas are forced on top of the liquid in sodas, increasing its concentration in the liquid.

8.3

1. Assumptions in the kinetic molecular theory include: negligible volume of gas particles, no intermolecular forces, random motion, elastic collisions, and proportionality between absolute temperature and energy.

2. $u_{rms} = \sqrt{\frac{3RT}{M}} = \sqrt{\frac{3\left(8.314 \frac{J}{mol \bullet K}\right)(100\ K)}{0.004 \frac{kg}{mol}}} = 790 \frac{m}{s}$

3. $\frac{r_1}{r_2} = \sqrt{\frac{M_2}{M_1}} \rightarrow r_2 = r_1\sqrt{\frac{M_1}{M_2}} = 400 \frac{m}{s}\sqrt{\frac{20.2 \frac{g}{mol}}{83.8 \frac{g}{mol}}} \approx 400 \times \frac{1}{2} = 200 \frac{m}{s}$

$\left(\text{actual} = 196.4 \frac{m}{s}\right)$

4. The rotten egg odor (hydrogen sulfide) first, almond (benzaldehyde) next, and wintergreen (methyl salicylate) last. Because all of the gases have the same temperature, they have the same kinetic energy; thus, the lightest molecules travel the fastest.

8.4

1. Real gas molecules have nonnegligible volume and attractive forces. Real gases deviate from ideal gases at high pressure (low volume) and low temperature.
2. According to the van der Waals equation, if a is increased while b remains negligible, the correction term $\left(\frac{n^2a}{V^2}\right)$ gets larger, and the pressure or volume must drop to compensate.
3. Increasing the volume of gas molecules while keeping attraction negligible makes the term $V - nb$ smaller; thus, the pressure or volume must rise to compensate.

EQUATIONS TO REMEMBER

(8.1) **Ideal gas law:** $PV = n\mathrm{R}T$

(8.2) **Density of a gas:** $\rho = \frac{m}{V} = \frac{PM}{\mathrm{R}T}$

(8.3) **Combined gas law:** $\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$

(8.4) **Avogadro's principle:** $\frac{n}{V} = k$ or $\frac{n_1}{V_1} = \frac{n_2}{V_2}$

(8.5) **Boyle's law:** $PV = k$ or $P_1V_1 = P_2V_2$

(8.6) **Charles's law:** $\frac{V}{T} = k$ or $\frac{V_1}{T_1} = \frac{V_2}{T_2}$

(8.7) **Gay-Lussac's law:** $\frac{P}{T} = k$ or $\frac{P_1}{T_1} = \frac{P_2}{T_2}$

(8.8) **Dalton's law (total pressure from partial pressures):** $P_\mathrm{T} = P_\mathrm{A} + P_\mathrm{B} + P_\mathrm{C} + \ldots$

(8.9) **Dalton's law (partial pressure from total pressure):** $P_\mathrm{A} = X_\mathrm{A}P_\mathrm{T}$

(8.10) **Henry's law:** $[\mathrm{A}] = k_\mathrm{H} \times P_\mathrm{A}$ or $\frac{[\mathrm{A}]_1}{P_1} = \frac{[\mathrm{A}]_2}{P_2} = k_\mathrm{H}$

(8.11) **Average kinetic energy of a gas:** $KE = \frac{1}{2}mv^2 = \frac{3}{2}k_\mathrm{B}T$

(8.12) **Root-mean-square speed:** $u_\mathrm{rms} = \sqrt{\frac{3\mathrm{R}T}{M}}$

(8.13) **Graham's law:** $\frac{r_1}{r_2} = \sqrt{\frac{M_2}{M_1}}$

(8.14) **Van der Waals equation of state:** $\left(P + \frac{n^2a}{V^2}\right)(V - nb) = n\mathrm{R}T$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following sets of conditions would be LEAST likely to result in ideal gas behavior?

A. High pressure and low temperature
B. Low temperature and large volume
C. High pressure and large volume
D. Low pressure and high temperature

2. What is the density of neon gas in $\frac{g}{L}$ at STP?

A. 452.3
B. 226.0
C. 1.802
D. 0.9018

3. A leak of helium gas through a small hole occurs at a rate of 3.22×10^{-5} $\frac{mol}{s}$. How will the leakage rates of neon and oxygen gases compare to helium at the same temperature and pressure?

A. Neon will leak faster than helium; oxygen will leak faster than helium.
B. Neon will leak faster than helium; oxygen will leak slower than helium.
C. Neon will leak slower than helium; oxygen will leak faster than helium.
D. Neon will leak slower than helium; oxygen will leak slower than helium.

4. A 0.040 g piece of magnesium is placed in a beaker of hydrochloric acid. Hydrogen gas is generated according to the following equation:

$$Mg\,(s) + 2\,HCl\,(aq) \rightarrow MgCl_2\,(aq) + H_2\,(g)$$

The gas is collected over water at 25°C, and the gauge pressure during the experiment reads 784 mmHg. The gas displaces a volume of 100 mL. The vapor pressure of water at 25°C is approximately 24.0 mmHg. Based on this data, how many moles of hydrogen are produced in this reaction? (Note: $R = 0.0821 \frac{L \cdot atm}{mol \cdot K} = 8.314 \frac{J}{K \cdot mol}$.)

A. 4.04×10^{-5} moles hydrogen
B. 4.09×10^{-3} moles hydrogen
C. 3.07×10^{-2} moles hydrogen
D. 3.11 moles hydrogen

5. Ideal gases:

I. have no volume.
II. have particles with no attractive forces between them.
III. have no mass.

A. I only
B. II only
C. I and II only
D. I, II, and III

6. An 8.00 g sample of $NH_4NO_3\,(s)$ is placed into an evacuated 10 L flask and heated to 227°C. After the NH_4NO_3 completely decomposes, what is the approximate pressure in the flask?

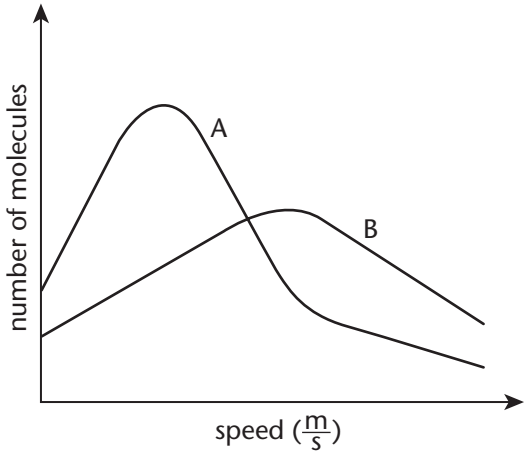
$$NH_4NO_3\,(s) \rightarrow N_2O\,(g) + H_2O\,(g)$$

A. 0.410 atm
B. 0.600 atm
C. 0.821 atm
D. 1.23 atm

7. The kinetic molecular theory states that:

A. the average kinetic energy of a molecule of gas is directly proportional to the temperature of the gas in kelvins.
B. collisions between gas molecules are inelastic.
C. gas particles occupy discrete areas of space.
D. all gas molecules have the same kinetic energy at the same temperature.

8. The plots of two gases at STP are shown below. One of the gases is 1.0 L of helium, and the other is 1.0 L of bromine. Which plot corresponds to each gas and why?



A. Curve A is helium and curve B is bromine because helium has a smaller molar mass than bromine.
B. Curve A is helium and curve B is bromine because the average kinetic energy of bromine is greater than the average kinetic energy of helium.
C. Curve A is bromine and curve B is helium because helium has a smaller molar mass than bromine.
D. Curve A is bromine and curve B is helium because the average kinetic energy of bromine is greater than the average kinetic energy of helium.

9. A balloon at standard temperature and pressure contains 0.20 moles of oxygen and 0.60 moles of nitrogen. What is the partial pressure of oxygen in the balloon?

A. 0.20 atm
B. 0.25 atm
C. 0.33 atm
D. 0.80 atm

10. Given that the gases at the center of the sun have an average molar mass of 2.00 $\frac{g}{mol}$, compressed to a density of 1.20 $\frac{g}{cm^3}$ under 1.30×10^9 atm of pressure, what is the temperature at the center of the sun?

A. 2.6×10^4 K
B. 2.6×10^6 K
C. 2.6×10^7 K
D. 2.6×10^{10} K

11. The gaseous state of matter is characterized by which of the following properties?

I. Gases are compressible.
II. Gases assume the volume of their containers.
III. Gas particles exist as diatomic molecules.

A. I only
B. I and II only
C. II and III only
D. I, II, and III

12. A gas at a temperature of 27°C has a volume of 60.0 mL. What temperature change is needed to increase this gas to a volume of 90.0 mL?

A. A reduction of 150°C
B. An increase of 150°C
C. A reduction of 13.5°C
D. An increase of 13.5°C

13. A gaseous mixture contains nitrogen and helium and has a total pressure of 150 torr. The nitrogen particles comprise 80 percent of the gas, and the helium particles make up the other 20 percent of the gas. What is the pressure exerted by each individual gas?

A. 100 torr nitrogen, 50.0 torr helium
B. 120 torr nitrogen, 30.0 torr helium
C. 30.0 torr nitrogen, 120 torr helium
D. 50.0 torr nitrogen, 100 torr helium

14. In which of the following situations is it impossible to predict how the pressure will change for a gas sample?

A. The gas is cooled at a constant volume.
B. The gas is heated at a constant volume.
C. The gas is heated, and the volume is simultaneously increased.
D. The gas is cooled, and the volume is simultaneously increased.

15. Experimenters notice that the molar concentration of dissolved oxygen in an enclosed water tank has decreased to one-half its original value. In an attempt to counter this decrease, they quadruple the partial pressure of oxygen in the container. What is the final concentration of the gas?

A. Half of the original concentration
B. The same as the original concentration
C. Double the original concentration
D. Quadruple the original concentration

Explanations to Discrete Practice Questions

1. A

Gases deviate from ideal behavior at higher pressures and lower volumes and temperatures, all of which force molecules closer together. The closer they are, the more they can participate in intermolecular forces, which violates the definition of an ideal gas. At extremely high pressures, low volumes, and low temperatures, the size of the gas particles becomes significant, which also violates the definition of an ideal gas.

2. D

Density equals mass divided by volume. The mass of 1 mole of neon gas equals 20.2 grams. At STP, 1 mole of neon occupies 22.4 L. Dividing the mass, 20.2 grams, by the volume, 22.4 L, gives an approximate density of 0.902 $\frac{g}{L}$.

3. D

Graham's law of effusion states that the relative rates of effusion of two gases at the same temperature and pressure are given by the inverse ratio of the square roots of the masses of the gas particles. In other words, a gas with a higher molar mass will leak more slowly than a gas with a lower molar mass. Both neon and oxygen gases will leak at slower rates than helium because they both have more mass more than helium.

4. B

The pressure of the gas is calculated by subtracting the vapor pressure of water from the measured pressure during the experiment: 784 mmHg – 24 mmHg = 760 mmHg, or 1 atm. This is because the reaction is carried out in an aqueous environment; the water present will contribute to the partial pressures of the gas over the liquid. The ideal gas law can be used to calculate the moles of hydrogen gas. The volume of the gas is 0.100 L, the temperature is 298 K, and $R = 0.0821 \frac{L \cdot atm}{mol \cdot K}$. Plugging in, we get:

$$n = \frac{PV}{RT} = \frac{(1\text{ atm})(0.1\text{ L})}{(0.0821 \frac{L \cdot atm}{mol \cdot K})(298\text{ K})} \approx \frac{1}{0.8 \times 300}$$

$$= \frac{1}{240} \approx 0.004$$

Choice (A) incorrectly substitutes 8.314 into the gas law, rather than 0.0821. Remember that the value of R depends on the other variables in the equation; using 1 atm in the numerator necessitates using 0.0821. **Choice (C)** incorrectly substitutes the wrong R and keeps the pressure in mmHg. **Choice (D)** also keeps the pressure in mmHg.

5. B

Ideal gases are said to have no attractive forces between molecules. While each particle within the gas is considered to have negligible volume, ideal gases as a whole certainly do have a measurable volume, thus option I is eliminated. Gases have molar masses, thus option III is eliminated.

6. D

The first thing to do is balance the given chemical equation: $NH_4NO_3(s) \rightarrow N_2O(g) + 2\,H_2O(g)$. The mass given is 8.00 g, which represents 0.1 mol NH_4NO_3 (molar mass = 80.0 $\frac{g}{mol}$). When 0.1 mol of the solid decomposes, it will form 0.1 mol N_2O and 0.2 mol water. This gives approximately 0.3 moles of gas product. The ideal gas equation can be used to obtain the pressure in the flask:

$$P = \frac{nRT}{V} = \frac{(0.3\text{ mol})\left(0.0821 \frac{L \cdot atm}{mol \cdot K}\right)(500\text{ K})}{(10\text{ L})} \approx 15 \times 0.08$$

$$= 1.2\text{ atm}$$

Choice (C) is the result if one assumes the equation is balanced, obtaining 0.2 mol gas as the product.

7. A

The average kinetic energy is directly proportional to the temperature of a gas in kelvins. The kinetic molecular theory states that collisions between molecules are elastic and thus do not result in a loss of energy, eliminating **choice (B)**. Gas particles are assumed to take up negligible space in kinetic molecular theory, eliminating **choice (C)**. While the average kinetic energy of any gas as a whole is the same at a given temperature, the particles themselves have a distribution of speeds (as seen in the Maxwell–Boltzmann distribution curve), eliminating **choice (D)**.

8. C

At STP, the difference between the distribution of speeds for helium and bromine gas is due to the difference in molar mass. Helium has a smaller molar mass than bromine. Particles with small masses travel faster than those with large masses, so the helium gas corresponds to curve B, which has a higher average speed. Because the gases are at the same temperature (273 K), they have the same average kinetic energy, eliminating **choices (B)** and **(D)**.

9. B

At STP, the pressure inside the balloon equals 1 atm. The total number of moles in the balloon equals 0.20 moles plus 0.60 moles, or 0.80 moles. P_{O_2} equals the mole fraction of oxygen ($\frac{0.20}{0.80}$) times the total pressure, 1 atm. The partial pressure of oxygen is therefore 0.25 atm.

10. C

The ideal gas law can be modified to include density (ρ) because the number of moles of gas, n, is equal to the mass divided by the molar mass. Thus, $PV = n\mathrm{R}T = \frac{m}{M}\mathrm{R}T \rightarrow P = \frac{m}{V} \times \frac{\mathrm{R}T}{M} = \frac{\rho \mathrm{R}T}{M}$. Isolating for temperature, we get:

$$T = \frac{PM}{\rho \mathrm{R}}$$

$$T = \frac{(1.3 \times 10^9 \text{ atm})\left(2.00 \frac{\text{g}}{\text{mol}}\right)}{\left(1.2 \frac{\text{g}}{\text{cm}^3}\right)\left(1000 \frac{\text{cm}^3}{\text{L}}\right)\left(0.0821 \frac{\text{L} \bullet \text{atm}}{\text{mol} \bullet \text{K}}\right)} \approx \frac{2.6 \times 10^9}{100}$$

$$= 2.6 \times 10^7 \text{ K}.$$

11. B

Gases are easily compressible because they travel freely with large amounts of space between molecules. Because gas particles are far apart from each other and in rapid motion, they tend to take up the volume of their container. Many gases exist as diatomic molecules, but this is not a property that characterizes all gases, eliminating option III.

12. B

We will use Charles's law. First, we must convert the temperature to kelvins by adding 273 to get 300 K as the initial temperature. Think of this as a proportionality: If the volume is multiplied by $\frac{3}{2}$, the temperature will also have to be multiplied by $\frac{3}{2}$. Thus the final temperature is 450 K, which represents a 150 K increase.

13. B

The partial pressure of each gas is found by multiplying the total pressure by the mole fraction of the gas. Because 80 percent of the molecules are nitrogen, the mole fraction of nitrogen gas is equal to 0.80. Similarly, for helium, the mole fraction is 0.20. To find the pressure exerted by nitrogen, multiply the total pressure (150 torr) by 0.80 to obtain 120 torr of nitrogen. The remainder, 30 torr, is attributable to helium.

14. C

Both a change in temperature and a change in volume can affect a gas's pressure. So if one of those two variables is kept constant, as in **choices (A)** and **(B)**, we'll definitely be able to predict which way the pressure will change. At a constant volume, heating the gas will increase its pressure, and cooling the gas will decrease it. What about when both temperature and volume are changing? If both changes have the same effect on pressure, then we can still predict which way it will change. This is the case in **choice (D)**. Cooling the gas and increasing its volume both decrease pressure. **Choice (C)**, on the other hand, presents too vague a scenario for us to predict definitively the change in pressure. Heating the gas would amplify the pressure,

while increasing the volume would decrease it. Without knowing the magnitude of each influence, it's impossible to say whether the pressure would increase, decrease, or stay the same.

15. C

Initially the concentration of the gas is decreased to one-half its original value. Recall that concentration (solubility) and partial pressure are directly related—as one increases, the other increases. If the experimenters then quadruple the partial pressure of oxygen in the vessel, the solubility is also increased by a factor of four. One-half times four gives twice the original concentration value. Misreading the answer choices as being related to the concentration before the experimenters increased the partial pressure leads to **choice (D)**.

Concept Summary 315

Introduction

What do first aid instant cold packs and sweet tea have in common? Not much—you might think—but both, in fact, demonstrate the same principles of solution chemistry. Instant cold packs contain two compartments, one holding water and the other ammonium nitrate. When the barrier between the two compartments is broken, it allows the ammonium nitrate to dissolve into the water. Sweet tea is made by dissolving a large amount of sugar into strongly brewed tea.

The creation of both the ammonium nitrate and sugar solutions is an endothermic process. However, the formation of the ammonium nitrate solution is much more endothermic than the formation of the sugar solution. This is why ammonium nitrate is useful in instant cold packs. When it dissolves in water, the system must absorb an amount of energy equal to 6.14 $\frac{\text{kcal}}{\text{mol}}$ of ammonium nitrate. The heat is absorbed from the surrounding environment, so the pack feels cool to the touch.

Although the dissolution of sugar into water is not as strongly endothermic, we nevertheless have an intuitive understanding of the process's endothermicity because we all know that the easiest way to dissolve lots of sugar into water (such as in tea or coffee) is to heat up the water and then add the sugar. Because heating the water increases the solubility of sugar, it must be that the dissolution of sugar into water is an endothermic process—think of Le Châtelier's principle and changes in temperature from Chapter 6 of *MCAT General Chemistry Review*.

In this chapter, our focus will be on the characteristics and behaviors of solutions, examining the nature of solutions, the formation of aqueous solutions, measurements of solution concentration, and finally, the qualitative and quantitative evaluation of solution equilibria.

9.1 Nature of Solutions

Many important chemical reactions, both in the laboratory and in nature, take place in solutions, including almost all reactions in living organisms. **Solutions** are homogeneous (the same throughout) mixtures of two or more substances that combine to form a single phase, usually the liquid phase. The MCAT will focus almost exclusively on solids dissolved into aqueous solutions, but it's important to remember that solutions can be formed from different combinations of the three phases of matter. For example, gases can be dissolved in liquids (carbonating soda); liquids can be dissolved in other liquids (ethanol in water); solids can even be dissolved in other solids (metal alloys). Incidentally, gases "dissolved" into other gases can be thought of as solutions, but are more properly defined only as **mixtures** because gas molecules do not interact all that much chemically, as described by the kinetic molecular theory of gases. As a point of clarification: all solutions are considered mixtures, but not all mixtures are considered solutions.

A solution consists of a **solute** (such as NaCl, NH_3, $C_6H_{12}O_6$, or CO_2) dissolved (dispersed) in a solvent (such as H_2O, benzene, or ethanol). The **solvent** is the component of the solution that remains in the same phase after mixing. If the two substances are already in the same phase (for example, a solution of two liquids), the solvent is the component present in greater quantity. If the two same-phase components are in equal proportions in the solution, then the component that is more commonly used as a solvent in other contexts is considered the solvent. Solute molecules move about freely in the solvent and interact with it by way of intermolecular forces such as ion–dipole, dipole–dipole, or hydrogen bonding. Dissolved solute molecules are also relatively free to interact with other dissolved molecules of different chemical identities; consequently, chemical reactions occur easily in solution.

SOLVATION

Solvation is the electrostatic interaction between solute and solvent molecules. This is also known as **dissolution**, and when water is the solvent, it can be called **hydration**. Solvation involves breaking intermolecular interactions between solute molecules and between solvent molecules and forming new intermolecular interactions between solute and solvent molecules together, as shown in Figure 9.1 (which was also shown in Chapter 4 of *MCAT General Chemistry Review* in the context of ions).

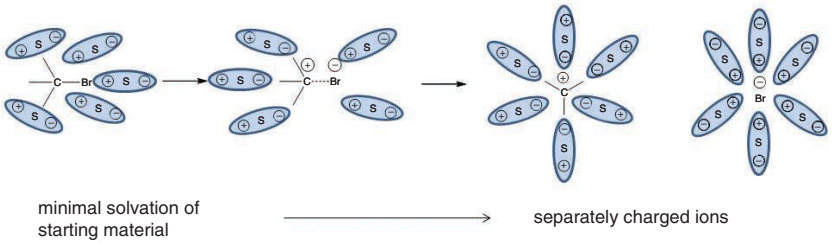

Figure 9.1. Solvation of a Polar Covalent Compound
S indicates a solvent particle.

When the new interactions are stronger than the original ones, solvation is exothermic, and the process is favored at low temperatures. The dissolution of gases into liquids, such as CO_2 into water, is an exothermic process because the only significant interactions that must be broken are those between water molecules—CO_2, as a gas, demonstrates minimal intermolecular interaction. Le Châtelier's principle tells us this is the reason that lowering the temperature of a liquid favors solubility of a gas in the liquid.

When the new interactions are weaker than the original ones, solvation is endothermic and the process is favored at high temperatures. Most dissolutions are of this type. Two such examples have already been given: dissolving ammonium nitrate or sugar into water. Because the new interactions between the solute and solvent are weaker than the original interactions between the solute molecules and between the solvent molecules, energy (heat) must be supplied to facilitate the formation of these weaker, less stable interactions. Sometimes the overall strength of the new interactions is approximately equal to the overall strength of the original interactions. In this case, the overall enthalpy change for the dissolution is close to zero. These types of solutions approximate the formation of an **ideal solution**, for which the enthalpy of dissolution is equal to zero.

The spontaneity of dissolution is dependent not only on the enthalpy change; solutions may form spontaneously for both endothermic and exothermic dissolutions. The second property that contributes to the spontaneity of dissolution is the entropy change that occurs in the process. At constant temperature and pressure, entropy always increases upon dissolution. As with any process, the spontaneity of dissolution depends on the change in Gibbs free energy: spontaneous processes are associated with a decrease in free energy, while nonspontaneous processes are associated with an increase in free energy. Thus, whether or not dissolution will happen spontaneously depends on both the change in enthalpy and the change in entropy for the solute and solvent of the system.

Consider, for example, the formation of another common solution: sodium chloride dissolved in water. When NaCl dissolves in water, its component ions

Bridge

Proteins dissolve in solution with their most hydrophilic amino acids on the outside and hydrophobic amino acids on the inside because this maximizes the increase in entropy during dissolution. As described in Chapter 1 of *MCAT Biochemistry Review*, a protein dissolves by forming a solvation layer.

dissociate from each other and become surrounded by water molecules. For this new interaction to occur, ionic bonds between Na^+ and Cl^- must be broken, and hydrogen bonds between water molecules must also be broken. This step requires energy and is therefore endothermic. Because water is polar, it can interact with each of the component ions through ion–dipole interactions: the partially positive hydrogen end of the water molecules will surround the Cl^- ions, and the partially negative oxygen end of the water molecules will surround the Na^+ ions, as shown in Figure 9.2. The formation of these ion–dipole bonds is exothermic, but the magnitude is slightly less than the energy required to break the ionic bonds and hydrogen bonds. As a result, the overall dissolution of table salt into water is endothermic (+3.87 $\frac{kJ}{mol}$) and favored at high temperatures.

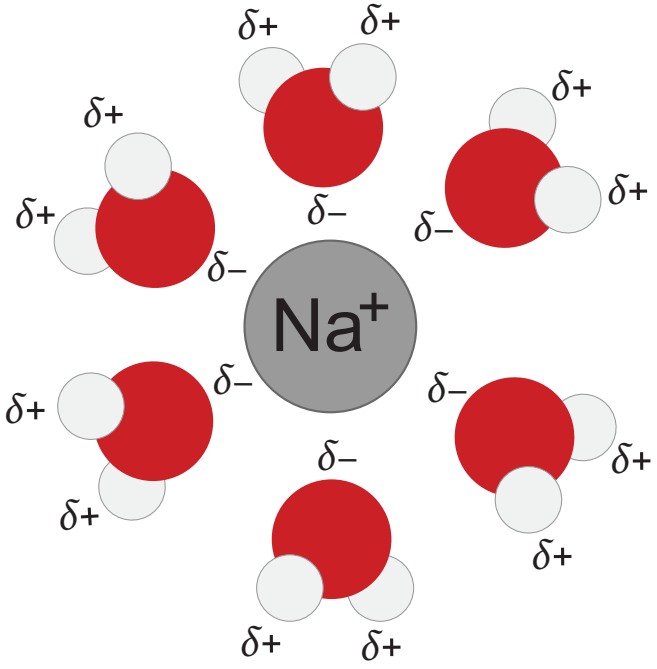

Figure 9.2. Solvation of Na^+ Ions in Aqueous Solutions

We've considered the enthalpy change for the formation of a sodium chloride solution, and now we need to examine the entropy change. Remember that entropy can be thought of as the degree to which energy is dispersed throughout a system or the amount of energy distributed from the system to the surroundings at a given temperature. Another way to understand entropy is the measure of molecular disorder, or the number of energy **microstates** available to a system at a given temperature. When solid sodium chloride dissolves into water, the rigidly ordered arrangement of the sodium and chloride ions is broken up as the ion–ion interactions are disrupted and new ion–dipole interactions with the water molecules are formed. The ions, freed from their lattice arrangement, have a greater number of energy microstates available to them (in simpler terms, they are freer to move around in different ways), and consequently,

their energy is more distributed and their entropy increases. The water, however, becomes more restricted in its movement because it is now interacting with the ions. The number of energy microstates available to it (that is, the water molecules' ability to move around in different ways) is reduced, so the entropy of the water decreases. In the end, the increase in the entropy experienced by the dissolved sodium chloride is greater than the decrease in the entropy experienced by the water, so the overall entropy change is positive—energy is, overall, dispersed by the dissolution of sodium chloride in water. Because of the relatively low endothermicity and relatively large positive change in entropy, sodium chloride will spontaneously dissolve in liquid water ($\Delta G = \Delta H - T\Delta S$).

SOLUBILITY

We often want to know more than just whether or not dissolution of a solute into a solvent will be spontaneous or nonspontaneous—we also want to know how much solute will dissolve into a given solvent. The **solubility** of a substance is the maximum amount of that substance that can be dissolved in a particular solvent at a given temperature. When this maximum amount of solute has been added, the dissolved solute is in equilibrium with its undissolved state, and we say that the solution is **saturated**. If more solute is added, it will not dissolve. For example, at 25°C, a maximum of 90.9 g glucose will dissolve in 100 mL H_2O. Thus, the solubility of glucose is 909 $\frac{g}{L}$. If more glucose is added to an already saturated glucose solution, it will not dissolve but rather will remain in solid form, **precipitating** to the bottom of the container. A solution in which the proportion of solute to solvent is small is said to be **dilute**, and one in which the proportion is large is said to be **concentrated**. Note that both dilute and concentrated solutions are still considered unsaturated if the maximum equilibrium concentration (saturation) has not yet been reached.

The solubility of substances in different solvents is ultimately a function of thermodynamics. When the change in Gibbs free energy for the dissolution reaction is negative at a given temperature, the process will be spontaneous, and the solute is said to be soluble. When the change in Gibbs free energy is positive, the process will be nonspontaneous, and the solute is said to be insoluble. Some solute–solvent systems have negative changes in free energy with very large magnitudes, so the equilibrium reaction strongly favors the dissolution of the solute. In general, solutes are considered soluble if they have a molar solubility above 0.1 *M* in solution. Others have only slightly negative changes in free energy, so the equilibrium position lies closer to the undissociated (reactants) side of the reaction. Those solutes that dissolve minimally in the solvent (molar solubility under 0.1 *M*) are called **sparingly soluble salts**.

AQUEOUS SOLUTIONS

The most common type of solution is the **aqueous solution**, in which the solvent is water. The aqueous state is denoted by the symbol (*aq*). Aqueous solutions rely on the interactions between water molecules and solutes in solutions. We have mentioned previously that hydration is often the process through which dissolution occurs. It is also important to note that in some solutions, such as acids, the formation of a complex called the **hydronium ion** ($\mathbf{H_3O^+}$) can occur. This is facilitated by the transfer of a hydrogen ion (H^+) from a molecule in solution to a water molecule (H_2O). The reaction of acetic acid (H^+ donor) with water is shown in Figure 9.3.

$$CH_3COOH\ (aq) + H_2O\ (l) \rightleftharpoons CH_3COO^-\ (aq) + H_3O^+\ (aq)$$

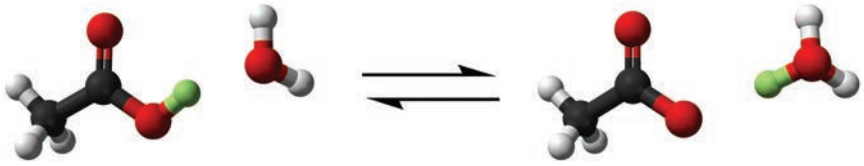

Figure 9.3. Transfer of a Proton in Solution, Forming the Hydronium Ion
The transferred proton is highlighted in green.

It is important to realize that H^+ is never found alone in solution because a free proton is difficult to isolate; rather, it is found bonded to an electron pair donor (carrier) molecule such as a water molecule. This is an example of a coordinate covalent bond. The hydronium ion and its effects on the solubilities of other compounds using Le Châtelier's principle will be described further in Chapter 10 of *MCAT General Chemistry Review*.

Because aqueous solutions are so common and so important to biological systems, the MCAT focuses on them above all others. In aqueous solutions, there are seven general solubility rules:

1. All salts containing ammonium (NH_4^+) and alkali metal (Group 1) cations are water-soluble.
2. All salts containing nitrate (NO_3^-) and acetate (CH_3COO^-) anions are water-soluble.
3. Halides (Cl^-, Br^-, I^-), excluding fluorides, are water-soluble, with the exceptions of those formed with Ag^+, Pb^{2+}, and Hg_2^{2+}.
4. All salts of the sulfate ion (SO_4^{2-}) are water-soluble, with the exceptions of those formed with Ca^{2+}, Sr^{2+}, Ba^{2+}, and Pb^{2+}.
5. All metal oxides are insoluble, with the exception of those formed with the alkali metals, ammonium, and CaO, SrO, and BaO, all of which hydrolyze to form solutions of the corresponding metal hydroxides.

MCAT Expertise

Because most solutions in the real world involve water as the solvent, it is not a surprise that they are common on the MCAT. These solubility rules are not bad to know, but memorizing them all may be a little excessive. It is never a bad thing to know facts, but being able to apply them is more important. Know rules 1 and 2 for sure, and be aware of some of the more common insoluble exceptions, like Pb^{2+} and Ag^+.

6. All hydroxides are insoluble, with the exception of those formed with the alkali metals, ammonium, and Ca^{2+}, Sr^{2+}, and Ba^{2+}.
7. All carbonates (CO_3^{2-}), phosphates (PO_4^{3-}), sulfides (S^{2-}), and sulfites (SO_3^{2-}) are insoluble, with the exception of those formed with the alkali metals and ammonium.

The MCAT will not expect memorization of all of the solubility rules, but it is worth knowing two absolutes: all salts of Group 1 metals, and all nitrate salts are soluble. Otherwise, familiarity with rules listed above will suffice—the MCAT generally supplies solubility information for most compounds. Sodium and nitrate ions are generally used as counterions to what is actually chemically important; for example, if a pH problem gives a sodium formate concentration of 0.10 *M*, it is *really* indicating that the concentration of the formate ion is 0.10 *M* because the sodium ion concentration does not affect pH. The only time one needs to worry about the nitrate ion concentration is in an oxidation–reduction reaction, for the nitrate ion can function—although only weakly—as an oxidizing agent. In all other cases with nitrate ions, only focus on the cation as the chemically reacting species.

COMPLEX ION FORMATION

We have mentioned the hydronium ion as a complex that forms in acidic solutions, but it is worthwhile to mention that there are even more varied forms of complex ions that can appear in solution. By definition, a **complex ion**—or **coordination compound**—refers to a molecule in which a cation is bonded to at least one electron pair donor (which could include the water molecule). The electron pair donor molecules are called **ligands**. An example of such a **complexation reaction** is shown for the *tetraaquadioxouranyl* cation, which has water (*aqua–*) and oxygen (*oxo–*) ligands, in Figure 9.4.

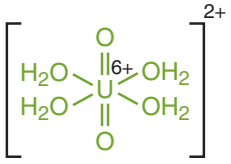

Figure 9.4. Structure of the Tetraaquadioxouranyl Complex Cation
Water and oxygen act as ligands with a U^{6+} cation.

Complexes are held together with **coordinate covalent bonds**, in which an electron pair donor (a Lewis base) and an electron pair acceptor (a Lewis acid) form very stable Lewis acid–base adducts. Most general chemistry courses do not stress the biological importance of coordination compounds. However, complex ions have profound biological applications in macromolecules such as proteins. For instance, many active sites of proteins utilize complex ion binding and transition metal complexes to carry out their function. One classic example is the iron cation

in hemoglobin, which can carry oxygen, carbon dioxide, and carbon monoxide as ligands, as shown in Figure 9.5.

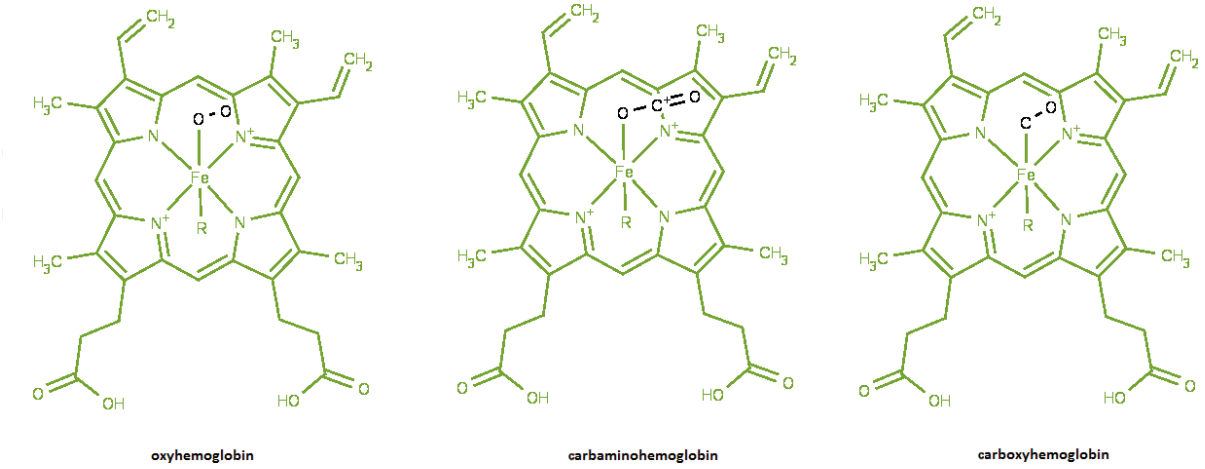

Figure 9.5. Hemoglobin Is a Classic Example of Biochemical Complex Formation
The iron in hemoglobin can bind various gases, leading to the formation of oxyhemoglobin (O_2), carbaminohemoglobin (CO_2), and carboxyhemoglobin (CO).

Many coenzymes (vitamins) and cofactors also contain complexes of transition metals, such as cobalamin (vitamin B_{12}), shown in Figure 9.6. The presence of a transition metal allows coenzymes and cofactors to bind other ligands or assist with electron transfer.

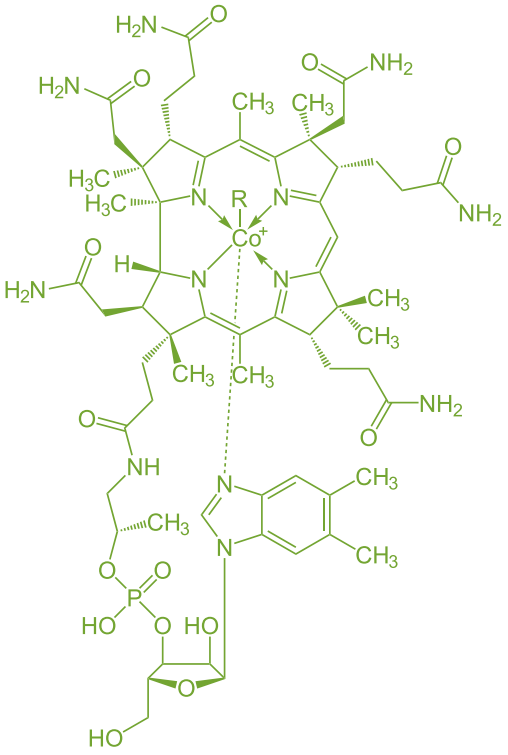

Figure 9.6. Cobalamin (Vitamin B_{12}) Contains a Cobalt Complex

Physical and chemical properties of complex ions are diverse, including a wide range of solubilities and varied chemical reactions. Inorganic complex ions are often fun to characterize because they tend to have vibrant, distinctive colors, as shown in Figure 9.7.

Figure 9.7. Nickel(II) Ion Complexes with Distinctive Colors
From left to right: hexaamminenickel(II), tris(ethylenediamine)nickel(II), tetrachloronickelate(II), and hexaaquanickel(II)

In some complexes, the central cation can be bonded to the same ligand in multiple places. This is called **chelation**, and it generally requires large organic ligands that can double back to form a second (or even third) bond with the central cation. Chelation therapy is often used to sequester toxic metals (lead, arsenic, mercury, and so on). Even biologically necessary metals, such as iron, can be toxic in overload states; an example of iron being chelated is shown in Figure 9.8.

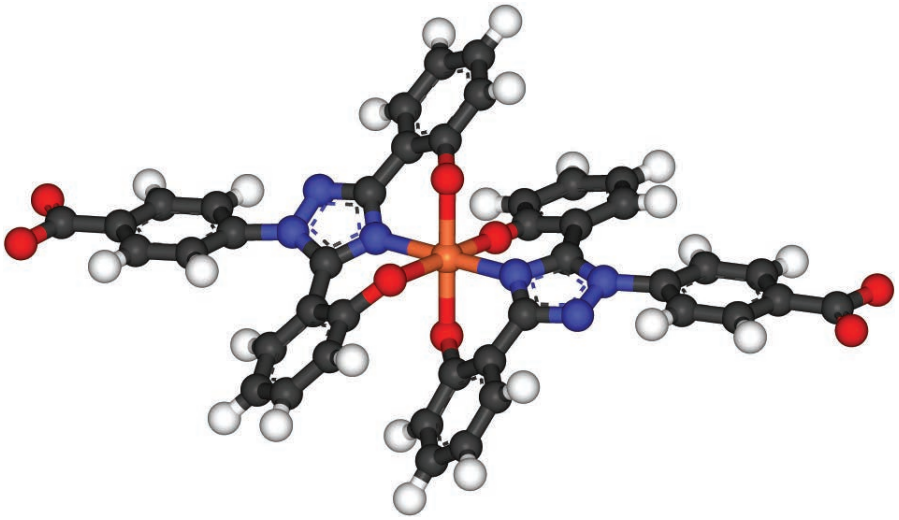

Figure 9.8. Chelation of Iron with Two Molecules of Deferasirox

MCAT Concept Check 9.1:
Before you move on, assess your understanding of the material with these questions.

1. Describe the process of solvation.

_____

_____

2. Describe the differences between solubility and saturation:
   - _____
   - _____

3. What is one way in which solubility of a compound can be increased?

_____

_____

4. Name two ions that form salts that are always soluble:
   - _____
   - _____

9.2 Concentration ★★

Concentration denotes the amount of solute dissolved in a solvent. There are many different ways of expressing concentration, and different units have been standardized for specific everyday situations. For example, alcohol content in liquors like vodka, gin, or rum is expressed in volume percent (volume of solute divided by volume of solution times 100 percent). Alcoholic proof is twice the volume percent. The sugar content of orange juice and other fruit juices is measured in units of degrees Brix (°Bx), which is a mass percent: mass of glucose divided by mass of solution times 100 percent.

UNITS OF CONCENTRATION

On the MCAT, concentrations are commonly expressed as percent composition by mass, mole fraction, molarity, molality, and normality.

Percent Composition by Mass

The **percent composition by mass** is given by the equation

$$\frac{\text{mass of solute}}{\text{mass of solution}} \times 100\%$$

Equation 9.1

Percent composition is used not only for aqueous solutions, but also for metal alloys and other solid-in-solid solutions.

Example: What is the percent composition by mass of a salt water solution if 100 g of the solution contains 20 g of NaCl?

Solution: $\frac{\text{mass of solute}}{\text{mass of solution}} \times 100\% = \frac{20\text{ g}}{100\text{ g}} \times 100\%$

=20% NaCl solution.

Mole Fraction

The **mole fraction** (X) of a compound is given by the equation

$$X_A = \frac{\text{moles of A}}{\text{total moles of all species}}$$

Equation 9.2

The sum of the mole fractions in a system will always equal 1. The mole fraction is used to calculate the vapor pressure depression of a solution, described later in this chapter, as well as the partial pressures of gases in a system, described in Chapter 8 of *MCAT General Chemistry Review*.

Example: If 92 g glycerol ($C_3H_8O_3$) is mixed with 90 g water, what will be the mole fractions of the two components? (Note: Molar mass of H_2O = 18 $\frac{g}{mol}$; molar mass of $C_3H_8O_3$ = 92 $\frac{g}{mol}$)

Solution: First, determine the number of moles of each compound:

90 g water × $\left[\frac{1\text{ mol}}{18\text{ g}}\right]$ = 5 mol water

92 g glycerol × $\left[\frac{1\text{ mol}}{92\text{ g}}\right]$ = 1 mole glycerol

Total number of moles = 5 + 1 = 6 moles

Then, determine the mole fractions:

$$X_{water} = \frac{5\text{ mol water}}{6\text{ mol total}} = 0.83$$

$$X_{glycerol} = \frac{1\text{ mol glycerol}}{6\text{ mol total}} = 0.17$$

MCAT Expertise

It is important to have a good idea of how to work with all of these ways of expressing concentration because more than one may show up on Test Day.

Molarity

The **molarity** (***M***) of a solution is defined as

$$M = \frac{\text{moles of solute}}{\text{liters of solution}}$$

Equation 9.3

Solution concentrations are usually expressed in terms of molarity, and this is the most common unit for concentration on the MCAT. Unless otherwise specified, representations of concentration using brackets—such as $[Na^+]$—indicate molarity. Note that the volume term in the denominator of molarity refers to the solution volume, *not* the volume of solvent used to prepare the solution—although the two values are often close enough to approximate the solution volume using the solvent volume. Molarity is used for rate laws, the law of mass action, osmotic pressure, pH and pOH, and the Nernst equation.

MCAT Expertise

Note that for dilute solutions, the volume of the solution is approximately equal to the volume of solvent used, which simplifies our calculations on Test Day. However, technical questions could ask you to distinguish between these two. For example, when you add two kilograms of sucrose (table sugar) to a liter of water at room temperature (achieving saturation), the volume of solution is certainly larger than 1 L!

Example: If enough water is added to 11 g of $CaCl_2$ to make 100 mL of solution, what is the molarity of the solution?

Solution:

First, calculate the number of moles of $CaCl_2$:

$$11\text{ g } CaCl_2\left[\frac{1\text{ mol}}{111.1\text{ g}}\right] = 0.1\text{ mol } CaCl_2$$

Then determine the molarity:

$$M = \frac{\text{moles of solute}}{\text{liters of solution}}$$

$$M = \frac{0.1\text{ mol}}{100\text{ mL} \times \frac{1\text{ L}}{1000\text{ mL}}} = 1\,M$$

Molality

The **molality** (***m***) of a solution is defined as

$$m = \frac{\text{moles of solute}}{\text{kilograms of solvent}}$$

Equation 9.4

For dilute aqueous solutions at 25°C, the molality is approximately equal to molarity because the density of water at this temperature is 1 kilogram per liter. However, note that this is an approximation and true only for dilute aqueous solutions. As aqueous solutions become more concentrated with solute, their densities become significantly different from that of pure water; most water-soluble solutes have molar masses significantly greater than that of water, so the density of the solution increases as the concentration increases. You won't use molality very often, so be mindful of the special situations when it is required: boiling point elevation and freezing point depression.

Example: If 10 g NaOH are dissolved in 500 g of water, what is the molality of the solution?

Solution:

First, calculate the number of moles of NaOH:

$$10\text{ g NaOH}\left[\frac{1\text{ mol}}{40\text{ g}}\right] = 0.25\text{ mol NaOH}$$

Then determine the molality:

$$m = \frac{\text{moles of solute}}{\text{kilograms of solvent}}$$

$$m = \frac{0.25\text{ mol}}{500\text{ g} \times \frac{1\text{ kg}}{1000\text{ g}}} = 0.5\,m$$

Normality

We discussed the related concepts of gram equivalent weight, equivalents, and normality in Chapter 4 of *MCAT General Chemistry Review*. The **normality** (*N*) of a solution is equal to the number of equivalents of interest per liter of solution. An equivalent is a measure of the reactive capacity of a molecule. Most simply, an equivalent is equal to a mole of the species of interest—protons, hydroxide ions, electrons, or ions.

To calculate the normality of a solution, we need to know what purpose the solution serves because it is the concentration of the reactive species with which we are concerned. For example, in acid–base reactions, we are most concerned with the concentration of hydrogen ions; in oxidation–reduction reactions, we are most concerned with the concentration of electrons. Normality is unique among concentration units in that it is reaction dependent. For example, in acidic solution, 1 mole of the permanganate ion $\left(MnO_4^-\right)$ will readily accept 5 moles of electrons, so a 1 *M* solution would be 5 *N*. However, in alkaline solution, 1 mole of permanganate will accept only 1 mole of electrons, so in alkaline solution, a 1 *M* permanganate solution would be 1 *N*.

MCAT Expertise

Simple ideas on Test Day will make things easier. So, when you come across normality, think of it as *molarity of the stuff of interest* in the reaction.

DILUTION

A solution is diluted when solvent is added to a solution of higher concentration to produce a solution of lower concentration. The concentration of a solution after dilution can be determined using the equation

$$M_iV_i = M_fV_f$$

Equation 9.5

where *M* is molarity, *V* is volume, and the subscripts i and f refer to the initial and final values, respectively.

Example: A chemist wishes to prepare 300 mL of a 1.2 *M* NaOH solution from a 5.5 *M* NaOH stock solution. What volume of stock solution should be diluted with pure water to obtain the desired solution?

Solution:

$$M_iV_i = M_fV_f \rightarrow V_i = \frac{M_fV_f}{M_i}$$

$$V_i = \frac{(1.2\ M)(300\ \text{mL})}{(5.5\ M)} = 65\ \text{mL}$$

Note that one can use mL or L in the equation, as long as the units are consistent.

MCAT Expertise

This equation is worthy of memorization. Note that a similar equation is used for the equivalence point in acid–base chemistry, as discussed in Chapter 10 of *MCAT General Chemistry Review*.

MCAT Concept Check 9.2:

Before you move on, assess your understanding of the material with these questions.

1. If you mix 180 g of the following compounds in 250 mL of water (density = 1 $\frac{\text{g}}{\text{mL}}$), what are their concentrations in molality, molarity, and normality (for acid–base chemistry)?

Compound	Molality	Molarity	Normality
Glucose (180 $\frac{\text{g}}{\text{mol}}$)			
Carbonate (60 $\frac{\text{g}}{\text{mol}}$)			

2. You are working in a sewage treatment facility and are assaying chlorine in a water sample. You need to dilute the water sample from 100 ppm stock to 25 ppm and create 100 mL of solution. Calculate the amount of stock solution needed and determine how you would create your final solution:

_____

_____

_____

3. A stock solution for making typical IV saline bags contains 90.0 g of NaCl per 10 liters of water (density = 1 $\frac{\text{g}}{\text{mL}}$). What is the mole fraction and the percent composition by mass of NaCl in the saline solutions?

   - Mole fraction:

_____

   - Percent composition by mass:

_____

9.3 Solution Equilibria ★★★★

The process of solvation, like other reversible chemical and physical processes, tends toward an equilibrium position, defined as the lowest energy state of a system under a given set of temperature and pressure conditions. Systems move spontaneously toward the equilibrium position, and any movement away from equilibrium is nonspontaneous. In the process of creating a solution, the equilibrium is defined as the **saturation point**, where the solute concentration is at its maximum value for the given temperature and pressure. Immediately after solute has been introduced into a solvent, most of the change taking place is dissociation because no dissolved solute is initially present. However, once solute is dissolved, the reverse process—precipitation of the solute—will begin to occur.

When the solution is dilute (unsaturated), the thermodynamically favored process is dissolution, and initially, the rate of dissolution will be greater than the rate of precipitation. As the solution becomes more concentrated and approaches saturation, the rate of dissolution lessens, while the rate of precipitation increases. Eventually, the saturation point of the solution is reached. The solution now exists in a state of dynamic equilibrium for which the rates of dissolution and precipitation are equal, and the concentration of dissolved solute reaches a steady-state (constant) value. Neither dissolution nor precipitation is more thermodynamically favored at equilibrium because favoring either would necessarily result in the solution no longer being in a state of equilibrium. At this point, the change in free energy is zero, as is the case for all systems at equilibrium.

An ionic solid introduced into a polar solvent dissociates into its component ions, and the dissociation of such a solute in solution may be represented by

$$A_mB_n\,(s) \rightleftharpoons m\,A^{n+}\,(aq) + n\,B^{m-}\,(aq)$$

On Test Day, the first step for any solution stoichiometry or solution equilibrium question is to write out the balanced dissociation reaction for the ionic compound in question. This first step is essential for correctly calculating the solubility product constant, ion product, molar solubility, or for determining the outcome of the common ion effect. In other words, it is the essential first step for nearly every solution chemistry problem on the MCAT.

SOLUBILITY PRODUCT CONSTANTS

Most solubility problems on the MCAT deal with solutions of sparingly soluble salts, which are ionic compounds that have very low solubility in aqueous solutions. You may wonder why any ionic compound would not be highly soluble in water.

The degree of solubility is determined by the relative changes in enthalpy and entropy associated with the dissolution of the ionic solute at a given temperature and pressure. One common sparingly soluble salt is silver chloride, AgCl, which dissociates in water according to the following equation:

$$AgCl\ (s) \rightleftharpoons Ag^{+}\ (aq) + Cl^{-}\ (aq)$$

The law of mass action can be applied to a solution at equilibrium; that is to say, when the solution is saturated and the solute concentration is at a maximum and is dynamically stable. For a saturated solution of an ionic compound with the formula A_mB_n, the equilibrium constant for its solubility in aqueous solution, called the **solubility product constant** (***K_{sp}***), can be expressed by

$$K_{sp} = [A^{n+}]^m[B^{m-}]^n$$

Equation 9.6

where the concentrations of the ionic constituents are equilibrium (saturation) concentrations. For example, we can express the K_{sp} of silver chloride as:

$$K_{sp} = [Ag^{+}][Cl^{-}]$$

You'll notice that, for the law of mass action of solutions, there is no denominator. Remember that pure solids and liquids do not appear in the equilibrium constant. Because the silver chloride solution was formed by adding pure solid silver chloride to pure water, neither the solid silver chloride nor the water is included. Indeed, dissociation reactions—by definition—have a solid salt as a reactant; thus, K_{sp} expressions should never have denominators.

Solubility product constants, like all other equilibrium constants (K_{eq}, K_a, K_b, and K_w) are temperature dependent. When the solution consists of a gas dissolved into a liquid, the value of the equilibrium constant, and hence the position of equilibrium (saturation), will also depend on pressure. Generally speaking, the solubility product constant increases with increasing temperature for non-gas solutes and decreases for gas solutes. Higher pressures favor dissolution of gas solutes, and therefore the K_{sp} will be larger for gases at higher pressures than at lower ones.

As solute dissolves into the solvent, the system approaches saturation, at which point no more solute can be dissolved and any excess will precipitate to the bottom of the container. We may not know whether the solution has reached saturation, and so to determine where the system is with respect to the equilibrium position, we can calculate a value called the **ion product** (***IP***), which is analogous to the reaction quotient, Q, for other chemical reactions. The ion product equation has the same form as the equation for the solubility product constant:

MCAT Expertise

On the MCAT, if you remember that K_{sp} is just a specialized form of K_{eq}, then you can simplify a lot of problems by using the same concepts that you do for all equilibria, including Le Châtelier's principle.

Real World

Because gases become more soluble in solution as pressure increases, a diver who has spent time at significant depths under water will have more nitrogen gas dissolved in his or her blood because nitrogen gas is the main inert gas in the air we breathe. If the diver rises to the surface too quickly, the abrupt decompression will lead to an abrupt decrease in gas solubility in the plasma, resulting in the formation of nitrogen gas bubbles in the bloodstream. The gas bubbles can get lodged in the small vasculature of the peripheral tissue, mostly around the large joints of the body, causing pain and tissue damage (hence the name, the *bends*). The condition is painful and dangerous and can be fatal if not properly treated.

$$IP = [A^{n+}]^m[B^{m-}]^n$$

Equation 9.7

The difference is that the concentrations used in the ion product equation are the concentrations of the ionic constituents at that given moment in time, which may differ from equilibrium concentrations. As with the reaction quotient Q, the utility of the ion product lies in comparing its value to that attained at equilibrium, K_{sp}. Each salt has its own distinct K_{sp} at a given temperature. If, at a given set of conditions, a salt's IP is less than the salt's K_{sp}, then the solution is not yet at equilibrium and is considered **unsaturated**. For unsaturated solutions, dissolution is thermodynamically favored over precipitation. If the IP is greater than the K_{sp}, then the solution is beyond equilibrium, and the solution is considered **supersaturated**. It is possible to create a supersaturated solution by dissolving solute into a hot solvent and then slowly cooling the solution. A supersaturated solution is thermodynamically unstable, and any disturbance to the solution, such as the addition of more solid solute or other solid particles, or further cooling of the solution, will cause spontaneous precipitation of the excess dissolved solute. If the calculated IP is equal to the known K_{sp}, then the solution is at equilibrium—the rates of dissolution and precipitation are equal—and the solution is considered **saturated**. The molarity of a solute in a saturated solution is called the **molar solubility** of that substance.

Key Concept

$IP < K_{sp}$: unsaturated, solute will continue to dissolve
$IP = K_{sp}$: saturated, solution is at equilibrium
$IP > K_{sp}$: supersaturated, precipitation will occur

Example: The molar solubility of $Fe(OH)_3$ in an aqueous solution was determined to be $4 \times 10^{-10} \frac{\text{mol}}{\text{L}}$. What is the value of the K_{sp} for $Fe(OH)_3$ at the same temperature and pressure?

Solution: The molar solubility is given as 4×10^{-10} M. The equilibrium concentration of each ion can be determined from the molar solubility and the balanced dissociation reaction of $Fe(OH)_3$. The dissociation reaction is:

$$Fe(OH)_3(s) \rightleftharpoons Fe^{3+}(aq) + 3\ OH^-(aq)$$

$$K_{sp} = [Fe^{3+}][OH^-]^3$$

If the molar solubility is 4×10^{-10} M, then 4×10^{-10} M $Fe(OH)_3$ has dissolved, yielding 4×10^{-10} M Fe^{3+} and $3 \times 4 \times 10^{-10}$ M OH^- (because there are three OH^- ions given off per $Fe(OH)_3$ molecule). Thus,

$$K_{sp} = \left[Fe^{3+}\right]\left[OH^-\right]^3$$

$$K_{sp} = (4 \times 10^{-10}M)(3 \times 4 \times 10^{-10}M)^3$$

$$K_{sp} = 27(4 \times 10^{-10})^4 = 27 \times 256 \times 10^{-40} \approx 30 \times 250 \times 10^{-40}$$

$$K_{sp} \approx 7.5 \times 10^{-37} \text{ (actual} = 6.9 \times 10^{-37})$$

Example: What are the concentrations of each of the ions in a saturated solution of PbI_2, given that the K_{sp} of PbI_2 is 8.5×10^{-9} at 25°C? If 5 g PbI_2 are dissolved in water to make 1 L of solution at 25°C, would the solution be saturated, unsaturated, or supersaturated?

Solution: The first step is to write out the dissociation reaction:

$$PbI_2(s) \rightarrow Pb^{2+}(aq) + 2\ I^-(aq)$$

$$K_{sp} = [Pb^{2+}][I^-]^2$$

Let x equal the concentration of Pb^{2+} at equilibrium. Then, $2x$ equals the concentration of I^- at equilibrium because $[I^-]$ is two times $[Pb^{2+}]$, based on the stoichiometric coefficients.

$$K_{sp} = (x)(2x)^2$$

$$8.5 \times 10^{-9} = 4x^3$$

$$2.1 \times 10^{-9} \approx x^3$$

$$1.3 \times 10^{-3} \approx x \text{ (actual: } 1.29 \times 10^{-3})$$

Therefore, $[Pb^{2+}]$ is about 1.3×10^{-3} M, and $[I^-]$ is about 2.6×10^{-3} M. Note that 1.3×10^{-3} M also represents the molar solubility of lead(II) iodide.

Next, we convert 5 g of PbI_2 into moles:

$$5\text{ g} \times \frac{1\text{ mol } PbI_2}{461.0\text{ g}} \approx 1 \times 10^{-2}\text{ mol}$$

1×10^{-2} mol PbI_2 in 1 L of solution represents a molarity of 1×10^{-2} M, which is almost ten times higher than the molar solubility. Therefore, this is a supersaturated solution.

Key Concept

Every sparingly soluble salt of general formula MX will have $K_{sp} = x^2$, where x is the molar solubility (assuming no common ion effect).

Key Concept

Every sparingly soluble salt of general formula MX_2 will have $K_{sp} = 4x^3$, where x is the molar solubility (assuming no common ion effect).

Key Concept

Every sparingly soluble salt of general formula MX_3 will have $K_{sp} = 27x^4$, where x is the molar solubility (assuming no common ion effect).

Finally, let's return to our discussion of complex ions and their solubility factors. Much like the examples we have seen previously, the solubility of complex ion solutions is determined by the K_{sp}. The formation of complex ions increases the solubility of a salt in solution.

For instance, consider free iron(III) (Fe^{3+}) in a solution of water. If a cyanide solution were added, an exceptionally stable iron and cyanide metal complex would form as the water molecules solvating the iron are replaced by excess cyanide ions:

$$Fe^{3+}(aq) + 6\ CN^-(aq) \rightarrow [Fe(CN)_6]^{3-}(aq) \qquad K_{sp} = 1.0 \times 10^{31}$$

Knowing the intricacies of why complexes are more stable in solution than isolated ions is beyond the scope of the MCAT; however, it should make sense that, if a complex ion contains multiple polar bonds between the ligands and the central metal ion, it should be able to engage in a very large amount of dipole–dipole interactions. This stabilizes the dissolution of the complex ion. The end result is that such complexes tend to have very high K_{sp} values.

When forming a complex ion, one must often use a mixture of solutions. For this reason, a distinction must be made between the K_{sp} of the solution and that of the complex ion itself. The dissolution of the original solution is termed K_{sp}, and the subsequent formation of the complex ion in solution is termed $\boldsymbol{K_f}$ (the **formation** or **stability constant** of the complex in solution). An example is shown below in which the diamminesilver(I) complex is formed in a silver chloride solution:

$$AgCl\,(s) \rightarrow Ag^+\,(aq) + Cl^-\,(aq) \qquad K_{sp} = 1.8 \times 10^{-10} = [Ag^+][Cl^-]$$

$$Ag^+\,(aq) + 2\,NH_3\,(aq) \rightarrow [Ag(NH_3)_2]^+ \qquad K_f = 1.6 \times 10^7 = \frac{\left[[Ag(NH_3)_2]^+\right]}{[Ag^+][NH_3]^2}$$

Notice that the formation constant (K_f) of the complex ion is significantly larger than the K_{sp} of the compound providing the metal ion. This is part of the explanation for why the initial dissolution of the metal ion is the rate-limiting step of complex ion formation. However, Le Châtelier's principle is at play in these reactions as well. Ultimately, complex ions form to become more soluble in solution. And as an amount of silver ion is being used up to form the complex ion itself, the dissociation reaction of AgCl shifts to the right, providing more silver for complex ion formation.

Example: A 0.1 mol sample of CuS is added to 1.00 L of 1.00 *M* NH_3. What is the final concentration of the complex ion, tetraamminecopper(II)?

$$CuS\,(s) \rightarrow Cu^{2+}\,(aq) + S^{2-}\,(aq) \qquad K_{sp} = 8 \times 10^{-37}$$

$$Cu^{2+}\,(aq) + 4\,NH_3\,(aq) \rightarrow [Cu(NH_3)_4]^{2+}\,(aq) \qquad K_f = 1.1 \times 10^{13}$$

Solution: First, we must determine the amount of copper ion produced from copper sulfide (CuS) in solution. If the formation of the complex ion occurred simultaneously, we can assume that almost all of the copper ions are liberated from the CuS salt as the dissociation of CuS is driven to completion. Thus, $[Cu^{2+}] = \frac{0.1\text{ mol}}{1.00\text{ L}} = 0.1\ M$.

Using some logic, if x amount of Cu^{2+} is used in complex ion formation, it will require $4x$ amount of NH_3, forming x amount of the complex ion. Thus, at equilibrium, the concentration of Cu^{2+} is 0.1 *M* (what was released from CuS) minus x. The concentration of NH_3 will be 1.00 *M* (what was originally present) minus $4x$. The concentration of the complex ion will be x.

Now, we can plug into K_f:

$$K_f = \frac{\left[[Cu(NH_3)_4]^{2+}\right]}{[Cu^{2+}][NH_3]^4}$$

$$1.1 \times 10^{13} = \frac{[x]}{[0.1\ M - x][1.00\ M - 4x]^4}$$

This math is well beyond what the MCAT expects students to be able to do without a calculator, so there must be another way to get to the answer. Consider that the K_f is very large (over 10 trillion!); therefore, the equilibrium is shifted very far to the right. In other words, almost all of the Cu^{2+} ions will be used up to form the complex. Therefore, the concentration of the complex ion is 0.1 *M*.

COMMON ION EFFECTS

The solubility of a substance varies depending on the temperature of the solution, the solvent, and in the case of a gas-phase solute, the pressure. Solubility is also affected by the addition of other substances to the solution. The effect of a complex ion increasing the solubility of a substance is not typical and is—in fact—opposite to the effect seen in many mixtures of solutions.

One of the more challenging solution chemistry problems on the MCAT is calculation of the equilibrium concentration of a salt in a solution that already contains one of the ions in that salt. The solubility of a salt is considerably reduced when it is dissolved in a solution that already contains one of its constituent ions as compared to its solubility in a pure solvent. This reduction in molar solubility is called the **common ion effect**. As described above, the molar solubility of a compound is its concentration (in moles per liter) at equilibrium at a given temperature. If *X* moles of A_mB_n (*s*) can be dissolved in one liter of solution to reach saturation, then the molar solubility of A_mB_n (*s*) is *X* molar.

Pay attention to the effect of the common ion: its presence results in a reduction in the molar solubility of the salt. Note, however, that the presence of the common ion has no effect on the value of the solubility product constant itself. For example, if a salt such as CaF_2 is dissolved into water already containing Ca^{2+} ions (from some other salt, perhaps $CaCl_2$), the solution will dissolve less CaF_2 than would an equal amount of pure water.

The common ion effect is really Le Châtelier's principle in action. Because the solution already contains one of the constituent ions from the products side of the dissociation equilibrium, the system will shift toward the left side, reforming the solid salt. As a result, molar solubility for the solid is reduced, and less of the solid dissolves in the solution—although the K_{sp} remains constant.

One can take advantage of the common ion effect to separate out specific compounds in a solution mixture. For example, in a solution of silver salts, one could add sodium or potassium chloride to preferentially precipitate silver(I) chloride. By adding an appropriate counterion in excess, the dissociation reaction shifts to the left, forming the solid salt.

Example: The K_{sp} of AgI in aqueous solution is 1×10^{-16}. If a $1 \times 10^{-5}\ M$ solution of $AgNO_3$ is saturated with AgI, what will be the final concentration of the iodide ion?

Solution: The concentration of Ag^+ in the original $AgNO_3$ solution will be $1 \times 10^{-5}\ M$ because $AgNO_3$ will fully dissociate. Some amount of AgI will dissociate into the solution. If this amount is called x, the silver concentration will become $1 \times 10^{-5}\ M + x$. Because no iodide was present in solution until the AgI began dissociating, the concentration of iodide will be x. Thus, the K_{sp} expression can be written as:

$$K_{sp} = [Ag^+][I^-]$$
$$1 \times 10^{-16} = [1 \times 10^{-5} M + x][x]$$

On the MCAT, the value of x is almost always sufficiently small to consider its addition or subtraction from another number negligible. Thus, the math can be simplified to:

$$1 \times 10^{-16} = [1 \times 10^{-5} M][x]$$
$$1 \times 10^{-11} = x$$

This question asked for the concentration of iodide, which—based on the equilibrium expression—is represented by x. Thus, $[I^-] = 1 \times 10^{-11}\ M$.

MCAT Concept Check 9.3:

Before you move on, assess your understanding of the material with these questions.

1. Calculate the K_{sp} of $Ni(OH)_2$ in water, given that its molar solubility is $5.2 \times 10^{-6}\ M$.

_____

_____

_____

2. The K_{sp} of $Ba(OH)_2$ is 5.0×10^{-3}. Assuming that barium hydroxide is the only salt added to form a solution, calculate the ion product of the following solutions based on the concentration of Ba^{2+}. Then, predict the behavior of the given solutions (dissolution, equilibrium, or precipitation):

$[Ba^{2+}]$	Ion Product	Behavior of Solution
0.5 M		
0.1 M		
0.05 M		

3. What is the molar solubility of $Fe(OH)_2$ ($K_{sp} = 1.8 \times 10^{-15}$) in a 0.1 *M* solution of NaOH?

_____

_____

_____

9.4 Colligative Properties

The **colligative properties** are physical properties of solutions that are dependent on the concentration of dissolved particles but not on the chemical identity of the dissolved particles. These properties—vapor pressure depression, boiling point elevation, freezing point depression, and osmotic pressure—are usually associated with dilute solutions.

RAOULT'S LAW

Raoult's law accounts for **vapor pressure depression** caused by solutes in solution. As solute is added to a solvent, the vapor pressure of the solvent decreases proportionately. For example, consider compound A in Figure 9.9. Compound A in its pure form (mole fraction = 1.0) has a particular vapor pressure, indicated by P_A°. At the same temperature, compound B has a lower vapor pressure, indicated by P_B°. Note that, as the concentration of B increases, the vapor pressure of A decreases. Indeed, as more solute is dissolved into solvent (as more B is dissolved into A), the vapor pressure of the solvent decreases.

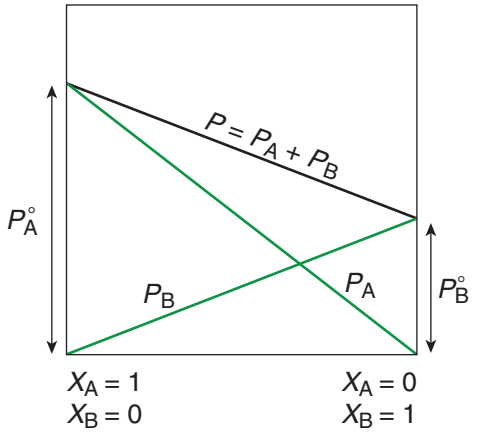

Figure 9.9. Raoult's Law
As more of solute B is dissolved in solvent A, the vapor pressure of solvent A decreases.

On a molecular level, the presence of the solute molecules can block the evaporation of solvent molecules but not their condensation. This reduces the vapor pressure of the solution compared to the pure solvent, as seen in Figure 9.10.

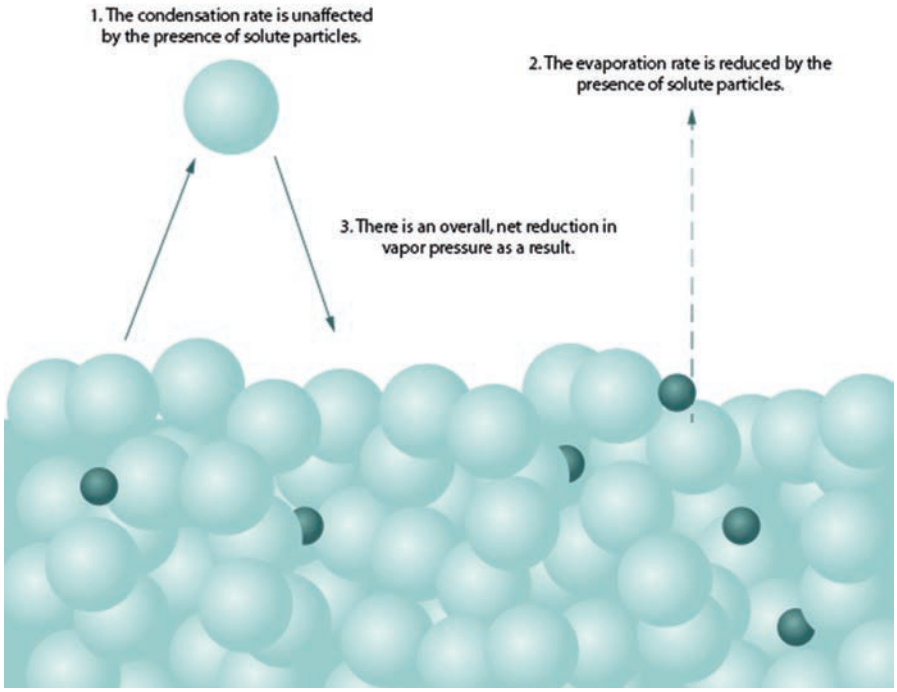

Figure 9.10. Molecular Basis of Raoult's Law

Raoult's law is expressed mathematically as

$$P_A = X_A P_A^\circ$$

Equation 9.8

where P_A is the vapor pressure of solvent A when solutes are present, X_A is the mole fraction of the solvent A in the solution, and P_A° is the vapor pressure of solvent A in its pure state.

Raoult's law holds only when the attraction between the molecules of the different components of the mixture is equal to the attraction between the molecules of any one component in its pure state. When this condition does not hold, the relationship between mole fraction and vapor pressure will deviate from Raoult's law. Solutions that obey Raoult's law are called ideal solutions.

Key Concept

Vapor pressure depression goes hand in hand with boiling point elevation. The lowering of a solution's vapor pressure would mean that a higher temperature is required to match atmospheric pressure, thereby raising the boiling point.

Example: What is the change in vapor pressure when 180 grams of glucose ($C_6H_{12}O_6$) are added to 0.18 L of water at 100°C?

Solution: The density of water at 100°C is close to 1 $\frac{g}{mL}$, and the vapor pressure of water at the same temperature is 1 atm because this is the boiling point of water.

In order to find the mole fraction of the solvent, first find the molar mass of the solute (glucose) and solvent (water). 180 g glucose represents 1 mole of glucose. 0.18 L of water has a mass around 180 g, which represents 10 moles of water. The mole fraction of water is therefore $\frac{10 \text{ mol water}}{11 \text{ mol total}} = 0.91$.

To find the vapor pressure change, we want to find the difference in the old pressure and the new pressure. The new pressure can be calculated from Raoult's law:

$$P_A = X_A P_A^\circ = (0.91)(1 \text{ atm}) = 0.91 \text{ atm}.$$

The change in vapor pressure is therefore 1 atm – 0.91 atm = 0.09 atm.

Example: What is the vapor pressure at room temperature of a mixture containing 58 g butane (C_4H_{10}) and 172 g hexane (C_6H_{14})? (Note: the vapor pressures of pure butane and pure hexane are 172 kPa and 17.6 kPa, respectively, at 25°C.)

Solution: First, determine the number of moles of each substance. 58 g butane represents 1 mole of butane. 172 g hexane represents 2 moles of hexane. Then, determine the mole fractions of each component of the mixture.

$$X_{\text{butane}} = \frac{\text{moles of butane}}{\text{total moles}} = \frac{1}{3}$$

$$X_{\text{hexane}} = \frac{\text{moles of hexane}}{\text{total moles}} = \frac{2}{3}$$

Then, calculate the vapor pressure of each component.

$$P_{\text{butane}}^\circ = X_{\text{butane}} P_{\text{butane}} = \frac{1}{3}(172 \text{ kPa}) \approx 57 \text{ kPa}$$

$$P_{\text{hexane}}^\circ = X_{\text{hexane}} P_{\text{hexane}} = \frac{2}{3}(17.6 \text{ kPa}) \approx 12 \text{ kPa}$$

The total vapor pressure is just the sum of these two vapor pressures. Thus, the total vapor pressure is 57 + 12 = 69 kPa (actual = 69.1 kPa).

BOILING POINT ELEVATION

When a nonvolatile solute is dissolved into a solvent to create a solution, the boiling point of the solution will be greater than that of the pure solvent. The boiling point is the temperature at which the vapor pressure of the liquid equals the ambient (incident) pressure. We've just seen that adding solute to a solvent results in a decrease in the vapor pressure of the solvent in the solution. If the vapor pressure of a solution is lower than that of the pure solvent, then more energy (and consequently a higher temperature) will be required before its vapor pressure equals the ambient pressure. The extent to which the boiling point of a solution is raised relative to that of the pure solvent is given by the formula

$$\Delta T_b = iK_b m$$

Equation 9.9

where ΔT_b is the increase in boiling point, i is the van 't Hoff factor, K_b is a proportionality constant characteristic of a particular solvent (which will be provided on Test Day), and m is the molality of the solution. The **van 't Hoff factor** corresponds to the number of particles into which a compound dissociates in solution. For example, $i = 2$ for NaCl because each formula unit of sodium chloride dissociates into two particles—a sodium ion and a chloride ion—when it dissolves. Covalent molecules such as glucose do not readily dissociate in water and thus have i values of 1.

Example: 400 g $AlCl_3$ is dissolved in 1.5 L of water at room temperature ($K_b = 0.512 \frac{K \cdot kg}{mol}$). How much does the boiling point increase after adding the aluminum chloride?

Solution: Water at room temperature has a density of 1 $\frac{g}{mL}$. Therefore, 1.5 L is the same as 1.5 kg. The van 't Hoff factor for aluminum chloride is 4 because it breaks down to form 1 aluminum cation and 3 chloride anions. To determine the molality, we will also need to know how many moles 400 g $AlCl_3$ represents.

$$400 \text{ g } AlCl_3 \times \frac{1 \text{ mol}}{133.5 \text{ g}} \approx 3 \text{ mol } AlCl_3$$

The molality is therefore $\frac{3 \text{ mol } AlCl_3}{1.5 \text{ kg}} = 2\ m$.

Then, plug into the boiling point elevation equation.

$$\Delta T_b = iK_b m = (4)(0.512 \frac{K \cdot kg}{mol})(2\ m) \approx 4 \text{ K (actual = 4.1 K)}$$

MCAT Expertise

The boiling point elevation formula calculates the amount that the normal boiling point is raised. The value calculated is not the boiling point itself.

FREEZING POINT DEPRESSION

The presence of solute particles in a solution interferes with the formation of the lattice arrangement of solvent molecules associated with the solid state. Thus, a greater amount of energy must be removed from the solution (resulting in a lower temperature)

in order for the solution to solidify. For example, pure water freezes at 0°C, but for every mole of solute dissolved in 1 kg of water, the freezing point is lowered by 1.86°C. Therefore, the K_f for water is 1.86 $\frac{K \cdot kg}{mol}$. As is the case for K_b, the values for K_f are unique to each solvent and will be provided on Test Day. The formula for calculating the freezing point depression for a solution is

$$\Delta T_f = iK_f m$$

Equation 9.10

where ΔT_f is the freezing point depression, i is the van 't Hoff factor, K_f is the proportionality constant characteristic of a particular solvent, and m is the molality of the solution. Freezing point depression is a colligative property and depends only on the concentration of particles, not on their identities.

Example: 400 g of $AlCl_3$ is dissolved in 1.5 L of water at room temperature (K_f = 1.86 $\frac{K \cdot kg}{mol}$). What is the new freezing point of this solution?

Solution: Using the same variables for i and m from the previous example,

$$\Delta T_f = iK_f m = (4)(1.86 \frac{K \cdot kg}{mol})(2\ m) \approx 15\ K \text{ (actual = 14.9 K)}$$

The normal freezing point of water is 273 K. The freezing point is going to be depressed (or decreased) by 15 K. The new freezing point is therefore 273 – 15 = 258 K = –15°C.

MCAT Expertise

As with boiling point elevation, there is a distinction between the calculated value and a final answer. The freezing point depression calculates the amount that the normal freezing point is lowered. As always, read the question to determine if it is asking for the change in temperature (ΔT) or the new (altered) boiling or freezing point.

This effect is the explanation for why we salt icy roads in the winter. Salt mixes with the snow and ice and initially dissolves into the small amount of liquid water that is in equilibrium with the solid phase (the snow and ice). The solute in solution causes a disturbance to the equilibrium such that the rate of melting is unchanged (because the salt can't interact with the solid water that is stabilized in a rigid lattice arrangement), but the rate of freezing is decreased (the solute displaces some of the water molecules from the solid–liquid interface and prevents liquid water from entering into the solid phase).

This imbalance causes more ice to melt than water to freeze. Melting is an endothermic process, so heat is initially absorbed from the liquid solution, causing the solution temperature to fall below the ambient temperature. Now, there is a temperature gradient, and heat flows from the warmer air to the cooler aqueous solution; this additional heat facilitates more melting—even though the temperature of the solution is actually colder than it was before the solute was added! The more the ice melts into liquid water, the more the solute is dispersed through the liquid. The resulting salt solution, by virtue of the presence of the solute particles, has a lower freezing point than the pure water and remains in the liquid state even at temperatures that would normally cause pure water to freeze.

OSMOTIC PRESSURE

Osmotic pressure is covered primarily in Chapter 8 of *MCAT Biochemistry Review*, but a brief recap is provided here. **Osmotic pressure** refers to a "sucking" pressure generated by solutions in which water is drawn into a solution. Formally, the osmotic pressure is the amount of pressure that must be applied to counteract this attraction of water molecules for the solution. The equation for osmotic pressure is

$$\prod = iMRT$$

Equation 9.11

where $\prod$ is the osmotic pressure, i is the van 't Hoff factor, M is the molarity of the solution, R is the ideal gas constant, and T is the temperature.

Water moves in the direction of higher solute concentration. For instance, pure water (no solute concentration) will traverse a semipermeable membrane to a solution containing solute particles (such as NaCl) and increase the level of the water as a result, as shown in Figure 9.11.

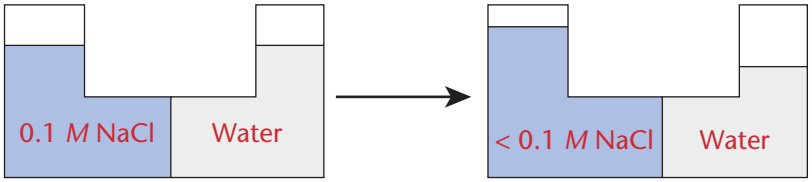

Figure 9.11. Change in Water Level Due to Osmotic Pressure

MCAT Concept Check 9.4:

Before you move on, assess your understanding of the material with these questions.

1. What is a colligative property?

_____

_____

2. How are molality and molarity related for water? How are they related for other solvents?
   - Water:

     _____
   - Other solvents:

     _____

3. Determine the vapor pressure of a solution containing 190 g $MgCl_2$ in 720 g water at room temperature: (Note: The vapor pressure of pure water at 25°C is 3.2 kPa.)

_____

_____

4. Determine the new boiling point of a solution containing 190 g $MgCl_2$ in 1800 g water at room temperature: ($K_b = 0.512 \frac{K \cdot kg}{mol}$)

_____

_____

5. Determine the freezing point depression of a solution containing 58.5 g of NaCl in 2160 g of water at room temperature: ($K_f = 1.86 \frac{K \cdot kg}{mol}$)

_____

_____

Conclusion

Our review of solution chemistry has provided an opportunity for us to consider the nature of solutions, solutes, and solvents, and the interactions between solutes and solvents in the formation of solutions. We reviewed solubility and the rules that reflect the solubility of common compounds in water. The different ways of expressing the amount of solute in solution were identified, and examples were given for each unit of concentration, including percent composition, mole fraction, molarity, molality, and normality. Next, we reviewed the thermodynamic principles of solution equilibria and defined unsaturated, saturated, and supersaturated solutions with respect to ion product (*IP*) and solubility product constant (K_{sp}). Subsequently, we discussed the common ion effect from the perspective of Le Châtelier's principle for a solution at equilibrium. And finally, we examined the colligative properties of solutions and the mathematics that govern them. The colligative properties—vapor pressure depression, boiling point elevation, freezing point depression, and osmotic pressure—are physical properties of solutions that depend on the concentration of dissolved particles but not on their chemical identities.

CONCEPT SUMMARY

Nature of Solutions

- **Solutions** are homogenous **mixtures** composed of two or more substances.
  - They combine to form a single phase, generally the liquid phase.
  - **Solvent** particles surround **solute** particles via electrostatic interactions in a process called **solvation** or **dissolution**.
  - Aqueous solutions are most important for the MCAT; solvation in water can also be called **hydration**.
  - Most dissolutions are endothermic, although the dissolution of gas into liquid is exothermic.
- **Solubility** is the maximum amount of a solute that can be dissolved in a given solvent at a given temperature; it is often expressed as **molar solubility**—the molarity of the solute at saturation.
- **Complex ions** or **coordination compounds** are composed of metallic ions bonded to various neutral compounds and anions, referred to as **ligands**.
  - Formation of **complex ions** increases the solubility of otherwise insoluble ions (the opposite of the common ion effect).
  - The process of forming a complex ion involves electron pair donors and electron pair acceptors such as those seen in **coordinate covalent bonding**.

Concentration

- There are many ways of expressing concentration.
  - **Percent composition by mass** (mass of solute per mass of solution times 100%) is used for aqueous solutions and solid-in-solid solutions.
  - The **mole fraction** (moles of solute per total moles) is used for calculating vapor pressure depression and partial pressures of gases in a system.
  - **Molarity** (moles of solute per liters of solution) is the most common unit for concentration and is used for rate laws, the law of mass action, osmotic pressure, pH and pOH, and the Nernst equation.
  - **Molality** (moles of solute per kilograms of solvent) is used for boiling point elevation and freezing point depression.
  - **Normality** (number of equivalents per liters of solution) is the molarity of the species of interest and is used for acid–base and oxidation–reduction reactions.

Solution Equilibria

- Saturated solutions are in equilibrium at that particular temperature.
- The **solubility product constant** (K_{sp}) is simply the equilibrium constant for a dissociation reaction.

- Comparison of the **ion product** (***IP***) to K_{sp} determines the level of saturation and behavior of the solution:
  - $IP < K_{sp}$: the solution is unsaturated, and if more solute is added, it will dissolve
  - $IP = K_{sp}$: the solution is saturated (at equilibrium), and there will be no change in concentrations
  - $IP > K_{sp}$: the solution is supersaturated, and a precipitate will form
- Formation of a complex ion in solution greatly increases solubility.
  - The **formation** or **stability constant** (K_f) is the equilibrium constant for complex formation. Its value is usually much greater than K_{sp}.
  - The formation of a complex increases the solubility of other salts containing the same ions because it uses up the products of those dissolution reactions, shifting the equilibrium to the right (the opposite of the common ion effect).
  - The **common ion effect** decreases the solubility of a compound in a solution that already contains one of the ions in the compound. The presence of that ion in solution shifts the dissolution reaction to the left, decreasing its dissociation.

Colligative Properties

- **Colligative properties** are physical properties of solutions that depend on the concentration of dissolved particles but not on their chemical identity.
- **Vapor pressure depression** follows **Raoult's law**.
  - The presence of other solutes decreases the evaporation rate of a solvent without affecting its condensation rate, thus decreasing its vapor pressure.
  - Vapor pressure depression also explains boiling point elevation—as the vapor pressure decreases, the temperature (energy) required to boil the liquid must be raised.
- **Freezing point depression** and **boiling point elevation** are shifts in the phase equilibria dependent on the molality of the solution.
- **Osmotic pressure** is primarily dependent on the molarity of the solution.
- For solutes that dissociate, the **van 't Hoff factor** (***i***) is used in freezing point depression, boiling point elevation, and osmotic pressure calculations.

ANSWERS TO CONCEPT CHECKS

9.1

1. Solvation refers to the breaking of intermolecular forces between solute particles and between solvent particles, with formation of intermolecular forces between solute and solvent particles. In an aqueous solution, water is the solvent.
2. Solubility is the amount of solute contained in a solvent. Saturation refers to the maximum solubility of a compound at a given temperature; one cannot dissolve any more of the solute just by adding more at this temperature.
3. Solubility of solids can be increased by increasing temperature. Solubility of gases can be increased by decreasing temperature or increasing the partial pressure of the gas above the solvent (Henry's law).
4. Group I metals, ammonium, nitrate, and acetate salts are always soluble.

9.2

1.

Compound	Molality	Molarity	Normality
Glucose ($180 \frac{g}{mol}$)	$\frac{1 \text{ mol}}{0.25 \text{ kg solvent}} = 4\ m$	Cannot be calculated directly because final volume is unknown, but close to value for molality (in dilute solutions, $M \approx m$)	~0 N (glucose is a neutral compound)
Carbonate ($60 \frac{g}{mol}$)	$\frac{3 \text{ mol}}{0.25 \text{ kg solvent}} = 12\ m$		Approximately 24 N (twice the molarity, which is close to 12 M)

2. $M_i V_i = M_f V_f \rightarrow V_i = \frac{M_f V_f}{M_i} = \frac{(25 \text{ ppm})(100 \text{ mL})}{(100 \text{ ppm})} = 25 \text{ mL}$. Thus, start with 25 mL of the stock solution and add 75 mL pure water to get 100 mL of solution with 25 ppm Cl_2.

3. $X_{NaCl} = \frac{\text{moles of NaCl}}{\text{total moles}} = \frac{90 \text{ g}\left[\frac{1 \text{ mol}}{58.5 \text{ g}}\right]}{90 \text{ g}\left[\frac{1 \text{ mol}}{58.5 \text{ g}}\right] + 10^4 \text{ g}\left[\frac{1 \text{ mol}}{18 \text{ g}}\right]} \approx \frac{1.5}{1.5 + 500} \approx$

$3 \times 10^{-3} (\text{actual} = 2.8 \times 10^{-3})$

Percent composition $= \frac{\text{mass of solute}}{\text{mass of solution}} \times 100\% = \frac{90 \text{ g}}{90 \text{ g} + 10^4 \text{ g}} \times 100\% \approx$

$\frac{90}{10^4} \times 100\% = 0.9\% \text{ (actual} = 0.89\%)$

9.3

1. $K_{sp} = [Ni^{2+}][OH^-]^2 = (5.2 \times 10^{-6}\ M)(10.4 \times 10^{-6}\ M)^2 \approx (5 \times 10^{-6})(100 \times 10^{-12})$ $= 500 \times 10^{-18} = 5 \times 10^{-16}$ (actual $= 5.6 \times 10^{-16}$)

2.

$[Ba^{2+}]$	Ion Product	Behavior of Solution
0.5 *M*	$(0.5\ M)(1\ M)^2 = 0.5$	$0.5 > 5.0 \times 10^{-3} \rightarrow$ precipitation
0.1 *M*	$(0.1\ M)(0.2\ M)^2 = 4.0 \times 10^{-3}$	$4.0 \times 10^{-3} < 5.0 \times 10^{-3} \rightarrow$ dissolution
0.05 *M*	$(0.05\ M)(0.1\ M)^2 = 5.0 \times 10^{-4}$	$5.0 \times 10^{-4} < 5.0 \times 10^{-3} \rightarrow$ dissolution

Note that the concentration of hydroxide is double that of barium, assuming $Ba(OH)_2$ was the only salt added to solution. While there will be a very small contribution of hydroxide from the autoionization of water, this amount is negligible compared to the values given in the question.

3. $K_{sp} = [Fe^{2+}][OH^-]^2 = (x)(0.1 + 2x)^2$. x is almost always negligible in addition or subtraction, so the math simplifies to $K_{sp} = (x)(0.1)^2$. Thus, $1.8 \times 10^{-15} = 0.01x$. x = molar solubility = 1.8×10^{-13}.

9.4

1. Colligative properties are those that depend on the amount of solute present, but not the actual identity of the solute particles. Examples include vapor pressure depression, boiling point elevation, freezing point depression, and osmotic pressure.
2. Molarity (*M*) and molality (*m*) are nearly equal at room temperature. This is only because 1 L solution is approximately equal to 1 kg solvent for dilute solutions (the denominators of the molarity and molality equations, respectively). For other solvents, molarity and molality differ significantly because their densities are not $1\ \frac{g}{mL}$ like water.
3. $190\text{ g } MgCl_2 \times \frac{1\text{ mol}}{95.3\text{ g}} = 2\text{ mol } MgCl_2$. $720\text{ g } H_2O \times \frac{1\text{ mol}}{18\text{ g}} = 40\text{ mol } H_2O$. $X_{water} = \frac{40\text{ moles water}}{42\text{ total moles}} \approx 0.95$

   $P_{water} = X_{water}P^{\circ}_{water} = (0.95)(3.2) \approx 3.0$ kPa (actual = 3.05 kPa)
4. $\Delta T_b = iK_bm = (3)(0.512\ \frac{K \bullet kg}{mol})(\frac{2\text{ mol } MgCl_2}{1.8\text{ kg water}}) \approx 2$ K (actual = 1.7 K). The new boiling point will be 373 + 2 = 375 K.
5. $\Delta T_f = iK_fm = (2)(1.86\ \frac{K \bullet kg}{mol})(\frac{1\text{ mol NaCl}}{2.16\text{ kg water}}) \approx 1.86$ K (actual = 1.72 K)

EQUATIONS TO REMEMBER

(9.1) **Percent composition by mass:** $\frac{\text{mass of solute}}{\text{mass of solution}} \times 100\%$

(9.2) **Mole fraction:** $X_A = \frac{\text{moles of A}}{\text{total moles of all species}}$

(9.3) **Molarity:** $M = \frac{\text{moles of solute}}{\text{liters of solution}}$

(9.4) **Molality:** $m = \frac{\text{moles of solute}}{\text{kilograms of solvent}}$

(9.5) **Dilution formula:** $M_i V_i = M_f V_f$

(9.6) **Solubility product constant:** $K_{sp} = [A^{n+}]^m [B^{m-}]^n$

(9.7) **Ion product:** $IP = [A^{n+}]^m [B^{m-}]^n$

(9.8) **Raoult's law (vapor pressure depression):** $P_A = X_A P_A^\circ$

(9.9) **Boiling point elevation:** $\Delta T_b = iK_b m$

(9.10) **Freezing point depression:** $\Delta T_f = iK_f m$

(9.11) **Osmotic pressure:** $\Pi = iMRT$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. An aqueous solution was prepared by mixing 70 g of an unknown nondissociating solute into 100 g of water. The solution has a boiling point of 101.11°C. What is the molar mass of the solute?
(Note: $K_b = 0.512 \frac{K \bullet kg}{mol}$)

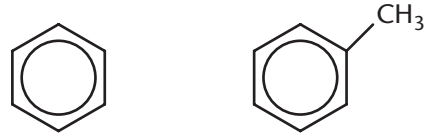
A. $322.58 \frac{g}{mol}$
B. $32.26 \frac{g}{mol}$
C. $123.24 \frac{g}{mol}$
D. $233.59 \frac{g}{mol}$

2. Which phases of solvent and solute can form a solution?

I. Solid solvent, gaseous solute
II. Solid solvent, solid solute
III. Gaseous solvent, gaseous solute

A. I and II only
B. I and III only
C. II and III only
D. I, II, and III

3. Two organic liquids, pictured in the figure below, are combined to form a solution. Based on their structures, will the solution closely obey Raoult's law?



benzene toluene

A. Yes; the liquids differ due to the additional methyl group on toluene and, therefore, will not deviate from Raoult's law.
B. Yes; the liquids are very similar and, therefore, will not deviate from Raoult's law.
C. No; the liquids differ due to the additional methyl group on toluene and, therefore, will deviate from Raoult's law.
D. No; the liquids both contain benzene rings, which will interact with each other and cause deviation from Raoult's law.

4. Which of the following explanations best describes the mechanism by which solute particles affect the melting point of ice?

A. Melting point is elevated because the kinetic energy of the substance increases.
B. Melting point is elevated because the kinetic energy of the substance decreases.
C. Melting point is depressed because solute particles interfere with lattice formation.
D. Melting point is depressed because solute particles enhance lattice formation.

5. The process of formation of a salt solution can be better understood by breaking the process into three steps:

1. Breaking the solute into its individual components
2. Making room for the solute in the solvent by overcoming intermolecular forces in the solvent
3. Allowing solute–solvent interactions to occur to form the solution

Which of the following correctly lists the enthalpy changes for these three steps, respectively?

A. Endothermic, exothermic, endothermic
B. Exothermic, endothermic, endothermic
C. Exothermic, exothermic, endothermic
D. Endothermic, endothermic, exothermic

6. The entropy change when a solution forms can be expressed by the term ΔS°_{soln}. When an ion dissolves and water molecules are ordered around it, the ordering would be expected to make a negative contribution to ΔS°_{soln}. An ion that has more charge density will have a greater hydration effect, or ordering of water molecules. Based on this information, which of the following compounds will have the most negative ΔS°_{soln}?

A. KCl
B. LiF
C. CaS
D. NaCl

7. When ammonia, NH_3, is used as a solvent, it can form complex ions. For example, dissolving AgCl in NH_3 will result in the complex ion $[Ag(NH_3)]^{2+}$. What effect would the formation of complex ions have on the solubility of a compound like AgCl in NH_3?

A. The solubility of AgCl will increase because complex ion formation will cause more ions to exist in solution, which interact with AgCl to cause it to dissociate.
B. The solubility of AgCl will increase because complex ion formation will consume Ag^+ ions and cause the equilibrium to shift away from solid AgCl.
C. The solubility of AgCl will decrease because Ag^+ ions are in complexes, and the Ag^+ ions that are not complexed will associate with Cl^- to form solid AgCl.
D. The solubility of AgCl will decrease because complex ion formation will consume Ag^+ ions and cause the equilibrium to shift toward the solid AgCl.

8. One hundred grams of sucrose are dissolved in a cup of hot water at 80°C. The cup of water contains 300.00 mL of water. What is the percent composition by mass of sugar in the resulting solution? (Note: Sucrose = $C_{12}H_{22}O_{11}$, density of water at 80°C = $0.975 \frac{g}{mL}$)

A. 25.0%
B. 25.5%
C. 33.3%
D. 34.2%

9. Which of the following combinations of liquids would be expected to have a vapor pressure higher than the vapor pressure that would be predicted by Raoult's law?

A. Ethanol and hexane
B. Acetone and water
C. Isopropanol and methanol
D. Nitric acid and water

10. The salt KCl is dissolved in a beaker. To an observer holding the beaker, the solution begins to feel colder as the KCl dissolves. From this observation, one could conclude that:

A. ΔS°_{soln} is large enough to overcome the unfavorable ΔH°_{soln}.
B. KCl is mostly insoluble in water.
C. ΔS°_{soln} must be negative when KCl dissolves.
D. boiling point depression will occur in this solution.

11. Which of the following will cause the greatest increase in the boiling point of water when it is dissolved in 1.00 kg H_2O?

A. 0.46 mol calcium sulfate
B. 0.54 mol iron(III) nitrate
C. 1.09 mol acetic acid
D. 1.11 mol sucrose

12. At sea level and 25°C, the solubility of oxygen gas in water is 1.25×10^{-3} *M*. In Denver, a city in the United States that lies high above sea level, the atmospheric pressure is 0.800 atm. What is the solubility of oxygen in water in Denver?

A. 1.00×10^{-3} *M*
B. 1.05×10^{-3} *M*
C. 1.50×10^{-3} *M*
D. 2.56×10^{-3} *M*

13. Lead is a toxic element that can cause many symptoms, including mental retardation in children. If a body of water is polluted with lead ions at 30 ppb (parts per billion), what is the concentration of lead expressed as molarity? (Note: The density of water is $1 \frac{g}{mL}$, and ppb = grams per 10^9 grams of solution)

A. 1.4×10^{-10} *M* Pb^{2+}
B. 1.4×10^{-7} *M* Pb^{2+}
C. 6.2×10^{-7} *M* Pb^{2+}
D. 6.2×10^{-6} *M* Pb^{2+}

14. A saturated solution of cobalt(III) hydroxide ($K_{sp} = 1.6 \times 10^{-44}$) is added to a saturated solution of thallium(III) hydroxide ($K_{sp} = 6.3 \times 10^{-46}$). What is likely to occur?

A. Both cobalt(III) hydroxide and thallium(III) hydroxide remain stable in solution.
B. Some cobalt(III) hydroxide precipitates and thallium(III) hydroxide remains stable in solution.
C. Some thallium(III) hydroxide precipitates and cobalt(III) hydroxide remains stable in solution.
D. Some of both cobalt(III) hydroxide and thallium(III) hydroxide precipitate.

15. The following equilibrium exists when AgBr ($K_{sp} = 7.7 \times 10^{-13}$) is in solution:

$$AgBr\ (s) \rightleftharpoons Ag^+\ (aq) + Br^-\ (aq)$$

What is the solubility of AgBr in a solution of 0.0010 *M* NaBr?

A. $7.7 \times 10^{-13} \frac{g}{L}$
B. $1.45 \times 10^{-12} \frac{g}{L}$
C. $7.7 \times 10^{-10} \frac{g}{L}$
D. $1.45 \times 10^{-7} \frac{g}{L}$

Explanations to Discrete Practice Questions

1. A

The equation $\Delta T_b = iK_b m$ can be used to solve this problem. The change in boiling point is 101.11 – 100 = 1.11°C. Then, we can plug that into:

$$\Delta T_b = iK_b m \rightarrow m = \frac{\Delta T_b}{iK_b} = \frac{1.11\ \text{K}}{(1)(0.512\ \frac{\text{K} \bullet \text{kg}}{\text{mol}})} \approx 2\ m$$

.

The van 't Hoff factor for this solute is 1 because the molecule does not dissociate into smaller components. Then, we can convert to grams of solute using the definition of molality: molality $= \frac{\text{moles of solute}}{\text{kg of solvent}} \rightarrow$ moles of solute $= (2\ m)(0.1\ \text{kg}) = 0.2$ mol. The mass used in this equation is 0.1 kg because 100 mL of water has a mass of 0.1 kg. Then, we can determine the molar mass: $\text{molar mass} = \frac{70\ \text{g}}{0.2\ \text{mol}} = 350\ \frac{\text{g}}{\text{mol}}$, which is closest to **choice (A)**.

2. D

All three choices can make a solution as long as the two components create a mixture that is of uniform appearance (homogenous). Hydrogen in platinum is an example of a gas in a solid. Brass and steel are examples of homogenous mixtures of solids. The air we breathe is an example of a homogenous mixture of gases; while these are more commonly simply referred to as mixtures, they still fit the criteria of a solution.

3. B

Benzene and toluene are both organic liquids and have very similar properties. They are both nonpolar and are almost exactly the same size. Raoult's law states that ideal solution behavior is observed when solute–solute, solvent–solvent, and solute–solvent interactions are all very similar. Therefore, benzene and toluene in solution will be predicted to behave as a nearly ideal solution.

4. C

Melting point depresses upon solute addition, making **choices (A)** and **(B)** incorrect. Solute particles interfere with lattice formation, the highly organized state in which solid molecules align themselves. Colder-than-normal conditions are necessary to create the solid structure.

5. D

The first step will most likely be endothermic because energy is required to break molecules apart. The second step is also endothermic because the intermolecular forces in the solvent must be overcome to allow incorporation of solute particles. The third step will most likely be exothermic because polar water molecules will interact with the dissolved ions, creating a stable solution and releasing energy.

6. C

CaS will cause the most negative $\Delta S^\circ_{\text{soln}}$ because the Ca^{2+} and S^{2-} ions have the highest charge density compared to the other ions. All of the other ions have charges of +1 or –1,whereas Ca^{2+} and S^{2-} each have charges with a magnitude of 2.

7. B

Formation of complex ions between silver ions and ammonia will cause more molecules of solid AgCl to dissociate. The equilibrium is driven toward dissociation because the Ag^+ ions are essentially being removed from solution when they complex with ammonia. This rationale is based upon Le Châtelier's principle, stating that when a chemical equilibrium experiences a change in concentration, the system will shift to counteract that change.

8. B

The mass percent of a solute equals the mass of the solute divided by the mass of the total solution times 100%. To find the mass of the solution, first find the mass of the solvent, water. Multiplying the volume of the water by the density gives a mass of 292.5 grams of water. Adding 100 grams of sugar yields a solution with a mass of 392.5 grams. Next, divide 100 grams of sugar by 392.5 grams and multiply by 100 to get 25.5%. **Choice (A)** results if water's density at 80°C is assumed to be 1 $\frac{g}{mL}$. While these answers are very close, it is clear that the mass of the water must be slightly *less* than 300 g, given the density value, so the percent composition of sucrose must be slightly *higher* than 25%. If we had forgotten to add the solute's mass to the solvent's, we would have calculated 34.2%, which is **choice (D)**. **Choice (C)** neglects both the addition step and the correct density value.

9. A

Mixtures that have a higher vapor pressure than predicted by Raoult's law have stronger solvent–solvent and solute–solute interactions than solvent–solute interactions. Therefore, particles do not want to stay in solution and more readily evaporate, creating a higher vapor pressure than an ideal solution. Two liquids that have different properties, like hexane (hydrophobic) and ethanol (hydrophilic, small) in **choice (A)**, would not have many interactions with each other and would cause positive deviation. **Choices (B)** and **(C)** are composed of liquids that are similar to one another and would not show significant deviation from Raoult's law. **Choice (D)** contains two liquids that would interact very well with each other, which would actually cause a negative deviation from Raoult's law—when attracted to one other, solutes and solvents prefer to stay in liquid form and have a lower vapor pressure than predicted by Raoult's law.

10. A

Dissolution is governed by enthalpy and entropy, which are related by the equation $\Delta G^\circ_{soln} = \Delta H^\circ_{soln} - T\Delta S^\circ_{soln}$. The cooling of the solution indicates that heat is used up in this bond-breaking reaction. In other words, dissolution is endothermic, and ΔH is positive. The reaction is occurring spontaneously, so ΔG must be negative. The only way that a positive ΔH can result in a negative ΔG is if entropy, ΔS, is a large, positive value as in **choice (A)**. Conceptually, that means that the only way the solid can dissolve is if the increase in entropy is great enough to overcome the increase in enthalpy. **Choice (B)** is incorrect because it is clearly stated in the question stem that KCl dissolves; further, all salts of Group 1 metals are soluble. **Choice (C)** is incorrect because ΔS°_{soln} must be positive in order for KCl to dissolve. Finally, **choice (D)** is incorrect because solute dissolution would cause the boiling point to elevate, not depress. It is also not a piece of evidence that could be found simply by observing the beaker's temperature change.

11. B

The equation to determine the change in boiling point of a solution is as follows: $\Delta T_b = iK_b m$. m is the molality of the solution, and K_b is the boiling point elevation constant. In this case, the solvent is always water, so K_b will be the same for each solution. What we do need to know is how many particles dissociate from each of the original species. This is referred to as the van 't Hoff factor (i) and is multiplied by our molality to demonstrate a normality (the concentration of the species of interest—in this case, all particles). We'll use normality values to determine which will cause the greatest change in boiling point.

Species	Number of Moles	Number of Dissolved Particles	$i \times m$ (Normality)
$CaSO_4$	0.46	2	0.92
$Fe(NO_3)_3$	0.54	4	2.16
CH_3COOH	1.09	Between 1 and 2 (acetic acid is a weak acid and a low percentage of the molecules will dissociate into 2 particles)	Between 1.09 and 2.18
$C_{12}H_{22}O_{11}$	1.11	1	1.11

It looks like we need to decide between iron(III) nitrate and acetic acid. No more calculations are necessary

because the fact that acetic acid is a weak acid tells us that only a few particles will dissociate into H^+ and acetate. Therefore, the normality of the acetic acid will be much closer to 1.09 than 2.18.

12. A

The solubility of gases in liquids is directly proportional to the atmospheric pressure. This is called Henry's law, and is discussed in Chapter 8 of *MCAT General Chemistry Review*. Even without the formula, we know there is a direct proportionality between partial pressure and solubility. Because 0.800 atm is 80% of the pressure at sea level (1 atm), oxygen's solubility will be 80% of 1.25×10^{-3}, which is 1.00×10^{-3} *M*.

13. B

30 ppb of Pb^{2+} is equivalent to 30 grams of Pb^{2+} in 10^9 grams of solution; given the extremely low concentration of lead, we can assume the mass of the water is around 10^9 grams, as well. From here, this is simply a dimensional analysis question. The units we want at the end are moles per liter (molarity), so we must covert from grams of lead to moles of lead and grams of water to liters of water:

$$\left[\frac{30 \text{ g } Pb^{2+}}{10^9 \text{ g } H_2O}\right]\left[\frac{10^3 \text{ g } H_2O}{1 \text{ L}}\right]\left[\frac{1 \text{ mol } Pb^{2+}}{207.2 \text{ g } Pb^{2+}}\right] \approx \frac{3 \times 10^4}{2 \times 10^{11}}$$

$$= 1.5 \times 10^{-7} \ M$$

14. C

Thallium(III) hydroxide has a lower K_{sp} value than cobalt(III) hydroxide. It is important to note that one can assume the molar solubility of thallium(III) hydroxide is lower than cobalt(III) hydroxide only because both salts have a formula MX_3 (one of one particle, three of another). When the solutions are mixed, $[OH^-]$ is at saturation levels in the cobalt solution—which is higher than saturation levels in the thallium solution. Therefore, the ion product for thallium(III) hydroxide is higher than its solubility product constant, and the system will shift left to form solid thallium(III) hydroxide, which precipitates.

15. D

The solubility of AgBr can be determined using the K_{sp} value given in the equation. Some amount of AgBr will dissolve. If we call this amount x, then there will be x amount of silver(I) formed and x amount of bromide—which is added to the 0.0010 *M* already present from NaBr.

$$AgBr \rightleftharpoons Ag^+ + Br^-$$

$$K_{sp} = [Ag^+][Br^-]$$

$$7.7 \times 10^{-13} = (x)(0.0010 \ M + x)$$

Remember that x is always very small. Even though 0.0010 *M* is also very small, it will still be much larger than the value of x on Test Day. Thus, the math can be simplified to: $7.7 \times 10^{-13} = (x)(0.001)$. Therefore, x, the molar solubility, is 7.7×10^{-10}, which looks like **choice (C).** However, the units are grams per liter, not molarity. Thus, we must multiply by the molar mass ($187.8 \frac{g}{mol}$):

$7.7 \times 10^{-10} \frac{mol}{L} \times 187.8 \frac{g}{mol} \approx 7.7 \times 10^{-10} \times 200$

$= 15.4 \times 10^{-8} = 1.54 \times 10^{-7}$, which is close to **choice (D)**.

Concept Summary 359

Introduction

Some medications can be applied as drops, salves, or creams to mucous membranes. Others are injected. Some employ a transdermal patch, while others are swallowed or inhaled. The route of administration of a drug compound is related to both the location of its target tissue (local or systemic), as well as the chemical and physical properties of the compound. For example, compounds that are water-soluble can be administered intravenously (an aqueous solution dripped directly into the bloodstream), while those that are lipid soluble can be administered transcutaneously (via a patch or a cream) or orally (in a pill or liquid suspension). The polarity, size, and charge of the drug compound will determine its solubility in polar or nonpolar environments and will be major contributing factors in determining the most effective and efficient route of administration.

Whether a drug compound has an ionic charge is usually a function of the acidic or basic nature of the compound. For example, a basic organic compound that is insoluble in water when neutral can be reacted with an acid to form a salt; because this salt is ionic, it is water-soluble. Correspondingly, an acidic organic compound that is insoluble in water when neutral can be reacted with a base to form a water-soluble salt. On the other hand, the protonated (acidic cationic) form of an organic compound can be reacted with a base to neutralize the compound and release it from its salt, changing (and usually reversing) its solubility in water.

Medical professionals aren't the only ones concerned about drug solubilities and routes of administration—there's a science to illicit drugs, too. One of the clearest examples of this is the difference between the two major forms of cocaine, a large alkaloid compound derived from the coca plant. Today, cocaine is used primarily in two different forms. Most commonly, the alkaloid compound is reacted with hydrochloric acid (which protonates its tertiary amine functional group), extracted with water, and dried to a water-soluble powder (cocaine hydrochloride); this powder either is snorted (insufflated) into the nasal cavity, where it is absorbed into the capillary beds, or is injected directly into the venous circulation. The salt form has a very high boiling point, which is close to the temperature at which cocaine degrades, and cannot be smoked. To produce a vaporizable form of cocaine that can be inhaled from a pipe, the cocaine hydrochloride must be reacted with a base, typically either ammonia (to produce pure freebase cocaine) or sodium bicarbonate (to produce the less-pure crack cocaine). The base reacts with the protonated tertiary amine, removing the hydrogen ion to reform the neutral alkaloid compound. The freebase cocaine is water insoluble and usually extracted with ether, or it is left in the aqueous solution, which is heated and evaporated. The freebase and crack forms of cocaine have much lower boiling points; consequently, they can be smoked without risk of degradation.

In this chapter, our focus will be those two classes of compounds—acids and bases—that are involved in so many important reactions. Acid–base reactions are an important topic for the MCAT; in fact, neutralization reactions are some of the most commonly tested reaction types on Test Day. We will begin with a review of the different definitions of acids and bases and their properties, including the characterization of acids and bases as either strong or weak. Focusing on weak acids and bases, we will discuss the significance of the equilibrium constants K_a and K_b for acids and bases, respectively. Finally, we will review acid–base titrations and buffer systems.

10.1 Definitions ★★★

Over the last century, chemists have used different definitions to identify compounds as acids or bases. Three definitions emerged, with each more inclusive than the former one.

ARRHENIUS

The first and most specific definition of an acid or base is the Arrhenius definition. An **Arrhenius acid** will dissociate to form an excess of H^+ in solution, and an **Arrhenius base** will dissociate to form an excess of OH^- in solution. These behaviors are generally limited to aqueous acids and bases. Arrhenius acids and bases are

easily identified; acids contain H at the beginning of their formula (HCl, HNO_3, H_2SO_4, and so on) and bases contain OH at the end of their formula (NaOH, $Ca(OH)_2$, $Fe(OH)_3$, and so on).

BRØNSTED–LOWRY

A more inclusive definition of acids and bases was proposed independently by Johannes Brønsted and Thomas Lowry in 1923. A **Brønsted–Lowry acid** is a species that donates hydrogen ions (H^+), while a **Brønsted–Lowry base** is a species that accepts them.

The advantage of this definition over Arrhenius's is that it is not limited to aqueous solutions. For example, OH^-, NH_3, and F^- are all Brønsted–Lowry bases because each has the ability to accept a hydrogen ion. However, neither NH_3 nor F^- can be classified as Arrhenius bases because they do not dissociate to produce an excess of OH^- ions in aqueous solutions. According to both of these definitions, there is only one way for a species to be an acid: producing hydrogen ions. The only differences between the two definitions for acids are the requirement of an aqueous medium in the Arrhenius definition and the acidity of water. In the Arrhenius definition, water is not considered an acid—it does not produce an excess of H^+ in solution. Water is, on the other hand, a Brønsted–Lowry acid because it is able to donate a proton to other species. Most acid–base chemistry reactions on the MCAT will involve the transfer of hydrogen ions in accordance with the Brønsted–Lowry definitions.

Brønsted–Lowry acids and bases always occur in pairs because the definitions require the transfer of a proton from the acid to the base. These are **conjugate acid–base pairs**, as described in the next section. For example, in the autoionization of water, H_3O^+ is the conjugate acid and OH^- is the conjugate base, as shown in Figure 10.1.

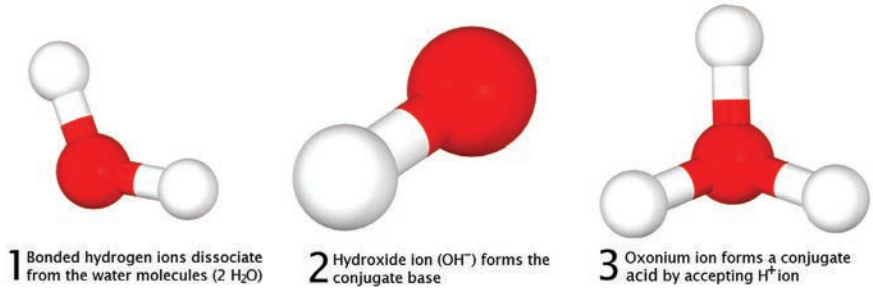

Figure 10.1. Autoionization of Water into Its Conjugate Acid and Conjugate Base

The hydroxide ion is the conjugate base; the oxonium (hydronium) ion is the conjugate acid.

$H_2O\ (l) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + OH^-\ (aq)$

MCAT Expertise

Any mention of the Arrhenius definition on Test Day will likely be in comparison to other definitions of acids. The Arrhenius definition is by far the most restrictive; the Brønsted–Lowry and Lewis definitions predominate on the MCAT.

MCAT Expertise

Every Arrhenius acid (or base) can also be classified as a Brønsted–Lowry acid (or base). Every Brønsted–Lowry acid (or base) can also be classified as a Lewis acid (or base). This logic does not always work the other way (for example, NH_3 is a Brønsted–Lowry base, but not an Arrhenius base).

LEWIS

Mnemonic

A Lewis **a**cid is an **a**cceptor of electron pairs.

At approximately the same time as Brønsted and Lowry's publications, Gilbert Lewis also proposed a definition for acids and bases. A **Lewis acid** is defined as an electron pair acceptor, and a **Lewis base** is defined as an electron pair donor, as shown in Figure 10.2. The electron pair being donated is a lone pair and is not involved in any other bonds.

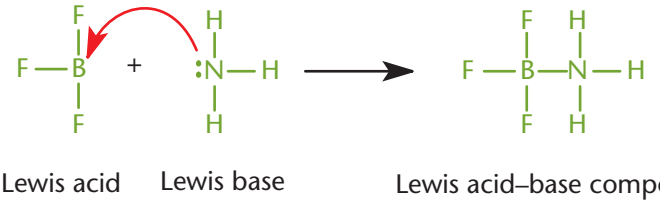

Figure 10.2. Lewis Acid–Base Chemistry
Boron trifluoride serves as the Lewis acid, accepting a lone pair. Ammonia serves as a Lewis base, donating a lone pair.

On the MCAT, Lewis acid–base chemistry appears with many names. The underlying idea is that one species pushes a lone pair to form a bond with another. This same chemistry can be called coordinate covalent bond formation (discussed in Chapter 3 of *MCAT General Chemistry Review*), complex ion formation (discussed in Chapter 9 of *MCAT General Chemistry Review*), or nucleophile–electrophile interactions (discussed in Chapter 4 of *MCAT Organic Chemistry Review*).

There is an intuitive approach to understanding the differences in the definitions we have discussed so far. The Lewis definition relies on a behavior that is not vastly different from the Brønsted–Lowry interactions—the only difference is the focus. For Brønsted–Lowry acids and bases, we follow the exchange of the hydrogen ion (H^+), which is essentially a naked proton. In the Lewis definition, the focus of the reaction is no longer on the proton, but instead the electrons forming the coordinate covalent bond. This difference can be seen using curved arrows, as shown in Figure 10.3.

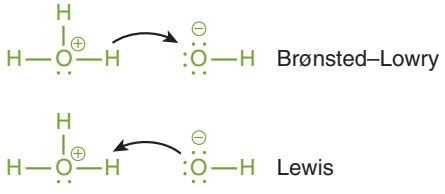

Figure 10.3. Comparison of Brønsted–Lowry and Lewis Definitions of Acids and Bases
In the Brønsted–Lowry definition, the focus is on the transfer of the proton. In the Lewis definition, the focus is on the attack of the Lewis acid (electrophile) by the lone pair of the Lewis base (nucleophile).

Note that the Lewis definition is the most inclusive: every Arrhenius acid is also a Brønsted–Lowry acid, and every Brønsted–Lowry acid is also a Lewis acid (and likewise for bases). However, the converse is not necessarily true. The Lewis definition encompasses some species not included within the Brønsted–Lowry definition; for example, BF_3 and $AlCl_3$ are species that can each accept an electron pair, which qualifies them as Lewis acids, but they lack a hydrogen ion to donate, disqualifying them as both Arrhenius and Brønsted–Lowry acids.

On the MCAT, you may encounter Lewis acids in the context of organic chemistry reactions because Lewis acids are often used as catalysts.

AMPHOTERIC SPECIES

An **amphoteric** species is one that reacts like an acid in a basic environment and like a base in an acidic environment. In the Brønsted–Lowry sense, an amphoteric species can either gain or lose a proton, making it **amphiprotic** as well. On the MCAT, water is the most common example. When water reacts with a base, it behaves as an acid:

$$H_2O + B^- \rightleftharpoons HB + OH^-$$

When water reacts with an acid, it behaves as a base:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

The partially dissociated conjugate base of a polyvalent acid is usually amphoteric. For example, HSO_4^- can either gain a proton to form H_2SO_4 or lose a proton to form SO_4^{2-}. The hydroxides of certain metals (such as Al, Zn, Pb, and Cr) are also amphoteric. Furthermore, species that can act as both oxidizing and reducing agents are often considered to be amphoteric as well because by accepting or donating electron pairs, they act as Lewis acids or bases, respectively.

Complex amphoteric molecules include amino acids that have a *zwitterion* intermediate with both cationic and anionic character, as shown in Figure 10.4. Such species are discussed in great detail in Chapter 1 of *MCAT Biochemistry Review*.

Figure 10.4. Amino Acid Zwitterions Are Complex Amphoteric Species
The amino group can release a proton (acid) and the carboxylate group can accept a proton (base).

Key Concept

Water, amino acids, and partially deprotonated polyprotic acids such as bicarbonate and bisulfate are common examples of amphoteric and amphiprotic substances. Metal oxides and hydroxides are also considered amphoteric but not necessarily amphiprotic because they do not give off protons.

ACID–BASE NOMENCLATURE

The names of most acids are related to the names of their parent anions (the anion that combines with H^+ to form the acid). Acids formed from anions with names that end in *–ide* have the prefix ***hydro–*** and the ending ***–ic***.

F^-	Fluoride	HF	Hydrofluoric acid
Cl^-	Chloride	HCl	Hydrochloric acid
Br^-	Bromide	HBr	Hydrobromic acid

Acids formed from oxyanions are called oxyacids. If the anion ends in *–ite* (less oxygen), then the acid will end with ***–ous acid***. If the anion ends in *–ate* (more oxygen), then the acid will end with ***–ic acid***. Prefixes in the names of the anions are retained. Some common examples include the following:

ClO^-	Hypochlorite	HClO	Hypochlorous acid
ClO_2^-	Chlorite	$HClO_2$	Chlorous acid
ClO_3^-	Chlorate	$HClO_3$	Chloric acid
ClO_4^-	Perchlorate	$HClO_4$	Perchloric acid
NO_2^-	Nitrite	HNO_2	Nitrous acid
NO_3^-	Nitrate	HNO_3	Nitric acid
CO_3^{2-}	Carbonate	H_2CO_3	Carbonic acid
SO_4^{2-}	Sulfate	H_2SO_4	Sulfuric acid
PO_4^{3-}	Phosphate	H_3PO_4	Phosphoric acid
BO_3^{3-}	Borate	H_3BO_3	Boric acid
CrO_4^{2-}	Chromate	H_2CrO_4	Chromic acid
CH_3COO^-	Acetate	CH_3COOH	Acetic acid

MCAT Expertise

There are some exceptions to the nomenclature rules. For instance, MnO_4^- is called permanganate even though there are no MnO_3^- or MnO_2^- ions.

MCAT Concept Check 10.1:

Before you move on, assess your understanding of the material with these questions.

1. Compare and contrast the three definitions for acids and bases:

Definition	Acid	Base
Arrhenius		
Brønsted–Lowry		
Lewis		

2. Utilizing Arrhenius acid naming trends, predict the acid formula and name for the following anions:

Anion	Acid Formula	Acid Name
MnO_4^-		
Titanate (TiO_3^{2-})		
I^-		
IO_4^-		

3. Identify which reactants are amphoteric species in the following reactions. For those species, determine if the compound is also amphiprotic.

Reaction	Amphoteric Reactant	Amphiprotic? (Y or N)
$HCO_3^- + HBr \rightleftharpoons H_2CO_3 + Br^-$		
$3\ HCl + Al(OH)_3 \rightleftharpoons AlCl_3 + 3\ H_2O$		
$2\ HBr + ZnO \rightleftharpoons ZnBr_2 + H_2O$		

10.2 Properties

Acids and bases are usually characterized according to their relative tendencies to either donate or accept hydrogen ions. Furthermore, aqueous acid and base solutions can be characterized according to their concentrations of hydrogen and hydroxide ions.

AUTOIONIZATION OF WATER AND HYDROGEN ION EQUILIBRIA

Because many acid–base reactions take place in water—especially on the MCAT—it is very important to understand the behavior of acidic and basic compounds in water. Only then can one fully appreciate the meaning and significance of such terms as *strong acid*, *weak base*, or measurements of pH and pOH.

The Acid–Base Behavior of Water

As described above, water is an **amphoteric** species: in the presence of a base it reacts as an acid, and in the presence of an acid, it reacts as a base. As an amphoteric compound, water can react with itself in a process called **autoionization**, seen previously in Figure 10.1. The autoionization of water is represented by the equation:

$$H_2O\ (l) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + OH^-\ (aq)$$

One water molecule donates a hydrogen ion to another water molecule to produce the **hydronium ion** (H_3O^+) and the **hydroxide ion** (OH^-). Many general chemistry courses depict the hydrogen ion simply as H^+, rather than as H_3O^+.

This is acceptable for representing the chemistry, but it is important to remember that the proton is never isolated in the solution; it is always attached to water or some other species that has the ability to accept it. Autoionization of water is a reversible reaction; therefore, the expression above is in equilibrium. For pure water at 298 K, the **water dissociation constant**, K_w, has been experimentally determined:

$$K_w = [H_3O^+][OH^-] = 10^{-14} \text{ at } 25°C \text{ (298 K)}$$

Equation 10.1

Each mole of water that autoionizes produces one mole each of hydrogen (or hydronium) ions and hydroxide ions, so the concentrations of the hydrogen ions and hydroxide ions are always equal in pure water at equilibrium. Thus, the concentration of each of the ions in pure water at equilibrium at 298 K is 10^{-7} *M*.

However, the concentrations of the two ions will not always be equal. In fact, they will only be equal when the solution is neutral. Nevertheless, the product of their respective concentrations will always equal 10^{-14} when the temperature of the solution is 298 K. For example, if a species donates hydrogen ions to pure water, the hydrogen ion concentration will increase, causing the system to shift toward the reactants in the autoionization process. The result is a decrease in the hydroxide ion concentration and a return to the equilibrium state. This is Le Châtelier's principle in action: the addition of product to a system at equilibrium causes the system to shift away from the products and toward the reactants. The shift away from the products necessarily decreases the hydroxide ion concentration such that the product of the concentrations of the dissolved ions equals K_w. The addition of a species that accepts hydrogen ions results in a decrease in the hydrogen ion concentration and causes the system to shift toward the products, thereby replacing hydrogen ions. This shift necessarily increases the hydroxide ion concentration and returns the system to equilibrium.

Before we introduce the scales used in measuring concentrations of hydrogen ions and hydroxide ions in different acid–base solutions, it is worthwhile to emphasize an important thermodynamic principle regarding the water dissociation constant (K_w) expression. K_w is an equilibrium constant; unless the temperature of the water is changed, the value for K_w cannot be changed. Thus, the product of the concentrations of the hydrogen ions and the hydroxide ions in an aqueous solution at 298 K must always equal 10^{-14}. However, at different temperatures, the value for K_w changes. At temperatures above 298 K, K_w will increase; this is a direct result of the endothermic nature of the autoionization reaction.

pH and pOH Scales

The concentrations of hydrogen ions and hydroxide ions in aqueous solutions can vary significantly, making the range of measurements on a linear scale

MCAT Expertise

The MCAT loves to test this concept: the value of K_w, like any other equilibrium constant, is dependent only on temperature. Therefore, isolated changes in concentration, pressure, or volume will not affect K_w.

unmanageable. The concentration scales for acidic and basic solutions are condensed into something more manageable through expression in logarithmic terms. These logarithmic scales are the **pH** and the **pOH** scales for the concentrations of hydrogen and hydroxide ions, respectively.

Using a logarithmic scale is not only mathematically convenient, but also useful for calculations. For instance, the reactivity of an acidic solution is not a function of hydrogen ion concentration but instead of the *logarithm* of the hydrogen ion concentration. pH and pOH are prototypical examples of p scales. A **p scale** is defined as the negative logarithm of the number of items.

The pH and pOH of a solution are given by

$$\text{pH} = -\log[\text{H}^+] = \log\frac{1}{[\text{H}^+]}$$

$$\text{pOH} = -\log[\text{OH}^-] = \log\frac{1}{[\text{OH}^-]}$$

Equation 10.2

For pure water at equilibrium and 298 K, the concentration of hydrogen ions equals the concentration of hydroxide ions (10^{-7} *M*). Therefore, pure water at 298 K has a pH of 7 and a pOH of 7 ($-\log 10^{-7} = 7$). If we take the negative logarithm of the entire water dissociation constant expression ($[H_3O^+][OH^-] = 10^{-14}$), we find that

$$\text{pH} + \text{pOH} = 14$$

Equation 10.3

for all aqueous solutions at 298 K. As pH increases, pOH decreases by the same amount. This relationship can be seen in Figure 10.5 below.

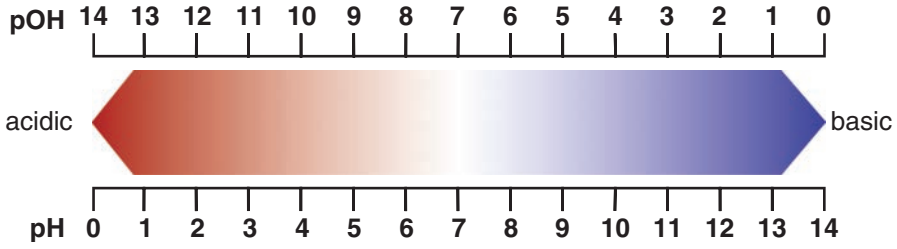

Figure 10.5. pH and pOH Scales
pH + pOH = 14 for aqueous solutions at 298 K.

For an aqueous solution at 298 K, a pH less than 7 (or pOH greater than 7) indicates a relative excess of hydrogen ions, and the solution is acidic; a pH greater than 7 (or pOH less than 7) indicates a relative excess of hydroxide ions, and the solution is basic. A pH (and pOH) equal to 7 indicates equal concentrations of hydrogen and hydroxide ions, resulting in a neutral solution.

Bridge

Logarithmic scales are used to condense very large absolute differences into small scale differences. Remember that sound level (dB) also uses a logarithmic scale, as discussed in Chapter 7 of *MCAT Physics and Math Review*.

MCAT Expertise

The K_w (like all equilibrium constants) will change if the temperature changes and, in turn, will change the significance of the pH scale. Be careful and read the system conditions given on the MCAT: pH = 7 = neutral is only valid at 25°C.

Bridge

In general, math using logarithms frequently appears on the MCAT; make sure to review how these mathematical concepts work in Chapter 10 of *MCAT Physics and Math Review*. Specifically, the equation pH + pOH = 14 comes from the fact that the log of a product is equal to the sum of logs; that is, $\log(xy) = \log x + \log y$.

Estimating Scale Values

An essential skill to hone for Test Day is the ability to quickly convert pH, pOH, pK_a, and pK_b values into nonlogarithmic form and vice-versa.

When the original value is a power of ten, the operation is relatively straightforward: changing the sign on the exponent gives the corresponding p scale value directly. For example, if $[H^+] = 0.001$ or 10^{-3}, then the pH = 3 and pOH = 11. Or, if $K_b = 1.0 \times 10^{-12}$, then $pK_b = 12$.

More difficulty arises when the value is not an exact power of ten. Rest assured that the MCAT is not a math test and is not interested in determining your ability to perform complex logarithmic calculations; an exact logarithmic calculation of a number that is not an integer power of ten is unnecessary on the MCAT. The testmakers are interested, however, in testing the ability to apply mathematical concepts appropriately in solving certain problems.

One can obtain a relatively close approximation of a p scale value using the following shortcut: if the nonlogarithmic value is written in proper scientific notation, it will be in the form $n \times 10^{-m}$, where n is a number between 1 and 10. Taking the negative logarithm and simplifying, the p value will be:

$$\begin{aligned} -\log(n \times 10^{-m}) &= -\log(n) - \log(10^{-m}) \\ &= m - \log(n) \end{aligned}$$

Because n is a number between 1 and 10, its logarithm will be a decimal between 0 and 1 ($\log 1 = 0$ and $\log 10 = 1$). The closer n is to 1, the closer $\log n$ will be to 0; the closer n is to 10, the closer $\log n$ will be to 1. As a reasonable approximation, one can say that

$$\text{p value} \approx m - 0.n$$

Equation 10.4

where $0.n$ represents sliding the decimal point of n one position to the left (dividing n by ten).

Example: If the K_a of an acid is 1.8×10^{-5}, then what is its pK_a?

Solution: $pK_a = -\log(1.8 \times 10^{-5}) = 5 - \log 1.8 \approx 5 - 0.18$
$= 4.82$ (actual = 4.74).

MCAT Expertise

Learning how to estimate when using logarithms is an important skill that can save a lot of time on Test Day.

STRONG ACIDS AND BASES

Strong acids and bases completely dissociate into their component ions in aqueous solutions. For example, when sodium hydroxide is added to water, the ionic compound dissociates according to the net ionic equation:

$$NaOH\ (s) \rightarrow Na^+\ (aq) + OH^-\ (aq)$$

Hence, in a 1 *M* NaOH solution, complete dissociation yields 1 *M* Na^+ and 1 *M* OH^-. The pH and pOH for this solution can be calculated as follows:

$$pH = 14 - pOH = 14 - (-\log[OH^-]) = 14 + \log(1\ M) = 14 + 0 = 14$$

Virtually no undissociated strong acid or base, such as NaOH, will remain in solution. This is why the dissociation of strong acids and bases is said to go to completion. In the NaOH example above, we assume that the concentration of OH^- from the autoionization of water is negligible due to addition of a strong base. The contribution of OH^- and H^+ ions from the autoionization of water is negligible if the concentration of the acid or base is significantly greater than 10^{-7} *M*. On the other hand, if the concentration of acid or base is close to 10^{-7} *M*, then the contribution from the autoionization of water is important.

Example: Calculate the pH of a 1×10^{-8} *M* solution of HCl.

Solution: At first, one may calculate the pH as $-\log [H^+] = -\log 10^{-8}\ M = 8$. However, this answer is not feasible: a pH of 8 cannot describe an acidic solution at 298 K because the presence of the acid will increase the hydrogen ion concentration to above 10^{-7} *M*, resulting in an acidic pH below 7.

Recognize that the acid concentration in this question is actually ten times less than the equilibrium concentration of hydrogen ions in pure water generated by the autoionization of water. Consequently, the hydrogen ion concentration from the water itself is significant and cannot be ignored. This can be represented in the equilibrium expression in which *x* represents the concentration of H_3O^+ and OH^- resulting from the autoionization of water:

$$K_w = [H_3O^+][OH^-] = [x + 10^{-8}][x] = 10^{-14}$$

Solving for *x* (which would require a quadratic equation—math that is beyond the scope of the MCAT) gives $x = 9.5 \times 10^{-8}$ *M*. The total concentration of hydrogen ions is $[H^+]_{total} = (9.5 \times 10^{-8}) + (1.0 \times 10^{-8}) = 1.05 \times 10^{-7}$ *M*. Notice that this is extremely close to the concentration of H^+ in pure water. The pH of this acidic solution can now be calculated as $pH = -\log(1.05 \times 10^{-7}) \approx 7$ (actual = 6.98). This pH is slightly lower than 7, as expected for a very dilute acidic solution. The point of all of this is: *stay alert and keep thinking critically, no matter how familiar the problem setups might seem to you!*

MCAT Expertise

Acid–base reactions that consist of a single-headed arrow generally indicate strong acids or bases (complete dissociation with no reversibility).

Strong acids commonly encountered on the MCAT include HCl (hydrochloric acid), HBr (hydrobromic acid), HI (hydroiodic acid), H_2SO_4 (sulfuric acid), HNO_3 (nitric acid), and $HClO_4$ (perchloric acid). Strong bases commonly encountered include NaOH (sodium hydroxide), KOH (potassium hydroxide), and other soluble hydroxides of Group IA metals. Calculation of the pH and pOH of strong acids and bases assumes complete dissociation of the acid or base in solution.

> **Example:** What is the pH of a solution with $[HClO_4] = 10\ M$?
>
> **Solution:** Because perchloric acid is a strong acid, it will fully dissociate in solution. Therefore, $[H^+] = 10\ M$ (note that the contribution from the autoionization of water is negligible). $pH = -\log [H^+] = -\log 10\ M = -1$. This question points out that the pH scale does not "end" at 0 and 14. There can be negative pH values and pH values greater than 14—but this implies a very high concentration of a strong acid or base.

WEAK ACIDS AND BASES

Before going any further in our discussion of acids and bases as *strong* or *weak*, verify that you are making the distinction between the chemical behavior of an acid or base with respect to its tendency to dissociate (that is, strong bases completely dissociate in aqueous solutions) and the concentrations of acid and base solutions. Although we may casually describe a solution's concentration as *strong* or *weak*, it is preferable to use the terms *concentrated* and *dilute*, respectively, because they are unambiguously associated with concentrations, rather than chemical behavior.

Continuing our focus on the chemical behavior of acids and bases, we will now consider those acids and bases that only partially dissociate in aqueous solutions. These are called **weak acids and bases**. A weak monoprotic acid, HA, will dissociate partially in water to achieve an equilibrium state:

$$HA\ (aq) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + A^-\ (aq)$$

Because the system exists in an equilibrium state, we can write the dissociation equation to determine the **acid dissociation constant** (K_a) as

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

Equation 10.5

The smaller the K_a, the weaker the acid, and consequently, the less it will dissociate. Note that water, as a pure liquid, is not incorporated into the equilibrium expression.

A weak monovalent Arrhenius base, BOH, undergoes dissociation to yield B^+ and OH^- in solution:

$$BOH\,(aq) \rightleftharpoons B^+\,(aq) + OH^-\,(aq)$$

The **base dissociation constant** (K_b) can be calculated as

$$K_b = \frac{[B^+][OH^-]}{[BOH]}$$

Equation 10.6

The smaller the K_b, the weaker the base, and consequently, the less it will dissociate. As with the acid dissociation expression, water is not included because it is a pure liquid.

Generally speaking, we can characterize a species as a weak acid if its K_a is less than 1.0 and as a weak base if its K_b is less than 1.0. On the MCAT, molecular (nonionic) weak bases are almost exclusively amines.

CONJUGATE ACID–BASE PAIRS

Because the Brønsted–Lowry definition of an acid–base reaction is one in which a hydrogen ion (proton) is transferred from an acid to a base, the two always occur in pairs called conjugates. A **conjugate acid** is the acid formed when a base gains a proton, and a **conjugate base** is the base formed when an acid loses a proton. For example,

$$HCO_3^-\,(aq) + H_2O\,(l) \rightleftharpoons CO_3^{2-}\,(aq) + H_3O^+\,(aq)$$

CO_3^{2-} is the conjugate base of HCO_3^-, a weak acid, and H_3O^+ is the conjugate acid of H_2O, a weak base. To find the K_a, we consider the equilibrium concentrations of the dissolved species:

$$K_a = \frac{[CO_3^{2-}][H_3O^+]}{[HCO_3^-]}$$

The reaction between bicarbonate and water is reversible. The reverse reaction would be:

$$CO_3^{2-}\,(aq) + H_2O\,(l) \rightleftharpoons HCO_3^-\,(aq) + OH^-\,(aq)$$

We can write the K_b for CO_3^{2-} as:

$$K_b = \frac{[HCO_3^-][OH^-]}{[CO_3^{2-}]}$$

If one adds the previous two reversible reactions, the net reaction is simply the dissociation of water:

$$\cancel{HCO_3^-} + H_2O \rightleftharpoons \cancel{CO_3^{2-}} + H_3O^+$$
$$\cancel{CO_3^{2-}} + H_2O \rightleftharpoons \cancel{HCO_3^-} + OH^-$$
$$2\,H_2O \rightleftharpoons H_3O^+ + OH^-$$

Because the net reaction is the autoionization of water, the equilibrium constant for the reaction is $K_w = [H_3O^+][OH^-] = 10^{-14}$, which is the product of K_a and K_b. Remember: the product of the concentrations of the hydrogen ion and the hydroxide ion must always equal 10^{-14} for acidic or basic aqueous solutions. Because water is an amphoteric species (both a weak acid and a weak base), all acid–base reactivity in water ultimately reduces to the acid–base behavior of water, and all acidic or basic aqueous solutions are governed by the dissociation constant for water. Thus, if the dissociation constant for one species or its conjugate is known, then the dissociation constant for the other can be determined using the following equations:

$$K_{a,acid} \times K_{b,conjugate\ base} = K_w = 10^{-14}$$
$$K_{b,base} \times K_{a,conjugate\ acid} = K_w = 10^{-14}$$

Equation 10.7

Key Concept

Be aware of the relationship between conjugate acids and bases because you will need to recognize these entities on the MCAT. Removing a proton from a molecule produces the conjugate base, and adding a proton produces the conjugate acid.

As is evident from these equations, K_a and K_b are inversely related. In other words, if K_a is large, then K_b is small, and vice-versa. By this logic, a strong acid (K_a approaching ∞) will produce a very weak conjugate base (for example, HCl is a strong acid and Cl^- is a very weak base), and a strong base will produce a very weak conjugate acid (for example, NaOH is a strong base and H_2O is a very weak acid). The conjugate of a strong acid or base is sometimes termed **inert** because it is almost completely unreactive.

Bridge

This thermodynamic preference for the bicarbonate ion intermediate is a major reason why the bicarbonate buffer system in the body is ideal for maintaining a stable pH. The homeostatic mechanisms involved are discussed in Chapter 6 of *MCAT Biology Review*.

On the other hand, weak acids and bases tend to have conjugates that are also weak. As seen above, CO_3^{2-} is a weak base; its conjugate acid, HCO_3^- is a weak acid. As it turns out, for this specific example, the reaction of CO_3^{2-} with water to produce HCO_3^- and OH^- occurs to a greater extent—is more thermodynamically favorable—than the reaction of HCO_3^- and water to produce CO_3^{2-} and H_3O^+. This fact makes this equilibrium ideal for buffering solutions as part of the bicarbonate buffer system, discussed in Chapter 6 of *MCAT Biology Review*.

One important theme for acid strength is the effect of induction. Electronegative elements positioned near an acidic proton increase acid strength by pulling electron density out of the bond holding the acidic proton. This weakens proton bonding

and facilitates dissociation. Thus, acids that have electronegative elements nearer to acidic hydrogens are stronger than those that do not, as shown in Figure 10.6.

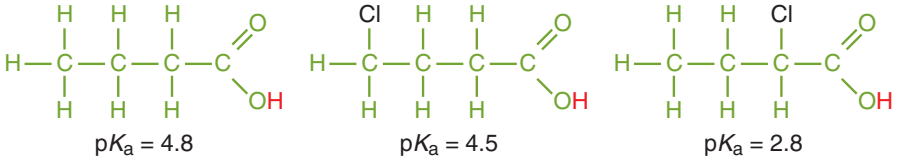

Figure 10.6. Inductive Effects from Electronegative Elements Increase Acidity

APPLICATIONS OF K_a AND K_b

The most common use of acid and base dissociation constants is to determine the concentration of one of the species in solution at equilibrium. On Test Day, you may be asked to calculate the concentration of the hydrogen ion (or pH), the concentration of the hydroxide ion (or pOH), or the concentration of either the original acid or base.

Example: Calculate the concentration of H_3O^+ in a 2.0 *M* aqueous solution of acetic acid, CH_3COOH. (Note: $K_a = 1.8 \times 10^{-5}$)

Solution: First, write the equilibrium reaction:

$$CH_3COOH\ (aq) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + CH_3COO^-\ (aq)$$

Next, write the expression for the acid dissociation constant:

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = 1.8 \times 10^{-5}$$

Then, recognize that acetic acid is a weak acid, so the concentration of CH_3COOH at equilibrium is equal to its initial concentration, 2.0 *M*, minus the amount dissociated, *x*. Likewise, $[H_3O^+] = [CH_3COO^-] = x$ because each molecule of CH_3COOH dissociates into one H^+ ion and one CH_3COO^- ion. Note that the contribution of H_3O^+ from water is negligible. Thus, the equation can be rewritten as follows:

$$K_a = \frac{[x][x]}{[2.0\ M - x]} = 1.8 \times 10^{-5}$$

Remember that the value of *x* is generally very small. Therefore, we can approximate that $2.0\ M - x \approx 2.0\ M$. This is further supported because acetic acid is a weak acid and only slightly dissociates in water. This simplifies the calculations:

$$K_a = \frac{[x][x]}{2.0\ M} = 1.8 \times 10^{-5}$$

$$x^2 = 3.6 \times 10^{-5} = 36 \times 10^{-6}$$

$$x = 6 \times 10^{-3}\ M$$

x represents the concentration of H_3O^+; therefore, $[H_3O^+] = 6 \times 10^{-3}\ M$.

In this example, note that x is significantly lower than the initial concentration of acetic acid (2.0 M), which validates the approximation; otherwise, it would have been necessary to solve for x using the quadratic formula. Fortunately, the value of x on Test Day is almost always sufficiently small to make this approximation. A rule of thumb is that the approximation is valid as long as x is less than 5 percent of the initial concentration. This typically occurs when K_a is at least 100 times smaller than the concentration of the starting solution. For example, if K_a is 10^{-4} and the concentration of the starting solution is 0.01 M (10^{-2} M), then the ratio between the values is 10^2 or 100. The error in this calculation should be no more than $\frac{1}{100} = 1\%$. On the other hand, if the K_a is 10^{-3} and the concentration is still 0.01 M, then the ratio between the values becomes 10, which could lead to $\frac{1}{10} = 10\%$ error. This degree of error may not be useful when identifying an answer choice on the MCAT.

Students often feel nervous making the assumption that x is negligible because they want to see precise answer choices. However, keep in mind that the MCAT quite deliberately tests students' ability to make reasonable assumptions under timed conditions to arrive at a feasible answer choice. Part of the skill of taking the MCAT is rounding appropriately to simplify math.

SALT FORMATION

Bridge

Remember the reaction types discussed in Chapter 4 of *MCAT General Chemistry Review*? Go back and review the section on neutralization reactions if this equation doesn't look familiar to you.

Acids and bases may react with each other to form a salt and often (but not always) water, in what is termed a **neutralization reaction**. For example,

$$HA\ (aq) + BOH\ (aq) \rightarrow BA\ (s) + H_2O\ (l)$$

The salt may precipitate out or remain ionized in solution, depending on its solubility and the amount produced. In general, neutralization reactions go to completion. The reverse reaction, in which the salt ions react with water to give back the acid or base, is known as **hydrolysis**.

Four combinations of strong and weak acids and bases are possible:

- Strong acid + strong base: $HCl + NaOH \rightarrow NaCl + H_2O$
- Strong acid + weak base: $HCl + NH_3 \rightarrow NH_4Cl$
- Weak acid + strong base: $HClO + NaOH \rightarrow NaClO + H_2O$
- Weak acid + weak base: $HClO + NH_3 \rightarrow NH_4ClO$

The products of a reaction between equal concentrations of a strong acid and a strong base are equimolar amounts of salt and water. The acid and base neutralize each other, so the resulting solution is neutral (pH = 7), and the ions formed in the reaction will not react with water because they are inert conjugates.

The product of a reaction between a strong acid and a weak base is also a salt, but often no water will be formed because weak bases are often not hydroxides. In this case, the cation of the salt is a weak acid and will react with the water solvent, re-forming some of the weak base through hydrolysis. For example:

- Reaction I: $HCl\,(aq) + NH_3\,(aq) \rightarrow NH_4^+\,(aq) + Cl^-\,(aq)$
- Reaction II: $NH_4^+\,(aq) + H_2O\,(l) \rightarrow NH_3\,(aq) + H_3O^+\,(aq)$

NH_4^+ is the conjugate acid of a weak base (NH_3) and is stronger than the conjugate base (Cl^-) of the strong acid, HCl. NH_4^+ will then transfer a proton to H_2O to form the hydronium ion. The increase in the concentration of the hydronium ion causes the system to shift away from autoionization, thereby reducing the concentration of hydroxide ion. Consequently, the concentration of the hydronium ion will be greater than that of the hydroxide ion at equilibrium, and as a result, the pH of the solution will fall below 7. This should make sense: a strong acid and a weak base produce a slightly acidic solution.

On the other hand, when a weak acid reacts with a strong base, the pH of the solution at equilibrium will be within the basic range because the salt hydrolyzes, with concurrent formation of hydroxide ions. The increase in hydroxide ion concentration will cause the system to shift away from autoionization, thereby reducing the concentration of the hydronium ion. Consequently, the concentration of the hydroxide ion will be greater than that of the hydronium ion at equilibrium, and as a result, the pH of the solution will rise above 7. Consider the reaction of acetic acid, CH_3COOH (weak acid) with sodium hydroxide, NaOH (strong base):

- Reaction I: $CH_3COOH\,(aq) + NaOH\,(aq) \rightarrow Na^+\,(aq) + CH_3COO^-\,(aq) + H_2O\,(l)$
- Reaction II: $CH_3COO^-\,(aq) + H_2O\,(l) \rightarrow CH_3COOH\,(aq) + OH^-\,(aq)$

The pH of a solution containing a weak acid and a weak base depends on the relative strengths of the reactants. For example, the weak acid HClO has a K_a of 3.2×10^{-8}, and the weak base NH_3 has a $K_b = 1.8 \times 10^{-5}$. Thus, an aqueous solution of HClO and NH_3 is basic because the K_a for HClO is less than the K_b for NH_3. That is, HClO is weaker as an acid than NH_3 is as a base. At equilibrium, therefore, the concentration of hydroxide ions will be greater than the concentration of hydronium ions in the aqueous solution.

In biology and biochemistry, neutralization reactions are often condensation reactions because they form bonds with a small molecule as a byproduct (usually water). The peptide bonds in proteins, for example, are created from the reaction of a carboxyl group (acid) and an amino group (base), while forming a water molecule, as shown in Figure 10.7. The salt in this reaction is the polypeptide itself; breaking it apart requires hydrolysis.

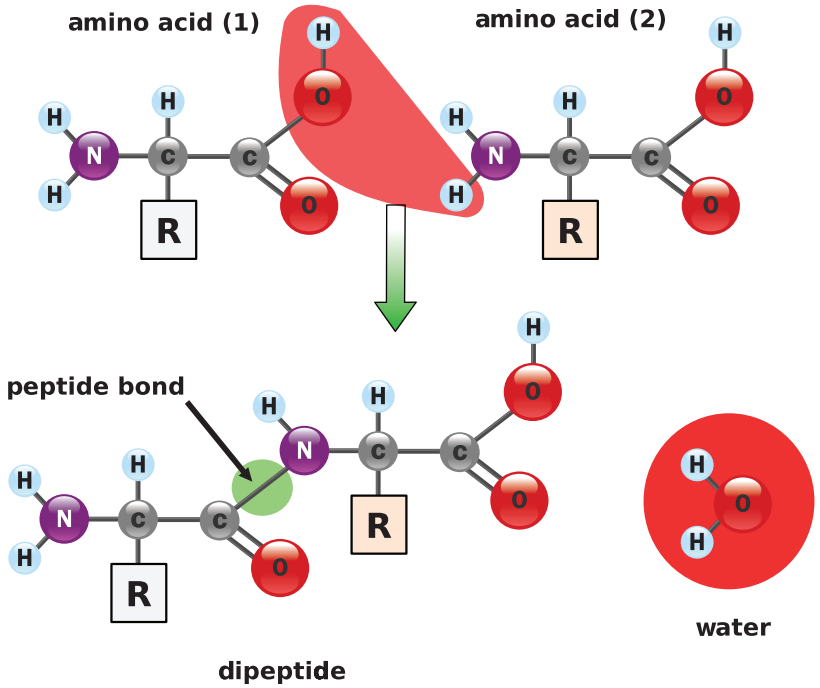

Figure 10.7. Peptide Bond Formation
An acidic carboxyl group reacts with a basic amino group.

MCAT Concept Check 10.2:
Before you move on, assess your understanding of the material with these questions.

1. What is an amphoteric species?

_____

_____

2. If a compound has a K_a value $\gg$ water, what does it mean about its behavior in solution? How does this compare with a solution that has only a slightly higher K_a than water?

_____

_____

3. If a compound has a K_b value $\gg$ water, what does it mean about its behavior in solution? How does this compare with a solution that has only a slightly higher K_b than water?

_____

_____

4. Complete the blank cells in the table by utilizing the mathematical relationships between pH, pOH, and ion concentrations. (Note: Round the numbers given and use logarithmic approximations to determine p values, without a calculator, to simulate Test Day math.)

pH	$[H_3O^+]$	pOH	$[OH^-]$	Acid or Base?
4				
	$8.89 \times 10^{-4}\ M$			
		5.19		
			$1.88 \times 10^{-6}\ M$	

5. What is the mathematical relationship between K_a, K_b, and K_w?

_____

_____

6. Identify the conjugate acid–base pairings in the reactions below:

Reaction	Acid	Base	Conjugate Acid	Conjugate Base
$H_2CO_3 + H_2O \rightleftharpoons HCO_3^- + H_3O^+$				
$H_2PO_4^- + H_2O \rightleftharpoons H_3PO_4 + OH^-$				

7. Determine the concentration of hydrogen ions and pH of a solution of 0.1 *M* acetic acid ($K_a = 1.8 \times 10^{-5}$).

_____

_____

10.3 Polyvalence and Normality ★

The relative acidity or basicity of an aqueous solution is determined by the relative concentrations of acid and base equivalents. An **acid equivalent** is equal to one mole of H^+ (or, more properly, H_3O^+) ions; a **base equivalent** is equal to one mole of OH^- ions. Some acids and bases are **polyvalent**; that is, each mole of the acid or base liberates more than one acid or base equivalent. Under the Brønsted–Lowry definition, such acids or bases could also be termed **polyprotic**. For example, the divalent diprotic acid H_2SO_4 undergoes the following dissociation in water:

$$H_2SO_4\ (aq) + H_2O\ (l) \rightarrow H_3O^+\ (aq) + HSO_4^-\ (aq)$$
$$HSO_4^-\ (aq) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + SO_4^{2-}\ (aq)$$

One mole of H_2SO_4 produces two acid equivalents (2 moles of H_3O^+). Notice that the first dissociation goes to completion, but the second dissociation reaches an equilibrium state. The acidity or basicity of a solution depends on the concentration of acidic or basic equivalents that can be liberated. The quantity of acidic or basic capacity is directly indicated by the solution's **normality**, described in Chapter 9 of *MCAT General Chemistry Review*. For example, each mole of H_3PO_4 yields three moles (equivalents) of H_3O^+. Therefore, a 2 *M* H_3PO_4 solution would be 6 *N*.

Another measurement useful for acid–base chemistry is **gram equivalent weight**. Chapter 4 of *MCAT General Chemistry Review* defined and discussed this term extensively. The gram equivalent weight is the mass of a compound that produces one equivalent (one mole of charge). For example, H_2SO_4 (molar mass: 98 $\frac{g}{mol}$) is a divalent acid, so each mole of the acid compound yields two acid equivalents. The gram equivalent weight is 98 ÷ 2 = 49 grams. That is, the complete dissociation of 49 grams of H_2SO_4 will yield one acid equivalent (one mole of H_3O^+). Common polyvalent acids include H_2SO_4, H_3PO_4, and H_2CO_3. Common polyvalent bases include $Al(OH)_3$, $Ca(OH)_2$, and $Mg(OH)_2$.

Bridge

To review normality in more detail, revisit the calculations performed in Chapter 4 of *MCAT General Chemistry Review*. These are critical calculations for polyvalent acids and bases.

MCAT Concept Check 10.3:

Before you move on, assess your understanding of the material with these questions.

1. What species are considered the equivalents for acids and bases, respectively?
   - Acids: _____
   - Bases: _____
2. Calculate the normality of the following solutions:
   - 2 *M* $Al(OH)_3$: _____
   - 16 *M* H_2SO_4: _____

10.4 Titration and Buffers ★★★★

Titration is a procedure used to determine the concentration of a known reactant in a solution. There are different types of titrations, including acid–base, oxidation–reduction, and complexometric (metal ion). The MCAT frequently tests the first two types. Complexometric (metal ion) titrations are outside the scope of the MCAT but focus on formation of complex ions, as described in Chapter 9 of *MCAT General Chemistry Review*.

GENERAL PRINCIPLES

Titrations are performed by adding small volumes of a solution of known concentration (the **titrant**) to a known volume of a solution of unknown concentration (the **titrand**) until completion of the reaction is achieved at the **equivalence point**.

Acid–Base Equivalence Points

In acid–base titrations, the equivalence point is reached when the number of acid equivalents present in the original solution equals the number of base equivalents added, or vice-versa. It is important to emphasize that, while a strong acid/strong base titration will have its equivalence point at a pH of 7, the equivalence point does *not* always occur at pH 7. When titrating polyprotic acids or bases (discussed later in this chapter), there are multiple equivalence points, as each acidic or basic conjugate species is titrated separately. This is shown in the speciation plot in Figure 10.8.

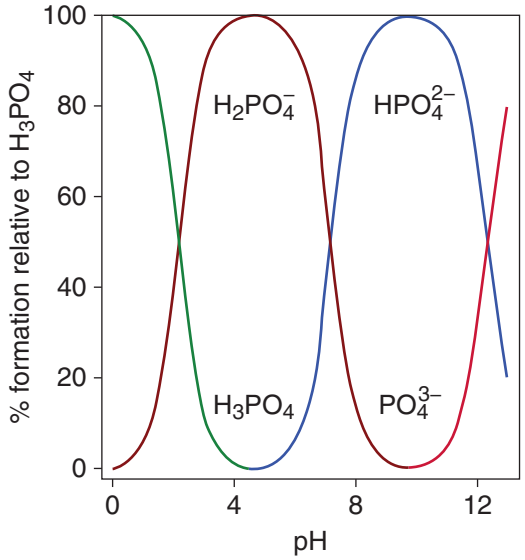

Figure 10.8. Speciation Plot of Phosphoric Acid
At any given pH, only two forms of the acid exist in solution; thus, each conjugate is titrated separately.

At the equivalence point, the number of equivalents of acid and base are equal. This fact allows us to calculate the unknown concentration of the titrand through the equation:

$$N_a V_a = N_b V_b$$

Equation 10.8

where N_a and N_b are the acid and base normalities, respectively, and V_a and V_b are the volumes of acid and base solutions, respectively. Note that, as long as both volumes use the same units, the units used do not have to be liters.

The equivalence point in an acid–base titration is determined in two common ways: evaluated by using a graphical method, plotting the pH of the unknown solution as a function of added titrant by using a **pH meter**, or estimated by watching for a color change of an added **indicator**.

Indicators

Indicators are weak organic acids or bases that have different colors in their protonated and deprotonated states. This small structural change—the binding or release of a proton—leads to a change in the absorption spectrum of the molecule, which we perceive as a color change. Indicators are generally vibrant and can be used in low concentrations without significantly altering the equivalence point. The indicator must always be a weaker acid or base than the acid or base being titrated; otherwise, the indicator would be titrated first! The point at which the indicator changes to its final color is not the equivalence point but rather the **endpoint**. If the indicator is chosen correctly and the titration is performed well, the volume difference between the endpoint and the equivalence point is negligible and may be corrected for or simply ignored.

Acid–base titrations can be performed for different combinations of strong and weak acids and bases. The most useful combinations involve at least one strong species. Weak acid/weak base titrations can be done but are not very accurate and therefore are rarely performed. The pH curve for the titration of a weak acid and weak base lacks the sharp change that normally indicates the equivalence point. Furthermore, indicators are less useful because the pH change is far more gradual.

Key Concept

Indicators change color as they shift between their conjugate acid and base forms

$$\underset{\text{(color 1)}}{\text{H–Indicator}} \rightleftharpoons \text{H}^+ + \underset{\text{(color 2)}}{\text{Indicator}^-}$$

Because this is an equilibrium process, we can apply Le Châtelier's principle. Adding H^+ shifts the equilibrium to the left. Adding OH^- removes H^+ and therefore shifts the equilibrium to the right.

MCAT Expertise

Any question involving the selection of an ideal indicator will require you to know what the pH of the reaction at the equivalence point will be, whether graphically or mathematically. Once you have determined where the equivalence point is, select the indicator that has the closest pK_a value to it.

STRONG ACID AND STRONG BASE

Let's consider the titration of 10 mL of a 0.1 *N* solution of HCl with a 0.1 *N* solution of NaOH. Plotting the pH of the solution *vs.* the quantity of NaOH added gives the curve shown in Figure 10.9.

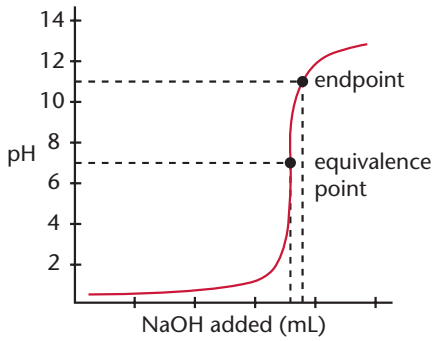

Figure 10.9. Monoprotic Strong Acid and Strong Base Titration Curve
A strong base, NaOH, is titrated into a solution of strong acid, HCl, to yield an equivalence point of pH = 7.

Key Concept

Compare the relative strength of the two solutions in a titration to determine if the pH of the equivalence point is less than, equal to, or greater than 7:

- Strong acid + weak base: equivalence point pH < 7
- Strong acid + strong base: equivalence point pH = 7
- Weak acid + strong base: equivalence point pH > 7

Because HCl is a strong acid and NaOH is a strong base, the equivalence point of the titration will be at pH 7, and the solution will be neutral. Note that the endpoint shown is close to, but not exactly equal to, the equivalence point; selection of a better indicator, one that changes colors at, say, pH 8, would have given a better approximation. Still, the amount of error introduced by the use of an indicator that changes color around pH 11 rather than pH 8 is not especially significant; it represents a mere fraction of a milliliter of excess NaOH solution.

In the early part of the curve when little base has been added, the acidic species predominates, so the addition of small amounts of base will not appreciably change either the $[OH^-]$ or the pH. Similarly, in the last part of the titration curve when an excess of base has been added, the addition of small amounts of base will not change the $[OH^-]$ significantly, and the pH will remain relatively constant. The addition of base will alter the concentrations of H^+ and OH^- near the equivalence point, and will elicit the most substantial changes in pH in that region. Remember: the equivalence point for strong acid/strong base titrations is always at pH 7 (for monovalent species).

If one uses a pH meter to chart the change in pH as a function of volume of titrant added, a good approximation can be made of the equivalence point by locating the midpoint of the region of the curve with the steepest slope.

WEAK ACID AND STRONG BASE

Titration of a weak acid, such as CH_3COOH, with a strong base, such as NaOH, produces the titration curve shown in Figure 10.10.

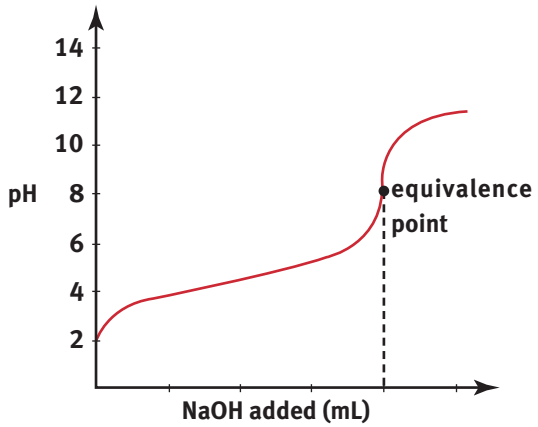

Figure 10.10. Weak Acid and Strong Base Titration Curve
A strong base, NaOH, is titrated into a solution of weak acid, CH_3COOH, to yield an equivalence point of pH > 7.

Compare Figure 10.10 with the curve in Figure 10.9. The first difference is that the initial pH of the weak acid solution is greater than the initial pH of the strong acid solution. Weak acids do not dissociate to the same degree that strong acids do; therefore, the concentration of H_3O^+ will generally be lower (and pH will be higher) in an equimolar solution of weak acid. The second difference is the shapes of the curves. The pH curve for the strong acid/strong base titration shows a steeper, more sudden rise in pH at the equivalence point. In the weak acid/strong base titration, the pH changes gradually early on in the titration and has a less sudden rise at the equivalence point. The third difference is the position of the equivalence point. While the equivalence point for a strong acid/strong base titration is pH 7, the equivalence point for a weak acid/strong base titration is above 7. This is because the reaction between the weak acid (HA) and strong base (OH^-) produces a weak conjugate base (A^-) and even weaker conjugate acid (H_2O). This produces a greater concentration of hydroxide ions than hydrogen ions at equilibrium (due to the common ion effect on the autoionization of water). Therefore, the equivalence point for weak acid/strong base titration is always in the basic range of the pH scale.

STRONG ACID AND WEAK BASE

The appearance of the titration curve for a weak base titrand and strong acid titrant will look like an inversion of the curve for a weak acid titrand and strong base titrant. The initial pH will be in the basic range (typical range: pH 10–12) and will demonstrate a gradual drop in pH with the addition of strong acid. The equivalence point will be in the acidic pH range because the reaction between the weak base and strong acid will produce a weak conjugate acid and even weaker conjugate base, as shown in Figure 10.11. The stronger conjugate acid will result in an equilibrium state with a concentration of hydrogen ions greater than that of the hydroxide ions. Therefore, the equivalence point for a weak base/strong acid titration is always in the acidic range of the pH scale.

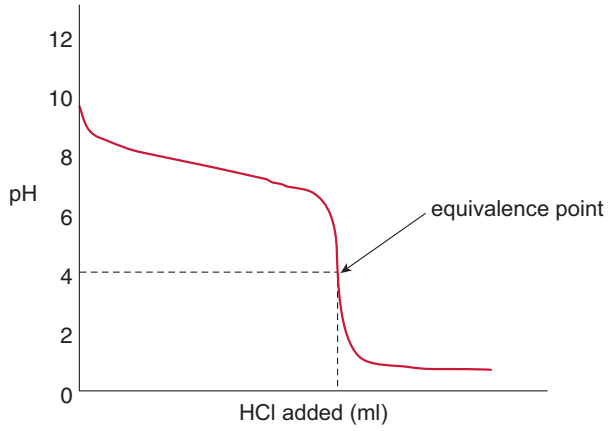

Figure 10.11. Strong Acid and Weak Base Titration Curve
A strong acid, HCl, is titrated into a solution of weak base, NH_3, to yield an equivalence point of pH < 7.

WEAK ACID AND WEAK BASE

The appearance of the titration curve for a weak base titrand and weak acid titrant will look like an intermediate of the previous types discussed. Because both the titrant and the titrand are weak, the initial pH is generally in the 3–11 range and will demonstrate a very shallow drop at the equivalence point. The equivalence point will be near neutral pH because the reaction is partially dissociative for both species.

POLYVALENT ACIDS AND BASES

The titration curve for a polyvalent acid or base looks different from that for a monovalent acid or base. Figure 10.12 shows the titration of Na_2CO_3 with HCl, in which the divalent (diprotic) acid H_2CO_3 is the ultimate product.

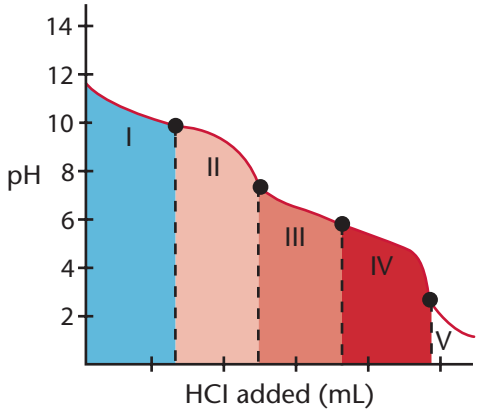

Figure 10.12. Polyvalent Titration
The multiple equivalence points indicate that this is a polyvalent titration.

In region I, little acid has been added, and the predominant species is CO_3^{2-}. In region II, more acid has been added, and the predominant species are CO_3^{2-} and HCO_3^-, in relatively equal concentrations. The flat part of the curve is the first buffer region (discussed in the next section), corresponding to the pK_a of HCO_3^- ($K_a = 5.6 \times 10^{-11}$; $pK_a = 10.25$). The center of the buffer region (the point between regions I and II) is sometimes termed the **half-equivalence point** because it occurs when half of a given species has been protonated (or deprotonated).

Region III begins with the equivalence point, at which all of the CO_3^{2-} is finally titrated to HCO_3^-. As the curve illustrates, a rapid change in pH occurs at the equivalence point (the point between regions II and III). In the latter part of region III, the predominant species is HCO_3^-, although some H_2CO_3 has formed as well.

At the beginning of region IV, the acid has neutralized approximately half of the HCO_3^-, and now H_2CO_3 and HCO_3^- are in roughly equal concentrations. This flat region is the second buffer region (and second half-equivalence point, between regions III and IV) of the titration curve, corresponding to the pK_a of H_2CO_3

MCAT Expertise

To identify which type of titration is being shown in a graph identify the starting position in the graph (pH $\gg$ 7 = titrand is a strong base, $>$ 7 (slightly) = weak base, $<$ 7 (slightly) = weak acid, and $\ll$ 7 pH = strong acid), and determine where the equivalence point is. Think of titrations like tug-of-war: the stronger the acid or base, the more it pulls the equivalence point into its pH territory.

($K_a = 4.3 \times 10^{-7}$; $pK_a = 6.37$). Region V starts with the second equivalence point, as all of the HCO_3^- is finally converted to H_2CO_3. Again, a rapid change in pH is observed near the equivalence point (the point between regions IV and V) as acid is added.

The titrations of the acidic and basic amino acids (which have acidic or basic side chains, respectively) will show curves similar to the one shown in Figure 10.12. But rather than two equivalence points, there will in fact be three: one corresponding to the titration of the carboxyl group and a second corresponding to the titration of the amino group, both of which are attached to the central carbon, as well as a third corresponding to either the acidic or basic side chain.

BUFFERS

A **buffer solution** consists of a mixture of a weak acid and its salt (which is composed of its conjugate base and a cation) or a mixture of a weak base and its salt (which is composed of its conjugate acid and an anion). Two examples of buffers that are common in the laboratory—and commonly tested on the MCAT—are a solution of acetic acid (CH_3COOH) and its salt, sodium acetate ($CH_3COO^-Na^+$), and a solution of ammonia (NH_3) and its salt, ammonium chloride ($NH_4^+Cl^-$). The acetic acid/sodium acetate solution is considered an acid buffer, and the ammonium chloride/ammonia solution is a base buffer. Buffer solutions have the useful property of resisting changes in pH when small amounts of acid or base are added. Consider a buffer solution of acetic acid and sodium acetate: (Note: The sodium ion has not been included because it is not involved in the acid–base reaction.)

$$CH_3COOH\ (aq) + H_2O\ (l) \rightleftharpoons H_3O^+\ (aq) + CH_3COO^-\ (aq)$$

When a small amount of strong base, such as NaOH, is added to the buffer, the OH^- ions from the NaOH react with the H_3O^+ ions present in the solution; subsequently, more acetic acid dissociates (the system shifts to the right), restoring the $[H_3O^+]$. The weak acid component of the buffer thereby serves to neutralize the strong base that has been added. The resulting increase in the concentration of the acetate ion (the conjugate base) does not create nearly as large an increase in hydroxide ions as the unbuffered NaOH would. Thus, the addition of the strong base does not result in a significant increase in $[OH^-]$ and does not appreciably change the pH.

Likewise, when a small amount of HCl is added to the buffer, H^+ ions from the HCl react with the acetate ions to form acetic acid. Acetic acid is weaker than the added hydrochloric acid (which has been neutralized by the acetate ions), so the increased concentration of acetic acid does not significantly contribute to the hydrogen ion concentration in the solution. Because the buffer maintains $[H^+]$ at approximately constant values, the pH of the solution is relatively unchanged.

The Bicarbonate Buffer System

In the human body, one of the most important buffers is the H_2CO_3/HCO_3^- conjugate pair in the plasma component of the blood, called the **bicarbonate buffer system**. Specifically, carbonic acid (H_2CO_3) and its conjugate base, bicarbonate (HCO_3^-), form a weak acid buffer for maintaining the pH of the blood within a fairly narrow physiological range. CO_2 (g), one of the waste products of cellular respiration, also has low solubility in aqueous solutions. The majority of the CO_2 transported from peripheral tissues to the lungs (where it will be exhaled out) is dissolved in the plasma in a "disguised" form through the bicarbonate buffer system. CO_2 (g) and water react in the following manner:

$$CO_2\,(g) + H_2O\,(l) \rightleftharpoons H_2CO_3\,(aq) \rightleftharpoons H^+\,(aq) + HCO_3^-\,(aq)$$

The bicarbonate buffer system is tied to the respiratory system. In conditions of metabolic acidosis (production of excess plasma H^+ not caused by the respiratory system itself), the breathing rate will increase to compensate and blow off a greater amount of carbon dioxide gas; this causes the system to shift to the left, thereby reducing $[H^+]$ and buffering against dramatic and dangerous changes to the blood pH. It is interesting to note that the bicarbonate buffer system ($pK_a = 6.37$) maintains a pH around 7.4, which is actually slightly outside the optimal buffering capacity of the system. Buffers have a narrow range of optimal activity ($pK_a \pm 1$). This actually makes sense—it is far more common for acidemia (too much acid in the blood) to occur than alkalemia (too much base in the blood). As acidemia becomes more severe, the buffer system actually becomes more effective and more resistant to further lowering of the pH.

The Henderson–Hasselbalch Equation

The **Henderson–Hasselbalch equation** is used to estimate the pH or pOH of a buffer solution. For a weak acid buffer solution,

$$pH = pK_a + \log\frac{[A^-]}{[HA]}$$

Equation 10.9

where $[A^-]$ is the concentration of the conjugate base and [HA] is the concentration of the weak acid. Note that when [conjugate base] = [weak acid], the $pH = pK_a$ because $\log(1) = 0$. This occurs at the half-equivalence points in a titration, and buffering capacity is optimal at this pH.

Likewise, for a weak base buffer solution,

$$pOH = pK_b + \log\frac{[B^+]}{[BOH]}$$

Equation 10.10

Real World

A number of conditions can affect the delicate pH balance of tissues in the body, including chronic obstructive pulmonary disease (COPD), renal tubular acidosis (RTA), diabetic ketoacidosis (DKA), lactic acidosis, metabolic diseases, poisonings and ingestions, and hyperventilation. The buffer system must be well maintained to mitigate these changes.

where $[B^+]$ is the concentration of conjugate acid and [BOH] is the concentration of the weak base. Similar to acid buffers, pOH = pK_b when [conjugate acid] = [weak base]. Buffering capacity is optimal at this pOH.

The Henderson–Hasselbalch equation is, in reality, just a rearrangement of the acid (or base) dissociation constant:

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

$$-\log K_a = -\log \frac{[H_3O^+][A^-]}{[HA]}$$

$$-\log K_a = -\log[H_3O^+] - \log \frac{[A^-]}{[HA]}$$

$$pK_a = pH - \log \frac{[A^-]}{[HA]}$$

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

One subtlety of buffer systems and Henderson–Hasselbalch calculations that usually goes unnoticed or is misunderstood by students is the effect of changing the concentrations of the conjugate pair but not changing the ratio of their concentrations. Clearly, changing the ratio of the conjugate base to the acid will lead to a change in the pH of the buffer solution. But what about changing the concentrations while maintaining a constant ratio? What would happen if the concentrations of both the acid and its conjugate base were doubled? While the pH would not change, the **buffering capacity**—the ability to which the system can resist changes in pH—has doubled. In other words, addition of a small amount of acid or base to this system will now cause even less deviation in the pH. As mentioned earlier, the buffering capacity is generally maintained within 1 pH unit of the pK_a value.

Example: What is the pH of a solution made from 1 L of 0.05 *M* acetic acid (CH_3COOH, $K_a = 1.8 \times 10^{-5}$) mixed with 500 mL of 1 *M* acetate (CH_3COO^-)?

Solution: First, determine the concentrations of acetic acid and acetate in the final solution. Because two solutions were mixed, there will be some dilution of both the acetic acid and acetate.

$$N_{i,CH_3COOH}V_{i,CH_3COOH} = N_{f,CH_3COOH}V_{f,CH_3COOH} \rightarrow N_{f,CH_3COOH} = \frac{N_{i,CH_3COOH}V_{i,CH_3COOH}}{V_{f,CH_3COOH}}$$

$$N_{f,CH_3COOH} = \frac{(0.05\,N)(1\,L)}{(1.5\,L)} = 0.033\,N$$

$$N_{i,CH_3COO^-}V_{i,CH_3COO^-} = N_{f,CH_3COO^-}V_{f,CH_3COO^-} \rightarrow N_{f,CH_3COO^-} = \frac{N_{i,CH_3COO^-}V_{i,CH_3COO^-}}{V_{f,CH_3COO^-}}$$

$$N_{f,CH_3COO^-} = \frac{(1\,N)(0.5\,L)}{(1.5\,L)} = 0.33\,N$$

Then, use the Henderson–Hasselbalch equation.

$$pH = pK_a + \log\frac{[A^-]}{[HA]} = -\log(1.8\times10^{-5}) + \log\frac{0.33\,N}{0.033\,N}$$

$$pH \approx 4.82 + 1 = 5.82 \text{ (actual} = 5.74)$$

MCAT Concept Check 10.4:

Before you move on, assess your understanding of the material with these questions.

1. Describe each of the following parts of a titration curve:
   - Buffering region:

     _____
   - Half-equivalence point:

     _____
   - Equivalence point:

     _____
   - Endpoint:

     _____

2. For a reaction involving a strong base and a weak acid, which of the following indicators would be best to indicate the endpoint of the titration? (Circle the correct answer.)
   - Phenolphthalein ($pK_a = 9.7$)
   - Bromothymol blue ($pK_a = 7.1$)
   - Bromocresol green ($pK_a = 4.7$)
   - Methyl yellow ($pK_a = 3.3$)

3. In which part of the pH range (acidic, basic, or neutral) will the equivalence points fall for each of the following titrations?
   - Strong acid + weak base: _____
   - Strong base + weak acid: _____
   - Strong acid + strong base: _____
   - Weak acid + weak base: _____

4. What is the purpose of a buffer solution?

   _____

   _____

5. What are the pH and pOH of a solution containing 5 mL of 5 *M* benzoic acid ($K_a = 6.3 \times 10^{-5}$) and 100 mL of 0.005 *M* benzoate solution?

Conclusion

In this chapter, we have reviewed the important principles of acid–base chemistry. We clarified the differences among the three definitions of acids and bases, including the nomenclature of some common Arrhenius acids. We investigated important properties of acids and bases, including the important acid–base behavior of water (autoionization) and hydrogen ion equilibria. We explained the mathematics of the pH and pOH logarithmic scales and demonstrated a useful Test Day shortcut for approximating the logarithmic value of hydrogen ion or hydroxide ion concentrations. Strong acids and bases are defined as compounds that completely dissociate in aqueous solutions, and weak acids and bases are compounds that only partially dissociate (to an equilibrium state). We discussed neutralization and salt formation upon reaction of acids and bases, and finally, we applied our fundamental understanding of acid–base reactivity to titrations and buffer systems. Titrations are useful for determining the concentration of a known acid or base solution. Weak acid and weak base buffers are useful for minimizing changes in pH upon addition of strong acid or base.

You've just accomplished a major task in the overall effort to earn points on Test Day. It's okay if you didn't understand everything on this first pass. Go back and review the concepts that were challenging for you and then complete the questions at the end of the chapter and MCAT practice passages to test your knowledge. Don't be alarmed if you find yourself reviewing parts or all of a chapter a second or third time—repetition is the key to success.

You are now two chapters away from completing this review of general chemistry. While we don't want to offer our congratulations prematurely, we want to acknowledge all the hard work you've invested in this process. Keep it up: success on Test Day is within your reach!

CONCEPT SUMMARY

Definitions

- **Arrhenius acids** dissociate to produce an excess of hydrogen ions in solution. **Arrhenius bases** dissociate to produce an excess of hydroxide ions in solution.
- **Brønsted–Lowry acids** are species that can donate hydrogen ions. **Brønsted–Lowry bases** are species that can accept hydrogen ions.
- **Lewis acids** are electron-pair acceptors. **Lewis bases** are electron-pair donors.
- All Arrhenius acids and bases are Brønsted–Lowry acids and bases, and all Brønsted–Lowry acids and bases are Lewis acids and bases; however, the converse of these statements is not necessarily true (that is, not all Lewis acids and bases are Brønsted–Lowry acids and bases, and not all Brønsted–Lowry acids and bases are Arrhenius acids and bases).
- **Amphoteric** species are those that can behave as an acid or base. **Amphiprotic** species are amphoteric species that specifically can behave as a Brønsted–Lowry acid or Brønsted–Lowry base.
  - Water is a classic example of an amphoteric, amphiprotic species—it can accept a hydrogen ion to become a hydronium ion, or it can donate a hydrogen ion to become a hydroxide ion.
  - Conjugate species of polyvalent acids and bases can also behave as amphoteric and amphiprotic species.

Properties

- The **water dissociation constant**, K_w, is 10^{-14} at 298 K. Like other equilibrium constants, K_w is only affected by changes in temperature.
- **pH** and **pOH** can be calculated given the concentrations of H_3O^+ and OH^- ions, respectively. In aqueous solutions, pH + pOH = 14 at 298 K.
- **Strong acids and bases** completely dissociate in solution.
- **Weak acids and bases** do not completely dissociate in solution and have corresponding **dissociation constants** (K_a and K_b, respectively).
- In the Brønsted–Lowry definition, acids have conjugate bases that are formed when the acid is deprotonated. Bases have conjugate acids that are formed when the base is protonated.
  - Strong acids and bases have very weak (**inert**) conjugates.
  - Weak acids and bases have weak conjugates.
- **Neutralization reactions** form salts and (sometimes) water.

Polyvalence and Normality

- An **equivalent** is defined as one mole of the species of interest.

- In acid–base chemistry, **normality** is the concentration of acid or base equivalents in solution.

- **Polyvalent** acids and bases are those that can donate or accept multiple electrons. The normality of a solution containing a polyvalent species is the molarity of the acid or base times the number of protons it can donate or accept.

Titration and Buffers

- **Titrations** are used to determine the concentration of a known reactant in a solution.
  - The **titrant** has a known concentration and is added slowly to the titrand to reach the equivalence point.
  - The **titrand** has an unknown concentration but a known volume.
- The **half-equivalence point** is the midpoint of the **buffering region**, in which half of the titrant has been protonated (or deprotonated); thus, $[HA] = [A^-]$ and a buffer is formed.
- The **equivalence point** is indicated by the steepest slope in a titration curve; it is reached when the number of acid equivalents in the original solution equals the number of base equivalents added, or vice-versa.
  - Strong acid and strong base titrations have equivalence points at pH = 7.
  - Weak acid and strong base titrations have equivalence points at pH > 7.
  - Weak base and strong acid titrations have equivalence points at pH < 7.
  - Weak acid and weak base titrations can have equivalence points above or below 7, depending on the relative strength of the acid and base.
- **Indicators** are weak acids or bases that display different colors in their protonated and deprotonated forms.
  - The indicator chosen for a titration should have a pK_a close to the pH of the expected equivalence point.
  - The **endpoint** of a titration is when the indicator reaches its final color.
- Multiple buffering regions and equivalence points are observed in polyvalent acid and base titrations.
- **Buffer solutions** consist of a mixture of a weak acid and its conjugate salt or a weak base and its conjugate salt; they resist large fluctuations in pH.
- **Buffering capacity** refers to the ability of a buffer to resist changes in pH; maximal buffering capacity is seen within 1 pH point of the pK_a of the acid in the buffer solution.
- The **Henderson–Hasselbalch equation** quantifies the relationship between pH and pK_a for weak acids and between pOH and pK_b for weak bases; when a solution is optimally buffered, $pH = pK_a$ and $pOH = pK_b$.

ANSWERS TO CONCEPT CHECKS

10.1

1.

Definition	Acid	Base
Arrhenius	Dissociates to form excess H^+ in solution	Dissociates to form excess OH^- in solution
Brønsted–Lowry	H^+ donor	H^+ acceptor
Lewis	Electron pair acceptor	Electron pair donor

2.

Anion	Acid Formula	Acid Name
MnO_4^-	$HMnO_4$	Permanganic acid
Titanate (TiO_3^{2-})	H_2TiO_3	Titanic acid
I^-	HI	Hydroiodic acid
IO_4^-	HIO_4	Periodic acid

3.

Reaction	Amphoteric Reactant	Amphiprotic? (Y or N)
$HCO_3^- + HBr \rightarrow H_2CO_3 + Br^-$	HCO_3^-	Yes
$3\ HCl + Al(OH)_3 \rightarrow AlCl_3 + 3\ H_2O$	$Al(OH)_3$	No
$2\ HBr + ZnO \rightarrow ZnBr_2 + H_2O$	ZnO	No

10.2

1. An amphoteric species can act as an acid or a base.
2. High K_a indicates a strong acid, which will dissociate completely in solution. Having a K_a slightly greater than water means the acid is a weak acid with minimal dissociation.
3. High K_b indicates a strong base, which will dissociate completely in solution. Having a K_b slightly greater than water means the base is a weak base with minimal dissociation.

4.

pH	$[H_3O^+]$	pOH	$[OH^-]$	Acid or Base?
4	$10^{-4}\ M$	10	$10^{-10}\ M$	Acid
3.05	$8.89 \times 10^{-4}\ M$	10.95	$1.12 \times 10^{-11}\ M$	Acid
8.81	$1.55 \times 10^{-9}\ M$	5.19	$6.46 \times 10^{-6}\ M$	Base
8.27	$5.32 \times 10^{-9}\ M$	5.73	$1.88 \times 10^{-6}\ M$	Base

(Note: exact answers are provided; your rounded answers should be relatively close to those listed here.)

5. $K_a \times K_b = K_w$

6.

Reaction	Acid	Base	Conjugate Acid	Conjugate Base
$H_2CO_3 + H_2O \rightleftharpoons HCO_3^- + H_3O^+$	H_2CO_3	H_2O	H_3O^+	HCO_3^-
$H_2PO_4^- + H_2O \rightleftharpoons H_3PO_4 + OH^-$	H_2O	$H_2PO_4^-$	H_3PO_4	OH^-

7. $K_a = \frac{[CH_3COO^-][H_3O^+]}{[CH_3COOH]} = \frac{[x][x]}{[0.1\,M - x]} \approx \frac{x^2}{0.1}$. Therefore, $x^2 = 1.8 \times 10^{-6} \rightarrow x \approx 1.3 \times 10^{-3}\,M$ (actual = $1.35 \times 10^{-3}\,M$). Then, pH = –log H_3O^+ ≈ 3 – 0.13 = 2.87 (actual = 2.88)

10.3

1. Acids use moles of H^+ (H_3O^+) as an equivalent. Bases use moles of OH^- as an equivalent.
2. 6 *N* $Al(OH)_3$; 32 *N* H_2SO_4

10.4

1. The buffering region occurs when [HA] ≈ [A^-] and is the flattest portion of the titration curve (resistant to changes in pH). The half-equivalence point is the center of the buffering region, where [HA] = [A^-]. The equivalence point is the steepest point of the titration curve, and occurs when the equivalents of acid present equal the equivalents of base added (or vice-versa). The endpoint is the pH at which an indicator turns its final color.
2. Phenolphthalein would be the preferred indicator for this titration.
3. A strong acid and weak base have an equivalence point in the acidic range. A strong base and weak acid have an equivalence point in the basic range. A strong acid and strong base have an equivalence point at pH = 7 (neutral). A weak acid and weak base can have an equivalence point in the acidic, neutral, or basic range, depending on the relative strengths of the acid and base.
4. A buffer solution is designed to resist changes in pH and has optimal buffering capacity within 1 pH point from its pK_a.
5. $$pH = pK_a + \log\frac{[A^-]}{[HA]} = -\log(6.3 \times 10^{-5}) + \log\frac{\left[\frac{(0.005\,N)(100\text{ mL})}{(105\text{ mL})}\right]}{\left[\frac{(5\,N)(5\text{ mL})}{(105\text{ mL})}\right]}$$

$$pH \approx 4.37 + \log\frac{(0.005\,N)(100\text{ mL})}{(5\,N)(5\text{ mL})} = 4.37 + \log\frac{0.5}{25} = 4.37 + \log(2 \times 10^{-2})$$

$$\approx 4.37 - 1.8 = 2.57 \text{ (actual = 2.50)}$$

$$pOH \approx 14 - 2.57 = 11.43 \text{ (actual = 11.50)}$$

EQUATIONS TO REMEMBER

(10.1) **Autoionization constant for water:** $K_w = [H_3O^+][OH^-] = 10^{-14}$ at 25°C (298 K)

(10.2) **Definitions of pH and pOH:** $pH = -\log[H^+] = \log\frac{1}{[H^+]}$

$$pOH = -\log[OH^-] = \log\frac{1}{[OH^-]}$$

(10.3) **Relationship of pH and pOH at 298 K:** pH + pOH = 14

(10.4) **p scale value approximation:** p value ≈ $m - 0.n$

(10.5) **Acid dissociation constant:** $K_a = \frac{[H_3O^+][A^-]}{[HA]}$

(10.6) **Base dissociation constant:** $K_b = \frac{[B^+][OH^-]}{[BOH]}$

(10.7) **Relationship of K_a and K_b at 298 K:** $K_{a,acid} \times K_{b,conjugate\ base} = K_w$;

$$K_{b,base} \times K_{a,conjugate\ acid} = K_w$$

(10.8) **Equivalence point:** $N_aV_a = N_bV_b$

(10.9) **Henderson–Hasselbalch equation (acid buffer):** $pH = pK_a + \log\frac{[A^-]}{[HA]}$

(10.10) **Henderson–Hasselbalch equation (base buffer):** $pOH = pK_b + \log\frac{[B^+]}{[BOH]}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following is not a Brønsted–Lowry base?

A. 
B. F^-

C.

D.

2. Which of the following is closest to the pH of a solution containing 5 m*M* H_2SO_4?

A. 1
B. 2
C. 3
D. 4

3. Which of the following represents chloric acid?

A. $HClO_3$
B. ClO_3^-
C. $HClO_2$
D. HClO

4. Which of the following bases is the weakest?

A. KOH
B. NH_3
C. CH_3NH_2
D. $Ca(OH)_2$

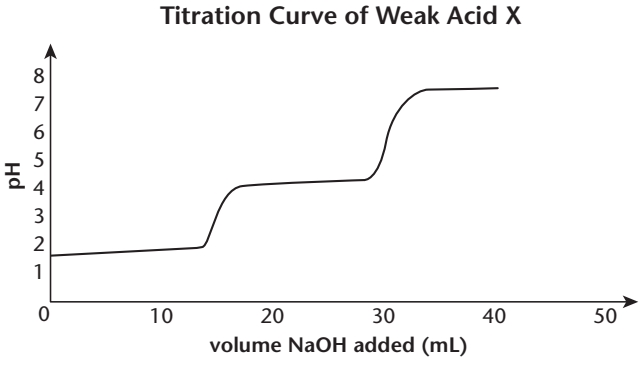
5. The function of a buffer is to:

A. maintain a neutral pH.
B. resist changes in pH when small amounts of acid or base are added.
C. slow down reactions between acids and bases.
D. speed up reactions between acids and bases.

6. What is the pH of a solution with an ammonium concentration of 70 m*M* and an ammonia concentration of 712 m*M*? (Note: The pK_b of ammonia is 3.45.)

A. 2.45
B. 4.45
C. 9.55
D. 11.55

Questions 7–9 refer to the titration curve of acid X shown below:



7. What is the approximate value of pK_{a1}?

A. 1.9
B. 2.9
C. 3.8
D. 4.1

8. At what pH is the second equivalence point?

A. pH = 3.0
B. pH = 4.1
C. pH = 5.9
D. pH = 7.2

9. What is the approximate value of pK_{a2}?

A. 3.6
B. 4.1
C. 5.5
D. 7.2

10. What is the gram equivalent weight of phosphoric acid?

A. 24.5 g
B. 32.7 g
C. 49.0 g
D. 98.0 g

11. What is the $[H_3O^+]$ of a 2 *M* aqueous solution of a weak acid HXO_2 with $K_a = 3.2 \times 10^{-5}$?

A. 6.4×10^{-5} *M*
B. 1.3×10^{-4} *M*
C. 4.0×10^{-3} *M*
D. 8.0×10^{-3} *M*

12. A solution is prepared with an unknown concentration of a theoretical compound with a K_a of exactly 1.0. What is the pH of this solution?

A. Higher than 7
B. Exactly 7
C. Less than 7
D. There is not enough information to answer the question.

13. Which of the following is NOT a characteristic of an amphoteric species?

A. Amphoteric species can act as an acid or a base, depending on its environment.
B. Amphoteric species can act as an oxidizing or reducing agent, depending on its environment.
C. Amphoteric species are sometimes amphiprotic.
D. Amphoteric species are always nonpolar.

14. What is the approximate pH of a 1.2×10^{-5} *M* aqueous solution of NaOH?

A. 4.92
B. 7.50
C. 9.08
D. 12.45

15. How many liters of 2 *M* $Ba(OH)_2$ are needed to titrate a 4 L solution of 6 *M* H_3PO_4?

A. 1.33 L
B. 12 L
C. 18 L
D. 56 L

Explanations to Discrete Practice Questions

1. D

A Brønsted–Lowry base is defined as a proton acceptor. Ammonia, fluoride, and water—**choices (A)**, **(B)**, and **(C)**, respectively—each accept a proton. **Choice (D)**, HNO_2, is a far better Brønsted–Lowry acid, donating a proton to solution.

2. B

First, convert the concentration to $5 \times 10^{-3}\ M$. Next, because sulfuric acid is a strong acid, we can assume that, for the majority of sulfuric acid molecules (although not all), both protons will dissociate. The concentration of hydrogen ions is therefore $2 \times 5 \times 10^{-3}$, or 10^{-2}. The equation for pH is pH = –log $[H^+]$. If $[H^+] = 10^{-2}\ M$, then pH = 2.

3. A

Answering this question is simply a matter of knowing nomenclature. Acids ending in *–ic* are derivatives of anions ending in *–ate,* while acids ending in *–ous* are derivatives of anions ending in *–ite*. ClO_3^-, **choice (B)**, is chlorate because it has more oxygen than the other commonly occurring ion, ClO_2^-, which is named chlorite. Therefore, $HClO_3$ is chloric acid. $HClO_2$, **choice (C)**, represents chlorous acid. HClO, **choice (D)**, represents hypochlorous acid.

4. B

Soluble hydroxides of Group IA and IIA metals are strong bases, eliminating **choices (A)** and **(D)**. **Choices (B)** and **(C)** are both weak bases; however, methylamine contains an alkyl group, which is electron-donating. This increases the electron density on the nitrogen in methylamine, making it a stronger (Lewis) base. Therefore, ammonia is the weakest base.

5. B

The purpose of a buffer is to resist changes in the pH of a reaction. Buffers are not generally used to affect the kinetics of a reaction, so **choices (C)** and **(D)** are incorrect. **Choice (A)** is correct only in specific circumstances where the pH of the buffer solution itself is neutral. Many natural buffer systems maintain pH in the acidic or basic ranges.

6. D

The question is asking for pH, but because of the information given, we must first find the pOH and then subtract it from 14 to get the pH. Use the Henderson–Hasselbalch equation:

$$\text{pOH} = \text{p}K_\text{b} + \log\frac{[\text{conjugate acid}]}{[\text{base}]} = 3.45 + \log\frac{70\ \text{m}M}{712\ \text{m}M}$$

$$\approx 3.45 + \log\frac{1}{10} = 3.45 - 1 = 2.45$$

If the pOH = 2.45, the pH = 14 – 2.45 = 11.55.

7. A

The first pK_a in this curve can be estimated by eye. It is located halfway between the starting point (when no base had yet been added) and the first equivalence point (the first steep portion of the graph, around 15 mL). This point is at approximately 7–8 mL on the *x*-axis, which corresponds to a pH of approximately 1.9. Notice that this region experiences very little change in pH, which is the defining characteristic of a buffer region.

8. C

The second equivalence point is the midpoint of the second steep increase in slope. This corresponds to approximately pH = 5.9.

9. B

The value of the second pK_a is found at the midpoint between the first and second equivalence points. In this curve, that corresponds to pH = 4.1. Just like the first pK_a, it is in the center of a flat buffering region.

10. B

Gram equivalent weight is the weight (in grams) that releases 1 acid or base equivalent from a compound. Because H_3PO_4 contains 3 protons, we find the gram equivalent weight by dividing the mass of one mole of the species by 3. The molar mass of phosphoric acid is 98 $\frac{g}{mol}$, so the gram equivalent weight is 32.7 g.

11. D

This question requires the application of the acid dissociation constant. Weak acids do not dissociate completely; therefore, all three species that appear in the balanced equation will be present in solution. Hydrogen ions and conjugate base anions dissociate in equal amounts, so $[H^+] = [XO_2^-]$. If the initial concentration of HXO_2 was 2 *M* and some amount *x* dissociates, we will have *x* amount of H_3O^+ and XO_2^- at equilibrium, with 2 *M* – *x* amount of HXO_2 at equilibrium.

$$K_a = \frac{[H_3O^+][XO_2^-]}{[HXO_2]} = \frac{(x)(x)}{2\,M - x} \approx \frac{x^2}{2}$$

Note that *x* was considered negligible when added or subtracted, per usual. Solving for *x*, we get:

$$\frac{x^2}{2} = 3.2 \times 10^{-5} \rightarrow x^2 = 6.4 \times 10^{-5} = 64 \times 10^{-6} \rightarrow$$
$$x = 8 \times 10^{-3}\ M$$

12. C

A higher K_a implies a stronger acid. Weak acids usually have a K_a that is several orders of magnitude below 1. The pK_a of a compound is the pH at which there are equal concentrations of acid and conjugate base; the pK_a of this compound would be –log 1 = 0. With such a low pK_a, this compound must be an acid. Therefore, the pH of any concentration of this compound must be below 7.

13. D

An amphoteric species is one that can act either as an acid or a base, depending on its environment. Proton transfers are classic oxidation–reduction reactions, so **choices (A)** and **(B)** are true. **Choice (C)** is true because many amphoteric species, such as water and bicarbonate, can either donate or accept a proton. **Choice (D)** is false, and thus the correct answer because amphoteric species can be either polar or nonpolar in nature.

14. C

NaOH is a strong base; as such, there will be 1.2×10^{-5} *M* OH^- in solution. Based on this information alone, the pOH must be between 4 and 5, and the pH must be between 9 and 10. Using the shortcut, pOH ≈ 5 – 0.12 = 4.88. pH = 14 – pOH = 9.12 (actual = 9.08).

15. C

Use the equivalence point equation: $N_aV_a = N_bV_b$. $Ba(OH)_2$ can dissociate to give two hydroxide ions, so its normality is 2 *M* × 2 = 4 *N*. H_3PO_4 can dissociate to give three hydronium ions, so its normality is 6 *M* × 3 = 18 *N*. Plugging into the equation, we get (18 *N*)(4 L) = (4 *N*)(V_b). Therefore, V_b is 18 L.

Introduction

You're on a night call in the emergency department (ED) when a 5-month-old infant patient's chart appears on your screen. You click through the triage notes and take note of what the mother reports: *poor sucking ability and loss of head control and motor skills*. You're puzzled by the findings and the previous ED admissions of lactic acidosis. You suspect diabetic ketoacidosis (DKA), liver, or kidney diseases—and possibly even poisoning—but nothing seems to fit. Minutes later, the child is brought into the examination room and does not stop crying. Over the course of an hour, another episode of lactic acidosis develops. The child is eventually admitted to the neonatal intensive care unit for long-term care.

Later, you ask the neonatologist about the patient. They point you to the charts and a genetic test performed shortly after birth. The child was diagnosed with Leigh's disease, an extremely rare mitochondrial disorder. In Leigh's disease, a number of key mitochondrial enzymes are disrupted and the process of oxidative phosphorylation is never achieved. Specifically, some of the most important enzymes that catalyze oxidation–reduction reactions, such as the *pyruvate dehydrogenase complex* and *succinate dehydrogenase complex*, are affected. When pyruvate cannot be oxidized to acetyl-CoA, it is instead fermented to lactic acid.

In biological systems, oxidation is coincident with the loss of electrons, sometimes in the form of hydrogen (dehydrogenation). The enzymes that catalyze these oxidations are called *dehydrogenases*. Many other macromolecules besides enzymes, such as vitamins, also carry out their functions by oxidizing or reducing other compounds. Iron in hemoglobin likewise undergoes rounds of oxidation and reduction as it carries oxygen from the lungs to tissues.

In this chapter, we focus our attention on the movement of electrons in chemical reactions. Such reactions are called oxidation–reduction (redox) reactions because they always occur in pairs. Oxidation–reduction reactions are particularly important because they tie into

a number of topics in organic chemistry and biochemistry. In fact, Chapters 5 through 10 of *MCAT Organic Chemistry Review* and Chapters 9 through 11 of *MCAT Biochemistry Review* all touch on oxidation–reduction reactions in different sets of molecules.

11.1 Oxidation–Reduction Reactions ★★

Reactions that involve the transfer of electrons from one chemical species to another can be classified as **oxidation–reduction** (**redox**) **reactions**.

OXIDATION AND REDUCTION

The law of conservation of charge states that electrical charge can be neither created nor destroyed. Thus, an isolated loss or gain of electrons cannot occur; **oxidation** (loss of electrons) and **reduction** (gain of electrons) must occur simultaneously, resulting in an electron transfer called a **redox reaction**. An **oxidizing agent** causes another atom in a redox reaction to undergo oxidation and is itself reduced. A **reducing agent** causes the other atom to be reduced and is itself oxidized. There are various mnemonics to remember these terms, as highlighted in the sidebar.

Being familiar with some common oxidizing and reducing agents can save significant time on Test Day, especially in organic chemistry reactions. Some of the commonly used agents on the MCAT are listed in Table 11.1. Note that almost all oxidizing agents contain oxygen or another strongly electronegative element (such as a halogen). Reducing agents often contain metal ions or hydrides (H^-).

Mnemonic

Redox reactions: choose one of the mnemonics and stick with it!

- **OIL RIG:** **O**xidation **I**s **L**oss of electrons, **R**eduction **I**s **G**ain of electrons.
- **LEO** the lion says **GER:** **L**oss of **E**lectrons is **O**xidation, **G**ain of **E**lectrons is **R**eduction.
- **LEORA** says **GEROA:** **L**oss of **E**lectrons is **O**xidation (**R**educing **A**gent), **G**ain of **E**lectrons is **R**eduction (**O**xidizing **A**gent).

Oxidizing Agents	Reducing Agents
O_2	CO
H_2O_2	C
F_2, Cl_2, Br_2, I_2 (halogens)	B_2H_6
H_2SO_4	Sn^{2+} and other pure metals
HNO_3	Hydrazine*
NaClO	Zn(Hg)*
$KMnO_4$*	Lindlar's catalyst*
CrO_3, $Na_2Cr_2O_7$*	$NaBH_4$*
Pyridinium chlorochromate (PCC)*	$LiAlH_4$*
NAD^+, FADH**	NADH, $FADH_2$**

* These oxidizing agents and reducing agents are commonly seen in organic chemistry reactions.

** These and other biochemical redox reagents often act as energy carriers in biochemistry reactions.

Table 11.1. Common Oxidizing and Reducing Agents

Note that biochemical redox reagents such as NAD^+ tend to act as both oxidizing and reducing agents at different times during metabolic pathways. As such, they act as mediators of energy transfer during many metabolic processes, as shown in Figure 11.1.

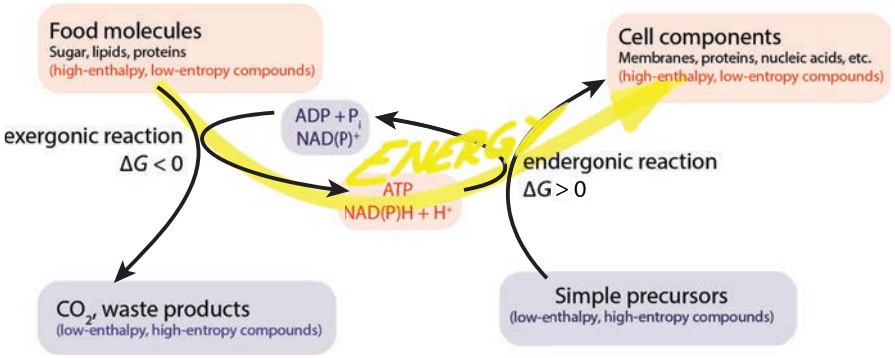

Figure 11.1. Oxidation and Reduction of Biochemical Compounds Serves as a Method of Energy Transfer

On a technical level, the term oxidizing agent or reducing agent is applied specifically to the atom that loses or gains electrons, respectively. However, many science texts will describe the compound as a whole (CrO_3, rather than Cr^{6+}) as the oxidizing or reducing agent.

ASSIGNING OXIDATION NUMBERS

It is important, of course, to know which atom is oxidized and which is reduced. **Oxidation numbers** are assigned to atoms in order to keep track of the redistribution of electrons during chemical reactions. Based on the oxidation numbers of the reactants and products, it is possible to determine how many electrons are gained or lost by each atom.

The oxidation number of an atom in a compound is assigned according to the following rules:

1. *The oxidation number of a free element is zero.* For example, the atoms in N_2, P_4, S_8, and He all have oxidation numbers of zero.
2. *The oxidation number for a monatomic ion is equal to the charge of the ion.* For example, the oxidation numbers for Na^+, Cu^{2+}, Fe^{3+}, Cl^-, and N^{3-} are +1, +2, +3, –1, and –3, respectively.
3. *The oxidation number of each Group IA element in a compound is +1.*
4. *The oxidation number of each Group IIA element in a compound is +2.*

Bridge

In Chapter 3 of *MCAT General Chemistry Review,* we illustrated that metals form cations and nonmetals form anions. To form a cation, a metal must lose electrons. Therefore, metals like to get oxidized (lose electrons) and act as good reducing agents. Nonmetals, on the other hand, like to get reduced (gain electrons) and act as good oxidizing agents.

MCAT Expertise

Think of the oxidation number as the typical charge of an element based on its group number, metallicity, and general location in the periodic table.

Key Concept

The conventions of formula writing put cation first and anion second. Thus HCl implies H^+, and NaH implies H^-. Use the way the compound is written on the MCAT along with the periodic table to determine oxidation states.

MCAT Expertise

Don't forget that you can click on "Periodic table" to pull it up on Test Day. Note the trends for assigning oxidation numbers; these general rules will help reduce the need to memorize individual oxidation numbers. Be aware that the transition metals can take on multiple oxidation states and therefore multiple oxidation numbers.

5. *The oxidation number of each Group VIIA element in a compound is –1, except when combined with an element of higher electronegativity.* For example, in HCl, the oxidation number of Cl is –1; in HOCl, however, the oxidation number of Cl is +1.
6. *The oxidation number of hydrogen is usually +1; however, its oxidation number is –1 in compounds with less electronegative elements (Groups IA and IIA).* Hydrogen is +1 in HCl, but –1 in NaH.
7. *In most compounds, the oxidation number of oxygen is –2.* The two exceptions are peroxides (O_2^{2-}), for which the charge on each oxygen is –1, and compounds with more electronegative elements, such as OF_2, in which oxygen has a +2 charge.
8. *The sum of the oxidation numbers of all the atoms present in a neutral compound is zero. The sum of the oxidation numbers of the atoms present in a polyatomic ion is equal to the charge of the ion.* Thus, for SO_4^{2-}, the sum of the oxidation numbers must be –2.

Oxidation number is often confused with **formal charge**, discussed in Chapter 3 of *MCAT General Chemistry Review*. Both account for the perceived charge on an element, but do so in different ways. Oxidation number assumes unequal division of electrons in bonds, "awarding" the electrons to the more electronegative element. Formal charge, on the other hand, assumes equal division of electrons in bonds, "awarding" one electron to each atom in the bond. In reality, the distribution of electron density lies somewhere between these two extremes. The assigning of oxidation number can be seen in Figure 11.2.

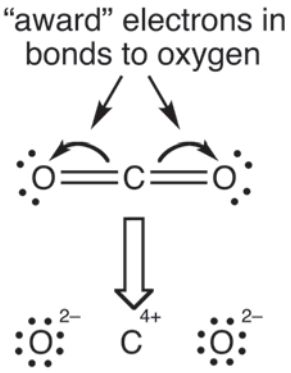

Figure 11.2. Assigning Oxidation Numbers to Carbon Dioxide

When assigning oxidation numbers, start with the known atoms (usually Group I and II, halides, and oxygen) and use this information to determine the oxidation states of the other atoms. Keep in mind that most transition metals can take on multiple oxidation states. When transition metals are oxidized or reduced, the absorption and emission of light from a metal is altered such that different frequencies are absorbed. For this reason, changes of oxidation state in transition metals usually correspond to a color change.

Example: Assign oxidation numbers to the atoms in the following reaction to determine the oxidizing and reducing agents.

$$SnCl_2 + PbCl_4 \rightarrow SnCl_4 + PbCl_2$$

Solution: All of these species are neutral, so the oxidation numbers of each compound must add up to zero. In $SnCl_2$, tin must have an oxidation number of +2 because there are two chlorines present and each chlorine has an oxidation number of –1. Similarly, the oxidation number of Sn in $SnCl_4$ is +4; the oxidation number of Pb is +4 in $PbCl_4$ and +2 in $PbCl_2$.

The oxidation number of Sn goes from +2 to +4; it loses electrons and thus is oxidized, making it the reducing agent. Because the oxidation number of Pb has decreased from +4 to +2, it gains electrons and is reduced, making it the oxidizing agent. The sum of the charges on both sides of the reaction is equal to zero, so charge has been conserved. Keep in mind that oxidation state also plays a role in nomenclature; the reactants in this reaction would be called tin(II) chloride and lead(IV) chloride.

BALANCING OXIDATION–REDUCTION REACTIONS

By assigning oxidation numbers to the reactants and products, one can determine how many moles of each species are required for conservation of charge and mass, which is necessary to balance the equation. To balance a redox reaction, both the net charge and the number of atoms must be equal on both sides of the equation. The most common method for balancing redox equations is the **half-reaction method**, also known as the **ion–electron method**, in which the equation is separated into two half-reactions—the oxidation part and the reduction part. Each half-reaction is balanced separately, and they are then added to give a balanced overall reaction.

Key Concept

Oxidizing agents oxidize *other* molecules, but are themselves *reduced*. Reducing agents reduce *other* molecules, but are themselves *oxidized*. If you determine one ion to be an oxidizing agent then the other must be a reducing agent.

MCAT Expertise

Methodical, step-by-step approaches like the half-reaction method are great for the MCAT. Usually, you will not have to go through *all* of these steps before you can narrow down your answer choices and may be able to find the correct answer partway through the problem with a little critical thinking.

Example: What are the relevant half-reactions for the oxidation of iodide with permanganate, shown below?

$$MnO_4^- + I^- \rightarrow I_2 + Mn^{2+}$$

Step 1: Separate the two half-reactions.

$$I^- \rightarrow I_2$$
$$MnO_4^- \rightarrow Mn^{2+}$$

Step 2: Balance the atoms of each half-reaction. First, balance all atoms except H and O. Next, in an acidic solution, add H_2O to balance the O atoms and then add H^+ to balance the H atoms. In a basic solution, use OH^- and H_2O to balance the O and H atoms.

$$2\,I^- \rightarrow I_2$$
$$MnO_4^- + 8\,H^+ \rightarrow Mn^{2+} + 4\,H_2O$$

Step 3: Balance the charges of each half-reaction. Add electrons as necessary to one side of the reaction so that the charges are equal on both sides.

$$2\,I^- \rightarrow I_2 + 2\,e^-$$
$$MnO_4^- + 8\,H^+ + 5\,e^- \rightarrow Mn^{2+} + 4\,H_2O$$

Step 4: Both half-reactions must have the same number of electrons so that they cancel each other out in the next step. In this example, you need to multiply the oxidation half-reaction by 5 and the reduction half-reaction by 2.

$$10\,I^- \rightarrow 5\,I_2 + 10\,e^-$$
$$2\,MnO_4^- + 16\,H^+ + 10\,e^- \rightarrow 2\,Mn^{2+} + 8\,H_2O$$

Step 5: Add the half-reactions, canceling out terms that appear on both sides of the reaction arrow.

$$2\,MnO_4^- + 16\,H^+ + 10\,I^- \rightarrow 2\,Mn^{2+} + 5\,I_2 + 8\,H_2O$$

Step 6: Confirm that mass and charge are balanced. There is a +4 net charge on each side of the reaction equation, and the atoms are stoichiometrically balanced.

MCAT Concept Check 11.1:

Before you move on, assess your understanding of the material with these questions.

1. For each of the reactions below, identify the oxidation states of the relevant atoms, the oxidizing agent, and the reducing agent:

Reaction	Oxidation Numbers	Oxidizing Agent	Reducing Agent
$2\ KI + H_2 \rightarrow 2\ K + 2\ HI$			
$Al + BPO_4 \rightarrow B + AlPO_4$			

2. Identify the oxidation and reduction half-reactions in the following redox reaction:

$$Zn + Cu^{2+} \rightarrow Zn^{2+} + Cu$$

- Oxidation:

_____

- Reduction:

_____

3. Balance the following redox reaction using the half-reaction method:

$$Mg\ (s) + HNO_3\ (aq) \rightarrow Mg^{2+}\ (aq) + NO\ (g)$$

11.2 Net Ionic Equations ★★

When we discussed reaction types in Chapter 4 of *MCAT General Chemistry Review*, we left out the rationale for why certain elements come together and others do not. Now that we have discussed oxidation–reduction reactions, it should be clearer that the gain and loss of electrons drives the formation of many compounds, especially ionic ones. Below, we will revisit many important reaction types and understand their basis in oxidation–reduction reactions.

OVERVIEW

In our discussion of acids and bases, we focused only on the presence of protons and hydroxide ions, with little concern for which species actually provided those ions. Similarly, in redox reactions, our focus is on the shifting of electrons more so than the identities of the ions themselves. Consider the following single-displacement reaction:

$$Zn\ (s) + CuSO_4\ (aq) \rightarrow Cu\ (s) + ZnSO_4\ (aq)$$

If we split the various species into all of the ions present, we get the **complete ionic equation**:

$$Zn\ (s) + Cu^{2+}\ (aq) + SO_4^{2-}\ (aq) \rightarrow Cu\ (s) + Zn^{2+}\ (aq) + SO_4^{2-}\ (aq)$$

Note that the sulfate ion is present on both sides of the equation in the same form; this ion is chemically inert during this reaction. In other words, the sulfate is not taking part in the overall reaction but simply remaining in the solution unchanged. We call such species **spectator ions**. Because the sulfate ion is not involved in the oxidation–reduction reaction, we can simplify the reaction to its **net ionic equation**, showing only the species that actually participate in the reaction:

$$Zn\ (s) + Cu^{2+}\ (aq) \rightarrow Cu\ (s) + Zn^{2+}\ (aq)$$

MCAT Expertise

Look for compounds such as polyatomic anions that retain their charge before and after reactions; these are usually spectator ions and will *not* be found in the net ionic equation.

When writing net ionic equations, all aqueous compounds should be split into their constituent ions. Solid salts, on the other hand, should be kept together as a single entity. Let's return to some of the other reactions we have seen previously, including combination, decomposition, combustion, and double-displacement (metathesis) reactions.

Combination Reactions

In **combination reactions**, two or more species come together to form a product. For example:

$$\overset{0}{H}_2\ (g) + \overset{0}{F}_2\ (g) \rightarrow 2\ \overset{+1\ -1}{H\,F}\ (aq)$$

The relevant half-reactions would be:

$$H_2 \rightarrow 2\,H^+ + 2\,e^-$$
$$F_2 + 2\,e^- \rightarrow 2\,F^-$$

The net ionic equation is:

$$H_2 + F_2 \rightarrow 2\,H^+ + 2\,F^-$$

In this reaction, molecular hydrogen acts as a reducing agent as it is oxidized from 0 to +1. Molecular fluorine is the oxidizing agent as it is reduced from 0 to –1. In this reaction, there is no spectator ion.

Decomposition Reactions

In **decomposition reactions**, one product breaks down into two or more species. For example:

$$\overset{-3\ +1}{(N\,H_4)_2}\overset{+6\ -2}{Cr_2O_7}\ (aq) \rightarrow \overset{0}{N_2}\ (g) + \overset{+3\ -2}{Cr_2O_3}\ (s) + 4\ \overset{+1\ -2}{H_2O}\ (g)$$

The relevant half-reactions would be:

$$2\ NH_4^+ \rightarrow N_2 + 8\ H^+$$
$$Cr_2O_7 + 8\ H^+ \rightarrow Cr_2O_3 + 4\ H_2O$$

The net ionic equation is:

$$2\ NH_4^+ + Cr_2O_7^{2-} \rightarrow N_2 + Cr_2O_3 + 4\ H_2O$$

In this reaction, the nitrogen atom in the ammonium cation acts as a reducing agent as it is oxidized from –3 to 0. The chromium in the dichromate anion acts as the oxidizing agent as it is reduced from +6 to +3. In this reaction, there is no spectator ion. Note that the net ionic equation is not significantly different from the original balanced equation.

Combustion Reactions

In **combustion reactions**, a fuel (usually a hydrocarbon) is mixed with an oxidant (usually oxygen), forming carbon dioxide and water. For example:

$$\overset{-4\ +1}{C\,H_4}\ (g) + 2\ \overset{0}{O_2}\ (g) \rightarrow \overset{+4\ -2}{C\,O_2}\ (g) + 2\ \overset{+1\ -2}{H_2O}\ (l)$$

The relevant half-reactions would be:

$$CH_4 + 2\ H_2O \rightarrow CO_2 + 8\ H^+ + 8\ e^-$$
$$2\ O_2 + 8\ H^+ + 8\ e^- \rightarrow 4\ H_2O$$

The net ionic equation is identical to the overall balanced equation because there are no spectator ions and no aqueous species:

$$CH_4 + 2\ O_2 \rightarrow CO_2 + 2\ H_2O$$

Combustion reactions can have complex half-reactions, depending on the type of fuel used. In this instance, carbon in methane is the reducing agent as it is oxidized from –4 to +4. Molecular oxygen is the oxidizing agent as it is reduced from 0 to –2.

Double-Displacement (Metathesis) Reactions

Double-displacement or **metathesis reactions** involve the switching of counter-ions. Because all ions generally retain their oxidation state, these are not usually oxidation–reduction reactions. For example:

$$\overset{+1}{\mathrm{Ag}}\overset{-1}{\overbrace{\mathrm{NO_3}}}\,(aq) + \overset{+1}{\mathrm{H}}\overset{-1}{\mathrm{Cl}}\,(aq) \rightarrow \overset{+1}{\mathrm{H}}\overset{-1}{\overbrace{\mathrm{NO_3}}}\,(aq) + \overset{+1}{\mathrm{Ag}}\overset{-1}{\mathrm{Cl}}\,(s)$$

Because all species retain the same oxidation numbers, this is not considered oxidation–reduction. The net ionic reaction would be:

$$\mathrm{Ag^+ + Cl^- \rightarrow AgCl}$$

The nitrate anion and hydrogen cation both act as spectator ions in this reaction.

In double-displacement reactions where both reactants and both products are aqueous, there is no net ionic reaction. For example:

$$\overset{+1}{\mathrm{Na}}\overset{-1}{\overbrace{\mathrm{NO_3}}}\,(aq) + \overset{+1}{\mathrm{H}}\overset{-1}{\mathrm{Cl}}\,(aq) \rightarrow \overset{+1}{\mathrm{H}}\overset{-1}{\overbrace{\mathrm{NO_3}}}\,(aq) + \overset{+1}{\mathrm{Na}}\overset{-1}{\mathrm{Cl}}\,(aq)$$

This reaction is not an oxidation–reduction reaction because no species change their oxidation states. Further, because all species are aqueous, the complete ionic reaction is:

$$\mathrm{Na^+ + NO_3^- + H^+ + Cl^- \rightarrow H^+ + NO_3^- + Na^+ + Cl^-}$$

Because all of the ions appear on both sides of the reaction, there is no net ionic reaction.

DISPROPORTIONATION REACTIONS

Disproportionation (or **dismutation**) is a specific type of redox reaction in which an element undergoes both oxidation and reduction in producing its products. Many biological enzymes utilize a disproportionation mechanism. An example of such a reaction is the catalysis of peroxides by *catalase*, an enzyme found in peroxisomes. Catalase is a critical biological enzyme used to protect cells from excessive oxidation by free radicals or reactive oxygen species. The activity of catalase can be seen when disinfecting a wound with hydrogen peroxide:

$$2\,\overset{+1}{\mathrm{H_2}}\overset{-1}{\mathrm{O_2}}\,(aq) \xrightarrow[\text{catalase}]{} 2\,\overset{+1}{\mathrm{H_2}}\overset{-2}{\mathrm{O}}\,(l) + \overset{0}{\mathrm{O_2}}\,(g)$$

As can be seen from this reaction, oxygen is disproportioned between water and molecular oxygen. In hydrogen peroxide, each oxygen has an oxidation state of –1 (the peroxide ion has a charge of –2 overall). In water, oxygen has an oxidation state

of –2, and in molecular oxygen, it has an oxidation state of 0. Therefore, the oxygen is both reduced and oxidized in this reaction.

Another related biological disproportionation mechanism is that of the enzyme *superoxide dismutase*. As the name implies, a *dismutase* catalyzes dismutation. This enzyme disproportions oxygen free radicals in the reaction

$$2\,\overset{-\frac{1}{2}}{O_2^{\bullet -}} + 2\,\overset{+1}{H^+} \rightarrow \overset{+1}{H_2}\overset{-1}{O_2} + \overset{0}{O_2}$$

where peroxide and oxygen are the disproportioned products. The oxidation state of oxygen in the free radical is $-\frac{1}{2}$ (a negative charge divided over two oxygen atoms), and it is reduced to –1 in the peroxide and oxidized to 0 in molecular oxygen.

Biochemical disproportionation reactions—and oxidation–reduction reactions in biological systems in general—are usually accomplished by enzymes. Structurally, these enzymes often have metals such as Cu and Zn in their active sites that act as reducing agents, as shown in Figure 11.3.

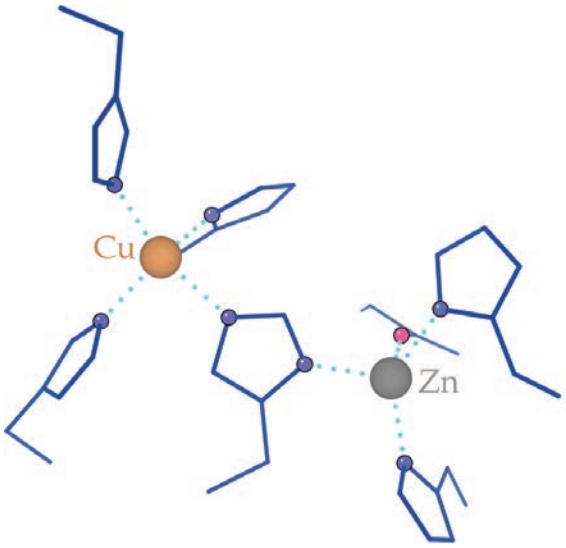

Figure 11.3. Active Site of Superoxide Dismutase
Cu and Zn atoms act as reducing agents, losing electrons during catalysis. The atoms are stabilized in position by histidine residues.

OXIDATION–REDUCTION TITRATIONS

Oxidation–reduction titrations are similar in setup to acid–base titrations, but the focus is different. Whereas acid–base titrations follow the movement of protons, as discussed in Chapter 10 of *MCAT General Chemistry Review*, redox titrations follow the transfer of charge (as electrons) to reach the equivalence point. Redox

titrations can utilize indicators that change color at a particular voltage (emf) value. Some common indicators are listed in Table 11.2. As for acid–base titrations, it is not necessary to memorize these indicators, but rather to understand their utility.

Indicator	Voltage of Color Change	Oxidized Form	Reduced Form
Bipyridine metal complexes	About +1 V	Colorless (Ru), Cyan (Fe)	Yellow (Ru), Red (Fe)
Diphenylamine	+0.76 V	Violet	Colorless
Safranin	+0.24 /−0.29 V*	Red-Violet	Colorless

* Safranin is unique in that its color change is not only voltage dependent, but also pH dependent.

Table 11.2. Common Indicators for Oxidation–Reduction (Redox) Titrations

One prototypical redox titration involves the use of starch indicators to identify iodine complexes. This specific redox titration is called an iodimetric titration because it relies on the titration of free iodine radicals. The presence of iodine is initially determined by a dark solution in the presence of starch, and at the endpoint of the titration, a colorless solution develops. A common general chemistry laboratory experiment involves the standardization of a thiosulfate solution using iodimetry, as described in the example below.

Example: A group of students prepares to standardize a $Na_2S_2O_3$ solution. 32 mL of the $Na_2S_2O_3$ solution is titrated into 50 mL of a 0.01 *M* KIO_3 solution to reach the equivalence point. They first titrate the KIO_3 solution until it loses color, then add a starch indicator until the reaction is complete. The reaction proceeds in these two steps:

$$IO_3^- + I^- + H^+ \rightarrow I_3^- + H_2O$$
$$I_3^- + S_2O_3^{2-} \rightarrow I^- + S_4O_6^{2-}$$

Determine the concentration of the sodium thiosulfate solution at the beginning of the experiment.

Solution: The titration is performed in two steps. In the first step, the iodate is converted into triiodide anions. The initial titration creates a colorless I_3^- solution in water, which then requires a starch indicator for the remainder of the titration.

In the second step, the triiodide ions are then reduced in the presence of thiosulfate to determine its concentration. Note that the reactions are unbalanced. It would be tempting to balance the first equation as

$$IO_3^- + 2I^- + 6H^+ \rightarrow I_3^- + 3H_2O$$

However, this reaction has a charge of +3 on the reactants side and −1 on the products side. In oxidation–reduction chemistry, we must balance not only for stoichiometry but also for charge. The correct balanced equations are:

$$IO_3^- + 8I^- + 6H^+ \rightarrow 3I_3^- + 3H_2O$$
$$I_3^- + 2S_2O_3^{2-} \rightarrow 3I^- + S_4O_6^{2-}$$

Keeping in mind that each iodate is used to make three triiodide anions, and each triiodide anion interacts with two thiosulfate anions, the mole ratio of thiosulfate to iodate is six to one:

$$IO_3^- + 8I^- + 6H^+ \rightarrow 3I_3^- + 3H_2O$$
$$3I_3^- + 6S_2O_3^{2-} \rightarrow 9I^- + 3S_4O_6^{2-}$$

Then, use stoichiometry to determine the molarity of the thiosulfate solution from the 50 mL potassium iodate solution.

$$0.01\,M\,IO_3^-\left[0.05\,L\right]\left[\frac{6\,mol\,S_2O_3^{2-}}{1\,mol\,IO_3^-}\right] = 3 \times 10^{-3}\,mol$$

Now, we can use the volume to find the molarity.

$$M_{S_2O_3^{2-}} = \frac{3\times10^{-3}\,mol}{32\,mL\left[\frac{1\,L}{1000\,mL}\right]} = \frac{3\times10^{-3}}{32\times10^{-3}} = \frac{3}{32} \approx 0.1\,M\,(\text{actual} = 0.094\,M)$$

Potentiometric titration is a form of redox titration where no indicator is used. Instead, the electrical potential difference (voltage) is measured using a voltmeter. As a redox titration progresses, its voltage changes; this is analogous to following an acid–base titration with a pH meter instead of a color indicator.

MCAT Concept Check 11.2:

Before you move on, assess your understanding of the material with these questions.

1. Write the net ionic equations for the reactions below:

   - $CuNO_3\ (aq) + NaCl\ (aq) \rightarrow CuCl\ (s) + NaNO_3\ (aq)$

   _____

   - $Mg\ (s) + AlCl_3\ (aq) \rightarrow Al\ (s) + MgCl_2\ (aq)$

   _____

2. In each of the reactions below, which element undergoes disproportionation? What are that element's oxidation states in the products?

   $3\ Cl_2\ (g) + 6\ NaOH\ (aq) \rightarrow 5\ NaCl\ (aq) + NaClO_3\ (aq) + 3\ H_2O\ (l)$

   - Element undergoing disproportionation:

   _____

   - Oxidation states in products:

   _____

   $S_2O_3^{2-}\ (aq) + 2\ H^+\ (aq) \rightarrow S\ (s) + SO_2\ (g) + H_2O\ (l)$

   - Element undergoing disproportionation:

   _____

   - Oxidation states in products:

   _____

3. A sample is assayed for lead by a redox titration with $I_3^-\ (aq)$. A 10.00 g sample is crushed, dissolved in sulfuric acid, and passed over a reducing agent so that all the lead is in the form Pb^{2+}. The $Pb^{2+}\ (aq)$ is completely oxidized to Pb^{4+} by 32.60 mL of a 0.7 *M* solution of NaI_3. The balanced equation for the reaction is:

   $$I_3^-\ (aq) + Pb^{2+}\ (aq) \rightarrow Pb^{4+}\ (aq) + 3\ I^-\ (aq)$$

   Calculate the mass of lead in the sample.

Conclusion

In this chapter, we covered the essential MCAT topic of oxidation–reduction reactions. We reviewed the rules for assigning oxidation numbers to help us keep track of the movement of electrons from the species that are oxidized (reducing agents) to the species that are reduced (oxidizing agents). We also covered the sequence of steps involved in balancing half-reactions, redox titrations, and disproportionation reactions.

In addition to understanding the fundamental chemical principles behind these reactions, you will begin to see these concepts resurface in *MCAT Organic Chemistry Review* and *MCAT Biochemistry Review*. Oxidation–reduction reactions are often used for energy transfer in biological systems, and any deficiencies in such systems are profoundly deleterious (such as metabolic, mitochondrial, and immunologic diseases). Our next chapter—the last of *MCAT General Chemistry Review*—brings the principles of oxidation–reduction reactions to their application in electrochemical cells. By the end of the next chapter, you will have reviewed all of the general chemistry knowledge required for Test Day!

CONCEPT SUMMARY

Oxidation–Reduction Reactions

- **Oxidation** is a loss of electrons, and **reduction** is a gain of electrons; the two are paired together in what is known as an **oxidation–reduction** (**redox**) reaction.
- An **oxidizing agent** facilitates the oxidation of another compound and is reduced itself in the process; a **reducing agent** facilitates the reduction of another compound and is itself oxidized in the process.
  - Common oxidizing agents almost all contain oxygen or a similarly electronegative element.
  - Common reducing agents often contain metal ions or hydrides (H^-).
- To assign oxidation numbers, one must know the common oxidation states of the representative elements.
  - Any free element or diatomic species has an oxidation number of zero.
  - The oxidation number of a monatomic ion is equal to the charge of the ion.
  - When in compounds, Group IA metals have an oxidation number of +1; Group IIA metals have an oxidation number of +2.
  - When in compounds, Group VIIA elements have an oxidation number of –1 (unless combined with an element with higher electronegativity).
  - The oxidation state of hydrogen is +1 unless it is paired with a less electronegative element, in which case it is –1.
  - The oxidation state of oxygen is usually –2, except in peroxides (when its charge is –1) or in compounds with more electronegative elements.
  - The sum of the oxidation numbers of all the atoms present in a compound is equal to the overall charge of that compound.
- When balancing redox reactions, the **half-reaction method**, also called the **ion–electron method**, is the most common.
  - Separate the two half-reactions.
  - Balance the atoms of each half-reaction. Start with all the elements besides H and O. In acidic solution, balance H and O using water and H^+. In basic solution, balance H and O using water and OH^-.
  - Balance the charges of each half-reaction by adding electrons as necessary to one side of the reaction.
  - Multiply the half-reactions as necessary to obtain the same number of electrons in both half-reactions.

- Add the half-reactions, canceling out terms on both sides of the reaction arrow.
- Confirm that the mass and charge are balanced.

Net Ionic Equations

- A **complete ionic equation** accounts for all of the ions present in a reaction. To write a complete ionic reaction, split all aqueous compounds into their relevant ions. Keep solid salts intact.
- **Net ionic equations** ignore spectator ions to focus only on the species that actually participate in the reaction. To obtain a net ionic reaction, subtract the ions appearing on both sides of the reaction, which are called **spectator ions**.
  - For reactions that contain no aqueous salts, the net ionic equation is generally the same as the overall balanced reaction.
  - For double displacement (metathesis) reactions that do not form a solid salt, there is no net ionic reaction because all ions remain in solution and do not change oxidation number.
- **Disproportionation** (**dismutation**) **reactions** are a type of redox reaction in which one element is both oxidized and reduced, forming at least two molecules containing the element with different oxidation states.
- **Oxidation–reduction titrations** are similar in methodology to acid–base titrations. These titrations follow transfer of charge.
  - Indicators used in such titrations change color when certain voltages of solutions are achieved.
  - **Potentiometric titration** is a form of redox titration in which a voltmeter or external cell measures the electromotive force (emf) of a solution. No indicator is used, and the equivalence point is determined by a sharp change in voltage.

ANSWERS TO CONCEPT CHECKS

11.1

1.

Reaction	Oxidation Numbers	Oxidizing Agent	Reducing Agent
$2\,KI + H_2 \rightarrow 2\,K + 2\,HI$	$2\overset{+1\,-1}{K\,I} + \overset{0}{H_2} \rightarrow 2\overset{0}{K} + 2\overset{+1\,-1}{H\,I}$	K^+ (charge goes from +1 to 0)	H_2 (charge goes from 0 to +1)
$Al + BPO_4 \rightarrow B + AlPO_4$	$\overset{0}{Al} + \overset{+3}{B}\overbrace{\overset{-3}{PO_4}} \rightarrow \overset{0}{B} + \overset{+3}{Al}\overbrace{\overset{-3}{PO_4}}$	B^{3+} (charge goes from +3 to 0)	Al (charge goes from 0 to +3)

2. Oxidation: $Zn \rightarrow Zn^{2+} + 2\,e^-$
   Reduction: $Cu^{2+} + 2\,e^- \rightarrow Cu$

3.
1. $\begin{cases} Mg \rightarrow Mg^{2+} \\ HNO_3 \rightarrow NO \end{cases}$
2. $\begin{cases} Mg \rightarrow Mg^{2+} \\ HNO_3 + 3\,H^+ \rightarrow NO + 2\,H_2O \end{cases}$
3. $\begin{cases} Mg \rightarrow Mg^{2+} + 2\,e^- \\ HNO_3 + 3\,H^+ + 3\,e^- \rightarrow NO + 2\,H_2O \end{cases}$
4. $\begin{cases} 3\,Mg \rightarrow 3\,Mg^{2+} + 6\,e^- \\ 2\,HNO_3 + 6\,H^+ + 6\,e^- \rightarrow 2\,NO + 4\,H_2O \end{cases}$
5. $2\,HNO_3 + 3\,Mg + 6\,H^+ \rightarrow 2\,NO + 3\,Mg^{2+} + 4\,H_2O$

11.2

1. $Cu^+ + Cl^- \rightarrow CuCl$

   $3\,Mg + 2\,Al^{3+} \rightarrow 3\,Mg^{2+} + 2\,Al$ (don't forget to balance the reaction!)

2. In the first reaction, chlorine undergoes disproportionation to have a –1 oxidation state in NaCl and a +5 oxidation state in $NaClO_3$.
   In the second reaction, sulfur undergoes disproportionation to have a 0 oxidation state in elemental sulfur and +4 oxidation state in SO_2.

3. $0.7\,M\ I_3^-\left[32.60\times10^{-3}\ L\right]\left[\frac{1\ mol\ Pb^{2+}}{1\ mol\ I_3^-}\right]\left[\frac{207.2\ g\ Pb^{2+}}{1\ mol\ Pb^{2+}}\right] \approx 0.7\times3\times2 = 4.2\ g$

   (actual = 4.73 g)

Analyzing Organic Reactions

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Consider the following equation:

$$6\ Na\ (s) + 2\ NH_3\ (aq) \rightarrow 2\ Na_3N\ (s) + 3\ H_2\ (g)$$

Which species acts as an oxidizing agent?

A. Na
B. N in NH_3
C. H in NH_3
D. H_2

2. How many electrons are involved in the following half-reaction after it is balanced?

$$Cr_2O_7^{2-} + H^+ + e^- \rightarrow Cr^{2+} + H_2O$$

A. 2
B. 8
C. 12
D. 16

3. Lithium aluminum hydride ($LiAlH_4$) is often used in laboratories because of its tendency to donate a hydride ion. Which of the following roles would lithium aluminum hydride likely play in a reaction?

A. Strong reducing agent only
B. Strong oxidizing agent only
C. Both a strong reducing agent and strong oxidizing agent
D. Neither a strong reducing agent nor a strong oxidizing agent

4. What is the oxidation number of chlorine in NaClO?

A. –1
B. 0
C. +1
D. +2

5. The following electronic configurations represent elements in their neutral form. Which element is the strongest oxidizing agent?

A. $1s^22s^22p^63s^23p^64s^2$
B. $1s^22s^22p^63s^23p^64s^23d^5$
C. $1s^22s^22p^63s^23p^64s^23d^{10}4p^1$
D. $1s^22s^22p^63s^23p^64s^23d^{10}4p^5$

6. Which of the following is the correct net ionic reaction for the reaction of copper with silver(I) nitrate?

A. $Cu + AgNO_3 \rightarrow Cu(NO_3)_2 + Ag$
B. $Cu + 2\ Ag^+ + 2\ NO_3^- \rightarrow Cu^{2+} + 2\ NO_3^- + 2\ Ag$
C. $2\ Ag^+ + 2\ NO_3^- \rightarrow 2\ NO_3^- + 2\ Ag^+$
D. $Cu + 2\ Ag^+ \rightarrow Cu^{2+} + 2\ Ag$

7. One way to test for the presence of iron in solution is by adding potassium thiocyanate to the solution. The product when this reagent reacts with iron is $FeSCN^{2+}$, which creates a dark red color in solution via the following net ionic equation:

$$Fe^{3+} + SCN^- \rightarrow FeSCN^{2+}$$

How many grams of iron sulfate would be needed to produce 2 moles of $FeSCN^{2+}$?

A. 110 g
B. 220 g
C. 400 g
D. 500 g

8. During the assigning of oxidation numbers, which of the following elements would most likely be determined last?

A. Ar
B. F
C. Sr
D. Ir

9. As methanol is converted to methanal, and then methanoic acid, the oxidation number of the carbon:

A. increases.
B. decreases.
C. increases, then decreases.
D. decreases, then increases.

10. In the compound KH_2PO_4, which element has the highest oxidation number?

A. K
B. H
C. P
D. O

11. If a certain metal has multiple oxidation states, its acidity as an oxide generally increases as the oxidation state increases. Therefore, which of the following tungsten compounds is likely to be the strongest acid?

A. WO_2
B. WO_3
C. W_2O_3
D. W_2O_5

12. Consider the following steps in the reaction between oxalic acid and chlorine:

I. $Cl_2 + H_2O \rightarrow HOCl + Cl^- + H^+$
II. $H_2C_2O_4 \rightarrow H^+ + HC_2O_4^-$
III. $HOCl + HC_2O_4^- \rightarrow H_2O + Cl^- + 2\ CO_2$

Which of these steps, occurring in aqueous solution, is an example of a disproportionation reaction?

A. I only
B. III only
C. I and III only
D. I, II, and III

13. Potentiometry in an oxidation–reduction titration is analogous to performing an acid–base titration with a(n):

A. acidic indicator.
B. basic indicator.
C. pH meter.
D. oxidizing agent.

14. After balancing the following oxidation–reduction reaction, what is the sum of the stoichiometric coefficients of all of the reactants and products?

$$S_8\ (s) + NO_3^-\ (aq) \rightarrow SO_3^{2-}\ (aq) + NO\ (g)$$

A. 4
B. 50
C. 91
D. 115

15. An assay is performed to determine the gold content in a supply of crushed ore. One method for pulling gold out of ore is to react it in a concentrated cyanide (CN^-) solution. The equation is provided below:

$$Au + NaCN + O_2 + H_2O \rightarrow Na[Au(CN)_2] + NaOH$$

An indicator is used during this reaction, and approximately 100 mL of a 2 *M* NaCN solution is used to reach the endpoint. How many moles of Au are present in the crushed ore?

A. 0.01 mol
B. 0.02 mol
C. 0.10 mol
D. 0.20 mol

Explanations to Discrete Practice Questions

1. C

The oxidizing agent is the species that is reduced in any given equation. In this problem, six hydrogen atoms with +1 oxidation states in NH_3 are reduced to three neutral H_2 molecules.

2. B

First, balance the atoms in the equation:

$$Cr_2O_7^{2-} + 14\ H^+ \rightarrow 2\ Cr^{2+} + 7\ H_2O$$

Now, adjust the number of electrons to balance the charge. Currently, the left side has a charge of +12 (–2 from dichromate and +14 from protons). The right side has a charge of +4 (+2 from each chromium cation). To decrease the charge on the left side from +12 to +4, we should add 8 electrons:

$$Cr_2O_7^{2-} + 14\ H^+ + 8\ e^- \rightarrow 2\ Cr^{2+} + 7\ H_2O$$

3. A

Hydride ions are composed of a hydrogen nucleus with two electrons, thereby giving it a negative charge and a considerable tendency to donate electrons. $LiAlH_4$ is therefore a strong reducing agent. Strong reducing agents tend to have metals or hydrides; strong oxidizing agents tend to have oxygen or a similarly electronegative element.

4. C

In NaClO (sodium hypochlorite), sodium carries its typical +1 charge, and oxygen carries its typical –2 charge. This means that the chlorine atom must carry a +1 charge in order to balance the overall charge of zero.

5. D

A strong oxidizing agent will be easily reduced, meaning that it will have a tendency to gain electrons. Atoms usually gain electrons if they are one or two electrons away from filling up their valence shell. **Choice (A)** has a full 4*s*-orbital, meaning that it can only gain an electron if it gains an entire subshell. **Choice (B)** has a stable, half-full 3*d*-orbital, so it is unlikely to pick up electrons unless it can gain five. **Choice (C)** has only a single electron in the outer shell, which is more likely lost upon ionization. **Choice (D)** would fill up its 4*p*-orbital by gaining one electron, so it is easily reduced.

6. D

A net ionic equation represents each of the aqueous ions comprising the reactants and products as individual ions, instead of combining them as formula units. Thus, **choice (A)** is not a net ionic reaction. The term *net* means that the correct answer does not include any spectator ions (ions that do not participate in the reaction). In this reaction, nitrate (NO_3^-) remains unchanged. Therefore, **choices (B)** and **(C)** are eliminated.

7. C

What you are shown is a net ionic equation. If two moles of FeSCN are created, two moles of Fe^{3+} must be used because the mole ratio is 1:1. Read the question stem carefully—we are asked for the mass of iron sulfate that is necessary, not the amount of iron, which would be 111.6 g, **choice (A)**. Iron sulfate has the formula $Fe_2(SO_4)_3$ because sulfate has a charge of –2 and iron has a charge of +3 (based on the net ionic equation). Therefore, one mole of iron sulfate is needed to make two moles of iron for the reaction. The molar

mass of iron sulfate is $2 \times 55.8 \frac{g}{mol} + 3 \times 32.1 \frac{g}{mol} + 12 \times 16.0 \frac{g}{mol} = 399.9 \frac{g}{mol}$.

8. D

When assigning oxidation numbers, one starts with elements of known oxidation state first, and determines the oxidation state of the other elements by deduction. As a noble gas, argon, **choice (A)**, will always have an oxidation state of 0. As a group VIIA element, fluorine, **choice (B)**, will have an oxidation state of 0 (by itself) or –1 (in a compound). As a group IIA element, strontium, **choice (C)**, will have an oxidation state of 0 (by itself) or +2 (in a compound). Like most transition metals, iridium, **choice (D)**, can have various oxidation states, ranging from –3 to +8. Therefore, one would have to determine the oxidation states of other atoms in an iridium-containing compound to determine iridium's oxidation number.

9. A

The formula for methanol is H_3COH, for methanal is H_2CHO, and for methanoic acid is HCOOH. If we assign oxidation numbers to carbon in each molecule, it starts at –2, then becomes 0, then becomes +2:

$$\overset{+1}{H_3}\overset{-2}{C}\overset{-2}{O}\overset{+1}{H} \rightarrow \overset{+1}{H}\overset{0}{C}\overset{+1}{H}\overset{-2}{O} \rightarrow \overset{+1}{H}\overset{+2}{C}\overset{-2}{O}\overset{-2}{O}\overset{+1}{H}$$

In general, it is often easier to think of oxidation as a gain of bonds to oxygen (or a similarly electronegative element) or loss of bonds to hydrogen for organic compounds. Therefore, because the carbon is oxidized as one converts from an alcohol to an aldehyde to a carboxylic acid, the oxidation number must increase.

10. C

Start with the atoms that have oxidation states of which you are certain. Potassium is a Group IA metal, and therefore must have an oxidation state of +1. Hydrogen is almost always +1, unless it is paired with a less electronegative element (which is not the case here). Oxygen is generally –2. Because there are four oxygens, they create a total negative charge of –8 which is partially balanced by two hydrogens (+2) and potassium (+1). Therefore, phosphorus has a +5 charge, making it the highest oxidation state.

11. B

Recall that oxygen has an oxidation state of –2. Therefore, in tungsten(IV) oxide, **choice (A)**, tungsten has an oxidation state of +4. In tungsten(VI) oxide, **choice (B)**, it has an oxidation state of +6. In tungsten(III) oxide, **choice (C)**, it is +3. In tungsten pentoxide, **choice (D)**, it is +5.

12. A

Step I is a disproportionation reaction because chlorine starts with an oxidation state of 0 in the reactants and ends up with an oxidation state of +1 in HOCl and –1 as Cl^-. In the other reactions, no element appears with different oxidation states in two different products. Therefore, only step I is a disproportionation reaction.

13. C

Potentiometry refers to carrying out an oxidation–reduction titration with a voltmeter present to get precise readings of the reaction's electromotive force (emf) to determine the endpoint. This is analogous to using a pH meter in an acid–base titration because it uses technology to get precise readings for plotting a titration curve. Indicators, as in **choices (A)** and **(B)**, can be used in both acid–base and redox titrations, but provide a qualitative (rather than quantitative) analysis of the titration. Oxidizing and reducing agents are used in redox titrations, not acid–base titrations, eliminating **choice (D)**.

14. D

Utilize the method described earlier to balance this redox reaction. The balanced half-reactions are:

$$S_8 + 24\,H_2O \rightarrow 8\,SO_3^{2-} + 48\,H^+ + 32\,e^-$$
$$NO_3^- + 4\,H^+ + 3\,e^- \rightarrow NO + 2\,H_2O$$

To get equal numbers of electrons in each half-reaction, the oxidation half-reaction will have to be multiplied by 3, and the reduction half-reaction will have to be multiplied by 32:

$$3\,S_8 + 72\,H_2O \rightarrow 24\,SO_3^{2-} + 144\,H^+ + 96\,e^-$$
$$32\,NO_3^- + 128\,H^+ + 96\,e^- \rightarrow 32\,NO + 64\,H_2O$$

This makes the overall reaction:

$$3\,S_8 + 32\,NO_3^- + 8\,H_2O \rightarrow 24\,SO_3^{2-} + 32\,NO + 16\,H^+$$

The sum of the stoichiometric coefficients is therefore 3 + 32 + 8 + 24 + 32 + 16 = 115.

15. C

First, balance the chemical equation:

$$4\,Au + 8\,NaCN + O_2 + 2\,H_2O \rightarrow 4\,Na[Au(CN)_2] + 4\,NaOH$$

Now, determine the number of moles of NaCN used in the reaction:

$$0.1\text{ L} \times 2\,\frac{\text{mol}}{\text{L}} = 0.2\text{ mol NaCN}$$

If 0.2 mol NaCN are used in the reaction, then $0.2\text{ mol NaCN} \times \frac{4\text{ mol Au}}{8\text{ mol NaCN}} = 0.1$ mol Au is oxidized.

Introduction

The mitochondria are powerhouses of energy. The primary purpose of the mitochondrion is to manufacture a deliverable and usable form of energy. By now, you are well aware of the complex processes by which the potential energy in the chemical bonds of carbohydrates, amino acids, and lipids is converted into the potential energy of the phosphate bond in adenosine triphosphate (ATP). ATP is then delivered to different parts of the cell, where it is used to energize most of the processes essential to the maintenance of life.

The mitochondria generate tremendous amounts of ATP—in humans, the average daily turnover of ATP is more than 50 kilograms! Without a continuous supply and replenishment of ATP, we wouldn't survive. ATP powers the contraction of our heart muscle and maintains the membrane potential essential for neurological function, among thousands of other essential roles. How do the mitochondria manufacture these packets of life-sustaining energy? Remember that mitochondria rely on their double-membrane structure to carry out the electron transport chain and oxidative phosphorylation. As such, mitochondria truly act as batteries of the cell. In fact, note the similarity between the proton-motive force of the mitochondria and the electromotive force of electrochemistry. Are these two terms the same thing or—at the very least—similar in nature?

Indeed, mitochondria and batteries do function in similar ways. Specifically, mitochondria function most similarly to a concentration cell. In both concentration cells and mitochondria, a concentration gradient of ions between two separated compartments—connected to each other by some means of charge conduction—establishes an electrical potential difference (voltage). This voltage, called electromotive force in

a concentration cell and proton-motive force in the mitochondria, provides the drive to move charge from one compartment to the other, creating current. In the concentration cell, an oxidation–reduction reaction takes place, and electrons move in the direction that causes the concentration gradient to be dissipated. In the mitochondria, the charge buildup is in the form of a hydrogen ion (proton) gradient between the intermembrane space and the matrix. Embedded in the inner membrane is ATP synthase, which serves a dual role as a proton channel and a catalyst for the formation of the high-energy phosphate bond in ATP. As the hydrogen ions flow down their electrochemical gradient, energy is dissipated, and this energy is harnessed by ATP synthase to form ATP.

In this final chapter of *MCAT General Chemistry Review*, we will focus our attention on the study of various electrochemical cells. Utilizing our knowledge of oxidation–reduction reactions from Chapter 11 of *MCAT General Chemistry Review*, we will study how these principles can be applied to create different types of electrochemical cells, including galvanic (voltaic), electrolytic, and concentration cells. Regarding the thermodynamics of electrochemistry, we will focus on the significance of reduction potentials and examine the relationship between electromotive force, the equilibrium constant, and Gibbs free energy.

12.1 Electrochemical Cells ★★★★

Electrochemical cells are contained systems in which oxidation–reduction reactions occur. There are three fundamental types of electrochemical cells: galvanic cells (also known as voltaic cells), electrolytic cells, and concentration cells. In addition, there are specific commercial cells such as Ni–Cd batteries through which we can understand these fundamental models.

Mnemonic

Electrodes in a electrochemical cell: **AN OX** and a **RED CAT**

The **an**ode is the site of **ox**idation; **red**uction occurs at the **cat**hode.

Galvanic cells and concentration cells house spontaneous reactions, whereas electrolytic cells contain nonspontaneous reactions. Remember that spontaneity is indicated by the change in Gibbs free energy, ΔG. All three types contain **electrodes** where oxidation and reduction take place. For all electrochemical cells, the electrode where oxidation occurs is called the **anode**, and the electrode where reduction occurs is called the **cathode**. Other descriptors of electrochemical cells include the **electromotive force** (**emf**), which corresponds to the voltage or electrical potential difference of the cell. If the emf is positive, the cell is able to release energy ($\Delta G < 0$), which means it is spontaneous. If the emf is negative, the cell must absorb energy ($\Delta G > 0$), which means it is nonspontaneous.

Furthermore, we can also state that, for all electrochemical cells, the movement of electrons is from anode to cathode, and the current (I) runs from cathode to anode.

This point can be a point of confusion among students. In physics, it is typical to state that current is the direction of flow of a positive charge through a circuit; this model was first proposed by Ben Franklin and continues to be used among physicists. Modern chemists are interested in the flow of electrons, but may discuss the current (a theoretical flow of positive charge) as a proxy for the flow of electrons; the current and the flow of electrons are always of equal magnitude but in opposite directions.

Last, it is important to note that all batteries are influenced by temperature changes. For instance, lead–acid batteries in cars, like most galvanic cells, tend to fail most in cold weather. The thermodynamic reasons behind this will be discussed later in this chapter.

Key Concept

Electrons move through an electrochemical cell opposite to the flow of current (*I*).

GALVANIC (VOLTAIC) CELLS

All of the nonrechargeable batteries you own are **galvanic cells**, also called **voltaic cells**. Accordingly, because household batteries are used to supply energy to a flashlight or remote control, the reactions in these cells must be spontaneous. This means that the reaction's free energy is decreasing ($\Delta G < 0$) as the cell releases energy to the environment. By extension, if the free energy change is negative for these cells, their electromotive force (E_{cell}) must be positive; the free energy change and electromotive force always have opposite signs.

Real World

Galvanic cells are commonly used as batteries; to be worthwhile (that is, producing energy to power some device or appliance), these batteries must be spontaneous!

Let's examine the inner workings of a galvanic (voltaic) cell. Two electrodes of distinct chemical identity are placed in separate compartments, which are called **half-cells**. The two electrodes are connected to each other by a conductive material, such as a copper wire. Along the wire, there may be other various components of a circuit, such as resistors or capacitors, but for now, we'll focus on the battery itself.

Surrounding each of the electrodes is an aqueous electrolyte solution composed of cations and anions. As shown in the **Daniell cell** illustrated in Figure 12.1, the cations in the two half-cell solutions can be of the same element as the respective metal electrode. Connecting the two solutions is a structure called a **salt bridge**, which consists of an inert salt. When the electrodes are connected to each other by a conductive material, charge will begin to flow as the result of an oxidation–reduction reaction that is taking place between the two half-cells. The redox reaction in a galvanic cell is spontaneous, and therefore the change in Gibbs free energy for the reaction is negative ($\Delta G < 0$). As the spontaneous reaction proceeds toward equilibrium, the movement of electrons results in a conversion of electrical potential energy into kinetic energy. By separating the reduction and oxidation half-reactions into two compartments, we are able to harness this energy and use it to do work by connecting various electrical devices into the circuit between the two electrodes.

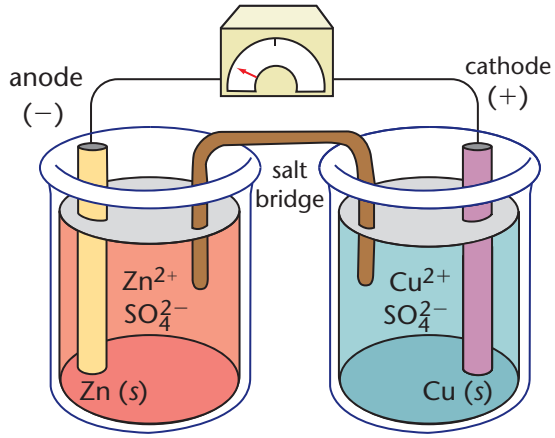

Figure 12.1. Daniell Cell
In this galvanic cell, zinc is the anode and copper is the cathode; each electrode is bathed in an electrolyte solution containing its cation and sulfate.

In the Daniell cell, a zinc electrode is placed in an aqueous $ZnSO_4$ solution, and a copper electrode is placed in an aqueous $CuSO_4$ solution. The anode of this cell is the zinc bar where Zn (*s*) is oxidized to Zn^{2+} (*aq*). The cathode is the copper bar, and it is the site of the reduction of Cu^{2+} (*aq*) to Cu (*s*). The half-cell reactions are written as follows:

$$Zn\ (s) \rightarrow Zn^{2+}\ (aq) + 2\ e^- \qquad E_{red} = -0.762\ V \qquad \text{(anode)}$$

$$Cu^{2+}\ (aq) + 2\ e^- \rightarrow Cu\ (s) \qquad E_{red} = +0.340\ V \qquad \text{(cathode)}$$

The net reaction is

$$Zn\ (s) + Cu^{2+}\ (aq) \rightarrow Zn^{2+}\ (aq) + Cu\ (s) \qquad E_{cell} = +1.102\ V$$

We will discuss the calculation of cell potential in the next section. For now, appreciate that the calculation can be accomplished by knowing each half-reaction. If the two half-cells were not separated, the Cu^{2+} ions would react directly with the zinc bar, and no useful electrical work would be done. Because the solutions and electrodes are physically separated, they must be connected by a conductive material to complete the circuit.

However, if only a wire were provided for this electron flow, the reaction would soon stop because an excess positive charge would build up on the anode, and an excess negative charge would build up on the cathode. Eventually, the excessive charge accumulation would provide a countervoltage large enough to prevent the oxidation–reduction reaction from taking place, and the current would cease. This charge gradient is dissipated by the presence of a **salt bridge**, which permits the exchange of cations and anions. The salt bridge contains an inert electrolyte, usually KCl or

NH_4NO_3, which contains ions that will not react with the electrodes or with the ions in solution. While the anions from the salt bridge (Cl^-) diffuse into the solution on the anode side ($ZnSO_4$) to balance out the charge of the newly created Zn^{2+} ions, the cations of the salt bridge (K^+) flow into the solution on the cathode side ($CuSO_4$) to balance out the charge of the sulfate ions left in solution when the Cu^{2+} ions are reduced to Cu and precipitate onto the electrode. This precipitation process onto the cathode itself can also be called **plating** or **galvanization**.

During the course of the reaction, electrons flow from the zinc anode through the wire and to the copper cathode. A voltmeter can be connected to measure this electromotive force. As mentioned earlier, the anions (Cl^-) flow externally from the salt bridge into the $ZnSO_4$, and the cations (K^+) flow externally from the salt bridge into the $CuSO_4$. This flow depletes the salt bridge and, along with the finite quantity of Cu^{2+} in the solution, accounts for the relatively short lifespan of the cell.

A **cell diagram** is a shorthand notation representing the reactions in an electrochemical cell. A cell diagram for the Daniell cell is as follows:

$$Zn\ (s)\ |\ Zn^{2+}\ (1\ M)\ ||\ Cu^{2+}\ (1\ M)\ |\ Cu\ (s)$$

The following rules are used in constructing a cell diagram:

1. The reactants and products are always listed from left to right in this form: anode | anode sol'n (concentration) || cathode sol'n (concentration) | cathode
2. A single vertical line indicates a phase boundary.
3. A double vertical line indicates the presence of a salt bridge or some other type of barrier.

ELECTROLYTIC CELLS

When comparing and contrasting galvanic and electrolytic cells, it is important to keep straight what remains consistent between the two types of cells and what differs. All types of electrochemical cells have a reduction reaction occurring at the cathode, an oxidation reaction occurring at the anode, a current flowing from cathode to anode, and electron flow from anode to cathode. However, **electrolytic cells**, in almost all of their characteristics and behavior, are otherwise the opposite of galvanic cells. Whereas galvanic cells house spontaneous oxidation–reduction reactions that generate electrical energy, electrolytic cells house nonspontaneous reactions that require the input of energy to proceed. Therefore, the change in free energy for an electrolytic cell is positive. This type of oxidation–reduction reaction driven by an external voltage source is called **electrolysis**, in which chemical compounds are decomposed. For example, electrolytic cells can be used to drive the

Key Concept

The purpose of the salt bridge is to exchange anions and cations to balance, or dissipate, newly generated charges.

Mnemonic

Electron flow in an electrochemical cell: **A** → **C** (order in the alphabet)

Electrons flow from **a**node to **c**athode in all types of electrochemical cells.

MCAT Expertise

Recognize and understand the shorthand cell notation for electrochemical cells on Test Day. Passages frequently use this format rather than spelling out which reactions take place at the anode and cathode.

nonspontaneous decomposition of water into oxygen and hydrogen gas. Another example, the electrolysis of molten NaCl, is illustrated in Figure 12.2.

Key Concept

Because electrolysis is nonspontaneous, the electrode (anode or cathode) can consist of any material so long as it can resist the high temperatures and corrosion of the process.

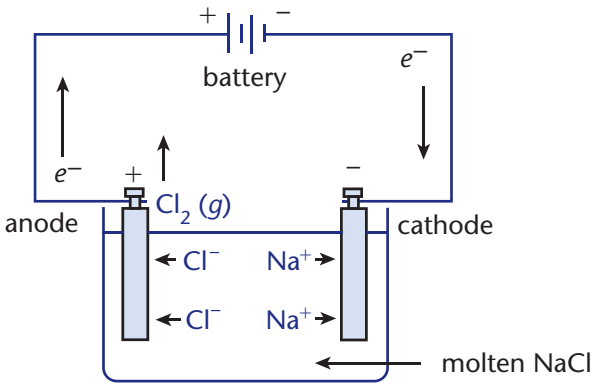

Figure 12.2. Electrolysis of Molten NaCl

In this electrolytic cell, molten NaCl is decomposed into Cl_2 (g) and Na (l). The external voltage source—a battery—supplies energy sufficient to drive the oxidation–reduction reaction in the direction that is thermodynamically unfavorable (nonspontaneous).

In this example, Na^+ ions migrate toward the cathode, where they are reduced to Na (l). At the same time, Cl^- ions migrate toward the anode, where they are oxidized to Cl_2 (g). Notice that the half-reactions do not need to be separated into different compartments; this is because the desired reaction is nonspontaneous. Note that sodium is a liquid at the temperature of molten NaCl; it is also less dense than the molten salt and, thus, is easily removed as it floats to the top of the reaction vessel.

This cell is used in industry as the major means of sodium and chlorine production. You may wonder why one would do so much work to obtain pure sodium and chlorine. Remember that these elements are never found naturally in their elemental form because they are so reactive. Thus, to use elemental sodium or chlorine gas in a reaction, it must be manufactured through processes such as these.

Key Concept

Faraday's laws state that the liberation of gas and deposition of elements on electrodes is directly proportional to the number of electrons being transferred during the oxidation–reduction reaction. Here, normality or gram equivalent weight is used. These observations are proxy measurements of the amount of current flowing in a circuit.

Michael Faraday was the first to define certain quantitative principles governing the behavior of electrolytic cells. He theorized that the amount of chemical change induced in an electrolytic cell is directly proportional to the number of moles of electrons that are exchanged during the oxidation–reduction reaction. The number of moles exchanged can be determined from the balanced half-reaction. In general, for a reaction that involves the transfer of n electrons per atom M,

$$M^{n+} + n\,e^- \rightarrow M\ (s)$$

Equation 12.1

According to this equation, one mole of metal M (*s*) will logically be produced if *n* moles of electrons are supplied to one mole of M^{n+}. Additionally, the number of moles of electrons needed to produce a certain amount of M (*s*) can now be related to the measurable electrical property of charge. One electron carries a charge of 1.6×10^{-19} coulombs (C). The charge carried by one mole of electrons can be calculated by multiplying this number by Avogadro's number, as follows:

$$\left[\frac{1.6\times10^{-19}\text{ C}}{\text{electron}}\right]\left[\frac{6.02\times10^{23}\text{ electrons}}{1\text{ mol }e^-}\right]=96{,}485\,\frac{\text{C}}{\text{mol }e^-}$$

This number is called the **Faraday constant**, and one **faraday** (**F**) is equivalent to the amount of charge contained in one mole of electrons (1 F = 96,485 C) or one equivalent. On the MCAT, you should round up this number to $10^5\ \frac{\text{C}}{\text{mol }e^-}$ to make calculations more manageable.

The **electrodeposition equation** summarizes this process and helps determine the number of moles of element being deposited on a plate:

$$\text{mol M} = \frac{It}{n\text{F}}$$

Equation 12.2

where mol M is the amount of metal ion being deposited at a specific electrode, *I* is current, *t* is time, *n* is the number of electron equivalents for a specific metal ion, and F is the Faraday constant. This equation can also be used to determine the amount of gas liberated during electrolysis.

Example: What mass of copper will be deposited in a Daniell cell if a current of 2 A flows through the cell for 3 hours?

Solution: We will use the equation $\text{mol M} = \frac{It}{n\text{F}}$

A Daniell cell uses a copper electrode in copper sulfate ($CuSO_4$) solution. Because the oxidation state of copper in solution is +2, $n = 2$. Now we can plug into the equation.

$$\text{mol M} = \frac{It}{n\text{F}} = \frac{(2\text{ A})(3\text{ hr})\left(3600\,\frac{\text{s}}{\text{hr}}\right)}{(2\text{ mol }e^-)\left(96{,}485\,\frac{\text{C}}{\text{mol }e^-}\right)} \approx \frac{3\times3600}{10^5}$$

$$= 0.1\text{ mol Cu (actual} = 0.11\text{ mol Cu)}$$

Then, we must determine the actual mass of copper being deposited. 0.1 mol Cu should have a mass of 6.35 g because the molar mass of copper is $63.5\ \frac{\text{g}}{\text{mol}}$ (actual = 7.11 g).

Key Concept

One faraday (F) is equivalent to the amount of charge contained in one mole of electrons (1 F = 96,485 C).

Mnemonic

Electrodeposition equation: Calculating **Moles of M**etal, **It** is **N**ot **F**un.

$$\text{mol M} = \frac{It}{n\text{F}}$$

CONCENTRATION CELLS

A **concentration cell** is a special type of galvanic cell. Like all galvanic cells, it contains two half-cells connected by a conductive material, allowing a spontaneous oxidation–reduction reaction to proceed, which generates a current and delivers energy. The distinguishing characteristic of a concentration cell is in its design: the electrodes are chemically identical. For example, if both electrodes are copper metal, they have the same reduction potential. Therefore, current is generated as a function of a concentration gradient established between the two solutions surrounding the electrodes. The concentration gradient results in a potential difference between the two compartments and drives the movement of electrons in the direction that results in equilibration of the ion gradient. The current will stop when the concentrations of ionic species in the half-cells are equal. This implies that the voltage (V) or electromotive force of a concentration cell is zero when the concentrations are equal; the voltage, as a function of concentrations, can be calculated using the **Nernst equation**.

Bridge

The maintenance of a resting membrane potential is discussed in Chapter 8 of *MCAT Biochemistry Review*. The conduction of an action potential is discussed in Chapter 4 of *MCAT Biology Review*. The transfer of ions and electrons during an action potential produces biochemical work.

In a biological system, a concentration cell is best represented by the cell membrane of a neuron, as shown in Figure 12.3. Sodium and potassium cations, and chlorine anions, are exchanged as needed to produce an electrical potential. The actual value depends on both the concentrations and charges of the ions. In this way, a **resting membrane potential** (V_m) can be maintained. Disturbances of the resting membrane potential, if sufficiently large, may stimulate the firing of an action potential.

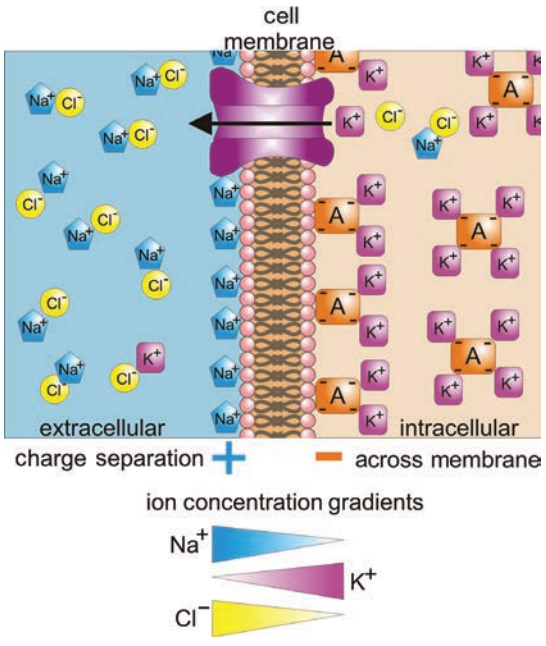

Figure 12.3. The Cell Membrane as an Example of a Concentration Cell
The electrochemical gradient created by separation of ions across the cell membrane is analogous to a cell with two electrodes composed of the same material.

RECHARGEABLE CELLS

A **rechargeable cell** or **rechargeable battery** is one that can function as both a galvanic and electrolytic cell.

Lead–Acid Batteries

A **lead–acid battery**, also known as a **lead storage battery**, is a specific type of rechargeable battery. As a voltaic cell, when fully charged, it consists of two half-cells—a Pb anode and a porous PbO_2 cathode, connected by a conductive material (concentrated 4 *M* H_2SO_4). When fully discharged, it consists of two $PbSO_4$ electroplated lead electrodes with a dilute concentration of H_2SO_4, as shown in Figure 12.4.

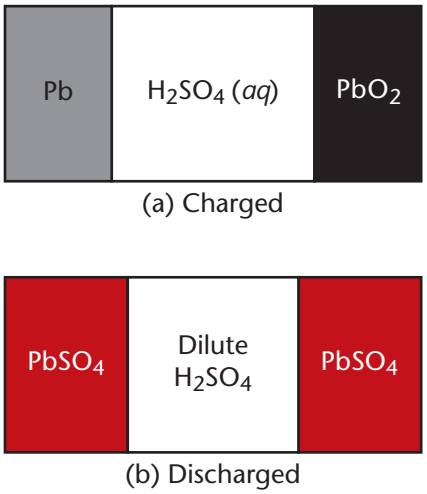

Figure 12.4. A Lead–Acid Battery
When charged (a), the cell contains a Pb anode and PbO_2 cathode; when discharged (b), both electrodes are coated with lead sulfate.

The oxidation half-reaction at the lead (negative) anode is:

$$Pb\,(s) + HSO_4^-\,(aq) \rightarrow PbSO_4\,(s) + H^+\,(aq) + 2\,e^- \qquad E^\circ_{red} = -0.356\ V$$

The reduction half-reaction at the lead(IV) oxide (positive) cathode is:

$$PbO_2\,(s) + SO_4^{2-}\,(aq) + 4\,H^+ + 2\,e^- \rightarrow PbSO_4\,(s) + 2\,H_2O \qquad E^\circ_{red} = 1.685\ V$$

Both half-reactions cause the electrodes to plate with lead sulfate ($PbSO_4$) and dilute the acid electrolyte when **discharging**. The lead anode is negatively charged and attracts the anionic bisulfate. The lead(IV) oxide cathode is a bit more complicated. This electrode is porous, which allows the electrolyte (sulfuric acid) to solvate the cathode into lead and oxide ions. Then, the hydrogen ions in solution

react with the oxide ions to produce water, and the remaining sulfate ions react with the lead to produce the electroplated lead sulfate.

Overall, the net equation for a discharging lead–acid battery is:

$$Pb\ (s) + PbO_2\ (s) + 2\ H_2SO_4\ (aq) \rightarrow 2\ PbSO_4\ (s) + 2\ H_2O$$
$$E^\circ_{cell} = 1.685 - (-0.356) = 2.041\ V$$

When **charging**, the lead–acid cell is part of an electrolytic circuit. These equations and electrode charge designations are the opposite because an external source reverses the electroplating process and concentrates the acid solution—this external source is very evident when one uses jumper cables to restart a car.

Lead–acid batteries, as compared to other cells, have some of the lowest energy-to-weight ratios (otherwise known as energy density). **Energy density** is a measure of a battery's ability to produce power as a function of its weight. Lead–acid batteries, therefore, require a heavier amount of battery material to produce a certain output as compared to other batteries.

Nickel–Cadmium Batteries

Nickel–cadmium batteries are also rechargeable cells. They consist of two half-cells made of solid cadmium (the anode) and nickel(III) oxide-hydroxide (the cathode) connected by a conductive material, typically potassium hydroxide (KOH). Most of us are familiar with AA and AAA cells made of Ni–Cd materials, inside of which the electrodes are layered and wrapped around in a cylinder, as shown in Figure 12.5.

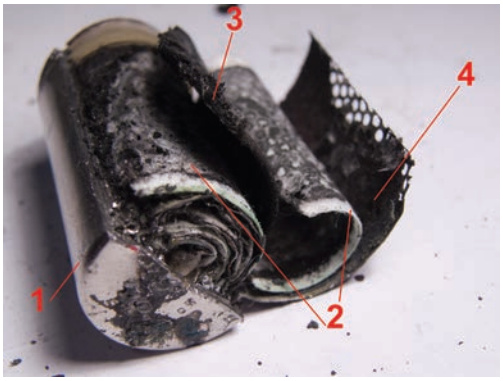

Figure 12.5. A Nickel–Cadmium Battery
(1) Metal casing, (2) salt bridge, (3) NiO(OH) cathode, (4) Cd anode

The oxidation half-reaction at the cadmium (negative) anode is:

$$Cd\ (s) + 2\ OH^-\ (aq) \rightarrow Cd(OH)_2\ (s) + 2\ e^- \qquad E^\circ_{red} = -0.86\ V$$

The reduction half-reaction at the nickel oxide–hydroxide (positive) cathode is:

$$2\ \mathrm{NiO(OH)}\ (s) + 2\ \mathrm{H_2O} + 2\ e^- \rightarrow 2\ \mathrm{Ni(OH)_2}\ (s) + 2\ \mathrm{OH^-} \qquad E^\circ_{\mathrm{red}} = 0.49\ \mathrm{V}$$

Both half-reactions cause the electrodes to plate with their respective products. Overall, the net equation for a Ni–Cd battery is

$$2\ \mathrm{NiO(OH)}\ (s) + \mathrm{Cd} + 2\ \mathrm{H_2O} \rightarrow 2\ \mathrm{Ni(OH)_2}\ (s) + \mathrm{Cd(OH)_2}\ (s)$$

$$E^\circ_{\mathrm{cell}} = 0.49 - (-0.86) = 1.35\ \mathrm{V}$$

As in our previous example, charging reverses the electrolytic cell potentials. Some Ni–Cd designs are vented for this reason to allow for the release of built up hydrogen and oxygen gas during electrolysis.

Ni–Cd batteries have a higher energy density than lead–acid batteries. The electrochemistry of the Ni–Cd half-reactions also tends to provide higher surge current. **Surge currents** are periods of large current (amperage) early in the discharge cycle. This is preferable in appliances such as remote controls that demand rapid responses. It is important to note that modern Ni–Cd batteries have largely been replaced by more efficient **nickel–metal hydride** (**NiMH**) **batteries**. These newer batteries have more energy density, are more cost effective, and are significantly less toxic. As the name suggests, in lieu of a pure metal anode, a metal hydride is used instead.

ELECTRODE CHARGE DESIGNATIONS

In a galvanic cell, current is spontaneously generated as electrons are released by the oxidized species at the anode and travel through the conductive material to the cathode, where reduction takes place. Because the anode of a galvanic cell is the source of electrons, it is considered the negative electrode; the cathode is considered the positive electrode, as shown in Figure 12.1 previously. Electrons, therefore, move from negative (low electrical potential) to positive (high electrical potential), while the current—the flow of positive charge—is from positive (high electrical potential) to negative (low electrical potential).

Conversely, the anode of an electrolytic cell is considered positive because it is attached to the positive pole of the external voltage source and attracts anions from the solution. The cathode of an electrolytic cell is considered negative because it is attached to the negative pole of the external voltage source and attracts cations from the solution.

In spite of this difference in designating charge (sign), oxidation always takes place at the anode and reduction always takes place at the cathode in both types of cells;

Key Concept

In a galvanic cell, the anode is negative and the cathode is positive. In an electrolytic cell, the anode is positive and the cathode is negative. This is because an external source is used to reverse the charge of an electrolytic cell. However, in both types of cells, reduction occurs at the cathode, and oxidation occurs at the anode; cations are attracted to the cathode, and anions are attracted to the anode.

Real World

Recognize that in any system in which batteries are placed, it is important to line up cathodes and anodes. Electronics tend to have (+) and (–) designations to line up the electrodes—think jumper cables, television remotes, and button batteries in watches.

Mnemonic

Anions are attracted to the **an**ode. **Cat**ions are attracted to the **cat**hode. This is true regardless of the type of cell (galvanic, electrolytic, or concentration cells).

electrons always flow through the wire from the anode to the cathode and current flows from cathode to anode. Finally, note that—regardless of its charge designation—the cathode always attracts cations and the anode always attracts anions. In the Daniell cell, for example, the electrons created at the anode by the oxidation of elemental zinc travel through the wire to the copper half-cell. There, they attract copper(II) cations to the cathode, resulting in the reduction of the copper ions to elemental copper, and drawing cations out of the salt bridge into the compartment. The anode, having lost electrons, attracts anions from the salt bridge at the same time that zinc(II) ions formed by the oxidation process dissolve away from the anode.

This is an important rule to understand not only for electrochemistry in the *Chemical and Physical Foundations of Biological Systems* section on Test Day, but also for electrophoresis in both this section and *Biological and Biochemical Foundations of Living Systems*. **Isoelectric focusing** is a technique used to separate amino acids or polypeptides based on their **isoelectric points** (**pI**). The positively charged amino acids (protonated at the solution's pH) will migrate toward the cathode; negatively charged amino acids (deprotonated at the solution's pH) will migrate toward the anode. The technique of isoelectric focusing is discussed in detail in Chapter 3 of *MCAT Biochemistry Review*.

MCAT Concept Check 12.1:

Before you move on, assess your understanding of the material with these questions.

1. Circle which electrode each of the following statements describes in a galvanic (voltaic) cell:
   - Site of oxidation: Anode Cathode
   - Electrons flow toward it: Anode Cathode
   - Current flows toward it: Anode Cathode
   - Has (–) designation: Anode Cathode
   - Attracts cations: Anode Cathode
2. Circle which electrode each of the following statements describes in an electrolytic cell:
   - Site of oxidation: Anode Cathode
   - Electrons flow toward it: Anode Cathode
   - Current flows toward it: Anode Cathode
   - Has (–) designation: Anode Cathode
   - Attracts cations: Anode Cathode
3. Write the cell diagram for the discharging state of a lead–acid battery:

_____

4. Which type of cell has a positive ΔG? A positive E_{cell}?
   - Positive ΔG: _____
   - Positive E_{cell}: _____

5. How much current is required to produce 0.23 kg Na from a molten NaCl electrolytic cell that runs for 30 hours? Assume the cell is 100% efficient.

_____

_____

_____

6. Fill in the following chart to summarize electrode charge designations of batteries we have analyzed:

Battery	State of Use	Galvanic or Electrolytic	Anode Material	Anode Charge	Cathode Material	Cathode Charge
Ni–Cd	Discharging					
Ni–Cd	Charging					
Molten NaCl	Discharging					
Daniell cell	Discharging					
Lead–acid	Charging					
Lead–acid	Discharging					

12.2 Cell Potentials ★★

For galvanic cells, the direction of spontaneous movement of charge is from the anode, the site of oxidation, to the cathode, the site of reduction. This is simple enough to remember, but it begs the question: how do we determine which electrode species will be oxidized and which will be reduced? The relative tendencies of different chemical species to be reduced have been determined experimentally, using the tendency of the hydrogen ion (H^+) to be reduced as an arbitrary zero reference point.

REDUCTION POTENTIALS

A reduction potential is measured in volts (V) and defined relative to the **standard hydrogen electrode** (**SHE**), which is given a potential of 0 V by convention. The species in a reaction that will be oxidized or reduced can be determined from the **reduction potential** of each species, defined as the tendency of a species to gain electrons and to be reduced. Each species has its own intrinsic reduction potential; the more positive the potential, the greater the tendency to be reduced.

Key Concept

A reduction potential is exactly what it sounds like. It tells us how likely a compound is to be reduced. The more positive the value, the more likely it is to be reduced—the more it *wants* to be reduced.

Standard reduction potential $\left(E^\circ_{\text{red}}\right)$ is measured under **standard conditions**: 25°C (298 K), 1 atm pressure, and 1 *M* concentrations. The relative reactivities of different half-cells can be compared to predict the direction of electron flow. A more positive E°_{red} means a greater relative tendency for reduction to occur, while a less positive E°_{red} means a greater relative tendency for oxidation to occur.

For galvanic cells, the electrode with the more positive reduction potential is the cathode, and the electrode with the less positive reduction potential is the anode. Because the species with a stronger tendency to gain electrons (that *wants* to gain electrons more) is actually doing so, the reaction is spontaneous and ΔG is negative. For electrolytic cells, the electrode with the more positive reduction potential is forced by the external voltage source to be oxidized and is, therefore, the anode. The electrode with the less positive reduction potential is forced to be reduced and is, therefore, the cathode. Because the movement of electrons is in the direction against the tendency or desires of the respective electrochemical species, the reaction is nonspontaneous and ΔG is positive.

Example: Given the following half-reactions and E°_{red} values, determine which species would be oxidized and which would be reduced in a galvanic cell.

$$Ag^+ + e^- \rightarrow Ag\ (s) \qquad E^\circ_{\text{red}} = +0.80\ \text{V}$$

$$Tl^+ + e^- \rightarrow Tl\ (s) \qquad E^\circ_{\text{red}} = -0.34\ \text{V}$$

Solution: In a galvanic cell, Ag^+ will be spontaneously reduced to Ag (*s*) and Tl (*s*) will be spontaneously oxidized to Tl^+ because Ag^+ has the more positive E°_{red}. Therefore, the net ionic equation would be:

$$Ag^+ + Tl\ (s) \rightarrow Tl^+ + Ag\ (s)$$

which is the sum of the two spontaneous half-reactions.

It should be noted that reduction and oxidation are opposite processes. Therefore, to obtain the oxidation potential of a given half-reaction, both the reduction half-reaction and the sign of the reduction potential are reversed. For instance, from the example above, the oxidation half-reaction and oxidation potential of Tl (*s*) are:

$$Tl\ (s) \rightarrow Tl^+ + e^- \qquad E^\circ_{\text{ox}} = +0.34\ \text{V}$$

Note that, in the examples of batteries given above (lead–acid storage batteries and nickel–cadmium batteries), the oxidation half-reaction was given with the reduction potential of the reverse reaction. These two quantities have equal magnitudes but opposite signs. On the MCAT, reduction potentials are generally given rather than oxidation potentials. Therefore, all references in this book (with exception of the thallium example immediately above) are given using reduction potentials—not oxidation potentials.

THE ELECTROMOTIVE FORCE

Standard reduction potentials are also used to calculate the **standard electromotive force** (**emf** or E°_{cell}) of a reaction, which is the difference in potential (voltage) between two half-cells under standard conditions. The emf of a reaction is determined by calculating the difference in reduction potentials between the two half-cells:

$$E^\circ_{\text{cell}} = E^\circ_{\text{red,cathode}} - E^\circ_{\text{red,anode}}$$

Equation 12.3

When subtracting standard potentials, do not multiply them by the number of moles oxidized or reduced. This is because the potential of each electrode does not depend on the size of the electrode (the amount of material), but rather the identity of the material. The standard reduction potential of an electrode will not change unless the chemical identity of that electrode is changed.

Example: Given that the standard reduction potentials for Sm^{3+} and $[RhCl_6]^{3-}$ are −2.41 V and +0.44 V, respectively, calculate the electromotive force of the following reaction:

$$Sm^{3+} + Rh + 6\ Cl^- \rightarrow [RhCl_6]^{3-} + Sm$$

Solution: First, determine the oxidation and reduction half-reactions. As written, the Rh is oxidized, and the Sm^{3+} is reduced:

$$Sm^{3+} + 3\,e^- \rightarrow Sm$$
$$Rh + 6\,Cl^- \rightarrow [RhCl_6]^{3-} + 3\,e^-$$

Now, we simply take the difference between the samarium(III) reduction potential and the hexachlororhodate(III) reduction potential. We need not change the sign on the hexachlororhodate(III) reduction potential because we are *subtracting* it from that of samarium(III).

Using the equation provided, the emf can be calculated as: −2.41 V − (+0.44 V) = −2.85 V. The cell is thus electrolytic. From this result, it is clear that the reaction would instead proceed spontaneously to the left, in which case the Sm would be oxidized while $[RhCl_6]^{3-}$ would be reduced with an emf of +2.85 V.

Key Concept

If you need to multiply each half-reaction by a common denominator to cancel out electrons when coming up with the net ionic equation, do *not* multiply the reduction potential, E°_{red}, by that number. That would indicate a change in the chemical identity of the electrode, which is not occurring.

MCAT Concept Check 12.2:
Before you move on, assess your understanding of the material with these questions.

1. How are standard reduction potentials measured?

_____

2. If a cell's electromotive force (emf) is denoted as a positive value, what does that mean? What if it is negative?
   - Positive emf:

     _____
   - Negative emf:

     _____

3. Given the following reactions, determine whether the cell is galvanic or electrolytic:
   - $2\ Fe^{3+}\ (aq) + 2\ Cl^{-}\ (aq) \rightarrow 2\ Fe^{2+}\ (aq) + Cl_2\ (g)$ ($E^{\circ}_{cell} = -0.59$ V):

     _____
   - $2\ Fe^{3+}\ (aq) + 2\ I^{-}\ (aq) \rightarrow 2\ Fe^{2+}\ (aq) + I_2\ (aq)$ ($E^{\circ}_{cell} = +0.25$ V):

     _____

4. Given the two half-reactions below, what would be the spontaneous oxidation–reduction reaction between these two species?

   $Fe^{3+} + 3\ e^{-} \rightarrow Fe$ $\qquad E^{\circ}_{red} = -0.036$ V

   $I_3^{-} + 2\ e^{-} \rightarrow 3\ I^{-}$ $\qquad E^{\circ}_{red} = +0.534$ V

_____

_____

12.3 Electromotive Force and Thermodynamics

Throughout our discussion of electrochemistry and the different types of electrochemical cells, we have been making references to the spontaneity or nonspontaneity of the redox reactions housed in each of the different cell types. Let's now look more formally at this topic by relating free energy to electromotive force (emf) and the concentrations of the oxidation–reduction reactants and products to the voltage of a cell at a given point in time.

GIBBS FREE ENERGY

By now, you should be familiar with the thermodynamic criterion for determining the spontaneity of a reaction: the change in Gibbs free energy, ΔG. This is the change in the amount of energy available in a chemical system to do work. In an electrochemical cell, the work done is dependent on the number of coulombs of charge transferred and the energy available. Thus, ΔG° and emf are related as follows:

$$\Delta G^\circ = -n\mathrm{F}E^\circ_{\text{cell}}$$

Equation 12.4

where ΔG° is the standard change in free energy, n is the number of moles of electrons exchanged, F is the Faraday constant, and E°_{cell} is the standard emf of the cell. Keep in mind that, if the Faraday constant is expressed in coulombs $\left(\frac{\text{J}}{\text{V}}\right)$, then ΔG° must be expressed in J, not kJ. Notice the similarity of this relationship to that expressed in the physics formula $W = q\Delta V$ for the amount of work available or needed in the transport of a charge q across a potential difference ΔV: $n \times \mathrm{F}$ is a charge, and E°_{cell} is a voltage. This application in electrostatics is discussed in Chapter 5 of *MCAT Physics and Math Review*.

Note the significance of the negative sign on the right side of the equation. ΔG° and E°_{cell} will always have opposite signs. Therefore, galvanic cells have negative ΔG° and positive E°_{cell} values; electrolytic cells have positive ΔG° and negative E°_{cell} values.

Example: Determine the standard change in free energy of a cell with the following net reaction. (Note: The standard reduction potential of iron(III) is +0.77 V; the standard reduction potential of molecular chlorine is +1.36 V.)

$$2\ \mathrm{Fe}^{3+}(aq) + 2\ \mathrm{Cl}^-(aq) \rightarrow 2\ \mathrm{Fe}^{2+}(aq) + \mathrm{Cl}_2(g)$$

Solution: First, separate the reaction into the half-reactions:

$$2\,\mathrm{Fe}^{3+} + 2\,e^- \rightarrow 2\,\mathrm{Fe}^{2+}$$
$$2\,\mathrm{Cl}^- \rightarrow \mathrm{Cl}_2 + 2\,e^-$$

In this reaction, iron(III) is reduced and is the cathode, whereas Cl^- is oxidized and is the anode. The reduction potential of chlorine is actually higher than that of iron(III); this means that the electrodes are serving the *opposite* role from their natural tendency, and the reaction is nonspontaneous. This is an electrolytic cell, and should have a negative emf value.

Now, determine the emf:

$$E^\circ_{\text{cell}} = E^\circ_{\text{red,cathode}} - E^\circ_{\text{red,anode}} = 0.77\ \text{V} - 1.36\ \text{V} = -0.59\ \text{V}$$

Bridge

Recall from Chapter 6 of *MCAT General Chemistry Review* that, if ΔG is positive, the reaction is nonspontaneous; if ΔG is negative, the reaction is spontaneous.

Use the emf to determine the free energy change:

$$\Delta G^\circ = -nFE^\circ_{cell} = -(2\,\text{mol}\,e^-)(96{,}485\,\frac{\text{C}}{\text{mol}\,e^-})(-0.59\,\text{V}) \approx 2\times10^5\times(0.6)$$

$$= 1.2\times10^5\,\text{J}\,(\text{actual} = 1.14\times10^5\,\text{J})$$

The free energy change is about +120 kJ, which represents a non-spontaneous reaction.

REACTION QUOTIENTS

So far, we have considered the calculation of a cell's emf only under standard conditions. However, electrochemical cells may have ionic concentrations that deviate from 1 *M*. Also, for the concentration cell, the concentrations of the ions in the two compartments *must* be different for there to be a measurable voltage and current. Concentration and the emf of a cell are related: emf varies with the changing concentrations of the species in the cell. When conditions deviate from standard conditions, one can use the **Nernst equation**:

$$E_{cell} = E^\circ_{cell} - \frac{RT}{n\text{F}}\ln Q$$

Equation 12.5

where E_{cell} is the emf of the cell under nonstandard conditions, E°_{cell} is the emf of the cell under standard conditions, R is the ideal gas constant, T is the temperature in kelvins, n is the number of moles of electrons, F is the Faraday constant, and Q is the reaction quotient for the reaction at a given point in time. The following simplified version of the equation can be used, assuming T = 298 K:

$$E_{cell} = E^\circ_{cell} - \frac{0.0592}{n}\log Q$$

Equation 12.6

MCAT Expertise

If the Nernst equation is needed on Test Day, stick with the $\log_{10}$ version because natural logarithm calculations get very tedious.

This simplified version of the equation brings together R, T (298 K), and F, and converts the natural logarithm to the base-ten logarithm to make calculations easier.

Remember that the reaction quotient, Q, for a general reaction aA + bB → cC + dD has the form:

$$Q = \frac{[\text{C}]^c[\text{D}]^d}{[\text{A}]^a[\text{B}]^b}$$

Equation 12.7

Although the expression for the reaction quotient Q has two terms for the concentrations of reactants and two terms for the concentrations of products, remember that only the species in solution are included. When considering the case of the Daniell cell, for example, only the concentrations of zinc and copper ions are considered:

$$Zn\ (s) + Cu^{2+}\ (aq) \rightarrow Zn^{2+}\ (aq) + Cu\ (s)$$

$$Q = \frac{[Zn^{2+}]}{[Cu^{2+}]}$$

The emf of a cell can be measured with a **voltmeter**. A **potentiometer** is a kind of voltmeter that draws no current and gives a more accurate reading of the difference in potential between two electrodes.

Example: Find the emf of a galvanic cell at 25°C based on the following standard reduction potentials:

$$Fe^{2+} + 2\ e^- \rightarrow Fe \qquad E^\circ_{red} = -0.44\ V$$
$$Cl_2 + 2\ e^- \rightarrow 2\ Cl^- \qquad E^\circ_{red} = +1.36\ V$$

In this cell, $[Fe^{2+}] = 0.01\ M$ and $[Cl^-] = 0.1\ M$.

Solution: First, determine the standard cell potential. Because the chlorine half-reaction has a higher reduction potential, it will be the cathode. Iron will act as the anode. The standard cell potential is:

$$E^\circ_{cell} = E^\circ_{red,cathode} - E^\circ_{red,anode} = 1.36\ V - (-0.44\ V) = +1.80\ V$$

Now, determine the net ionic equation. Remember that iron is being oxidized, so its reduction half-reaction in the question stem will have to be reversed. The net ionic equation is:

$$Fe + Cl_2 \rightarrow Fe^{2+} + 2\ Cl^-$$

From this equation, we can determine the value of the reaction quotient:

$$Q = [Fe^{2+}][Cl^-]^2 = (0.01\ M)(0.1\ M)^2 = 10^{-4}$$

Now, plug into the Nernst equation, keeping in mind that two electrons are transferred ($n = 2$):

$$E_{cell} = E^\circ_{cell} - \frac{0.0592}{n}\log Q = 1.8 - \frac{0.0592}{2}\log 10^{-4}$$
$$= 1.8 + \frac{4 \times 0.0592}{2} \approx 1.8 + 0.12 = 1.92\ V$$

In this case, the cell actually has a higher voltage than it normally would due to the concentrations of ions present.

Bridge

While a mathematically rigorous equation, the Nernst equation has a powerful use in biochemistry for calculating resting and depolarized membrane potentials based on concentrations of ions. Its more extended version, the Goldman–Hodgkin–Katz equation, is discussed in Chapter 8 of *MCAT Biochemistry Review*. Equation 8.2 in that chapter looks slightly different than Equation 12.6 here. This is because the temperature is different (310 K rather than 298 K) and the units are different (mV instead of V).

EQUILIBRIA

As discussed in Chapter 7 of *MCAT General Chemistry Review*, ΔG° can also be determined in another manner:

$$\Delta G^\circ = -RT \ln K_{eq}$$

Equation 12.8

where R is the ideal gas constant, T is the absolute temperature, and K_{eq} is the equilibrium constant for the reaction.

Combining the two expressions that solve for standard free energy change, we see that

$$\Delta G^\circ = -nFE^\circ_{cell} = -RT \ln K_{eq}$$

or

$$nFE^\circ_{cell} = RT \ln K_{eq}$$

By extension, if the values for n, T, and K_{eq} are known, then E°_{cell} for the reaction is easily calculated. On the MCAT, you will not be expected to calculate natural logarithm values in your head. That being said, these equations can still be tested but in a conceptual way.

Analysis of the equations shows us that, for redox reactions with equilibrium constants less than 1 (equilibrium state favors the reactants), the E°_{cell} will be negative because the natural logarithm of any number between 0 and 1 is negative. These properties are characteristic of electrolytic cells, which house nonspontaneous oxidation–reduction reactions. Instead, if the equilibrium constant for the reaction is greater than 1 (equilibrium state favors the products), the E°_{cell} will be positive because the natural logarithm of any number greater than 1 is positive. These properties are characteristic of galvanic cells, which house spontaneous oxidation–reduction reactions. If the equilibrium constant is equal to 1 (concentrations of the reactants and products are equal at equilibrium), the E°_{cell} will be equal to zero. An easy way to remember this is that $E^\circ_{cell} = 0$ V for any concentration cell with equimolar concentrations in both half-cells because there is no net ionic equation (both half-cells contain the same ions).

Knowing the effects of concentration on equilibria, we can now derive the change in Gibbs free energy of an electrochemical cell with varying concentrations using the equation

$$\Delta G = \Delta G^\circ + RT \ln Q$$

Equation 12.9

MCAT Expertise

Whether it is log or ln, remember that a logarithm will be positive when equilibrium constants are greater than 1, negative when equilibrium constants are less than 1, and 0 when equilibrium constants are equal to 1.

Key Concept

If E°_{cell} is positive, ln K_{eq} is positive. This means that K_{eq} must be greater than one and that the equilibrium lies to the right (products are favored).

where ΔG is the free energy change under nonstandard conditions, $\Delta G°$ is the free energy change under standard conditions (which can be determined from Equation 12.4 or Equation 12.8 above), R is the ideal gas constant, T is the temperature, and Q is the reaction quotient.

MCAT Concept Check 12.3:

Before you move on, assess your understanding of the material with these questions.

1. Fill in the table to show the relationships between the equilibrium constant, Gibbs free energy, and electromotive force (emf), assuming standard conditions:

K_{eq}	$\Delta G°$: (+) or (–)?	Reaction: Spontaneous or Nonspontaneous?	$E°_{cell}$: (+) or (–)?
1.2×10^{-2}			
2×10^{2}			
1			

2. Given the following reaction quotients and equilibrium constants, determine the direction of the reaction and the sign of E_{cell}:

Q	K_{eq}	Reaction Direction (Forward, Backward, or Equilibrium)	Sign of E_{cell}
10^{-3}	10^{-2}		
10^{2}	1.1		
1	1		

Conclusion

In this chapter, we covered the essential MCAT topic of electrochemistry. We reviewed the behavior of many different types of electrochemical cells. Galvanic cells rely on spontaneous oxidation–reduction reactions to produce current and supply energy. The concentration cell is a special type of galvanic cell for which the current is dependent on an ion concentration gradient rather than a difference in reduction potential between two chemically distinct electrodes. Electrolytic cells rely on external voltage sources to drive a nonspontaneous oxidation–reduction reaction called electrolysis. Finally, we considered the thermodynamics of the different cell types. Galvanic and concentration cells have positive electromotive forces (emf) and negative free energy changes, whereas electrolytic cells have negative electromotive forces and positive free energy changes.

In retrospect, the content you have learned in *MCAT General Chemistry Review* has numerous organic (biological) and inorganic applications. And as you prepare to be a physician, you must begin to understand and treat the individual as a sum of many intertwining systems and parts. Many body systems and parts rely on electrochemical cells: the heart is a self-paced electrochemical cell, the neurons of the brain and spinal cord are rechargeable concentration cells, and every cell that contains mitochondria (all cells except erythrocytes) rely on the proton-motive force across the inner mitochondrial membrane to function. Our discussion here of inorganic systems has value through analogy to many biological systems.

Without further delay, we want to offer you our heartiest congratulations for completing this final chapter of *MCAT General Chemistry Review*. The hard work, time, and energy you have invested in a careful and thorough review of the topics covered within the pages of this book will pay off on Test Day. We hope that we have been successful in meeting our goals in writing this *Kaplan MCAT Review* series: to assess the general concepts and principles essential to correctly and efficiently answer the general chemistry questions on the MCAT; to guide you in the development of critical thinking skills necessary for analyzing passages, question stems, and answer choices; and to provide holistic preparation for your Test Day experience. In addition to all of these, we aimed to relate the science to everyday life experiences and future experiences as a physician, demystify the concepts, and have some fun in the process. We are grateful for the opportunity to have been a part of your journey to success on the MCAT, and—beyond that—success in your medical education and future practice as the great physician you deserve to be!

CONCEPT SUMMARY

Electrochemical Cells

- An **electrochemical cell** describes any cell in which oxidation–reduction reactions take place. Certain characteristics are shared between all types of electrochemical cells.
  - **Electrodes** are strips of metal or other conductive materials placed in an **electrolyte** solution.
  - The **anode** is always the site of oxidation. It attracts anions.
  - The **cathode** is always the site of reduction. It attracts cations.
  - Electrons flow from the anode to the cathode.
  - Current flows from the cathode to the anode.
- **Cell diagrams** are shorthand notation that represent the reactions taking place in an electrochemical cell.
  - Cell diagrams are written from anode to cathode with electrolytes (the solution) in between.
  - A vertical line represents a phase boundary, and a double vertical line represents a salt bridge or other physical boundary.
- **Galvanic** (**voltaic**) **cells** house spontaneous reactions ($\Delta G < 0$) with a positive electromotive force.
- **Electrolytic cells** house nonspontaneous reactions ($\Delta G > 0$) with a negative electromotive force. These nonspontaneous cells can be used to create useful products through electrolysis.
- **Concentration cells** are a specialized form of a galvanic cell in which both electrodes are made of the same material. Rather than a potential difference causing the movement of charge, it is the concentration gradient between the two solutions.
- The charge on an electrode is dependent on the type of electrochemical cell one is studying.
  - For galvanic cells, the anode is negatively charged and the cathode is positively charged.
  - For electrolytic cells, the anode is positively charged and the cathode is negatively charged.
- **Rechargeable batteries** are electrochemical cells that can experience **charging** (electrolytic) and **discharging** (galvanic) states. Rechargeable batteries are often ranked by **energy density**—the amount of energy a cell can produce relative to the mass of battery material.
  - **Lead–acid batteries**, when discharging, consist of a Pb anode and a PbO_2 cathode in a concentrated sulfuric acid solution. When charging, the

$PbSO_4$-plated electrodes are dissociated to restore the original Pb and PbO_2 electrodes and concentrate the electrolyte. These cells have a low energy density.

- **Nickel–cadmium batteries** (**Ni–Cd**), when discharging, consist of a Cd anode and a NiO(OH) cathode in a concentrated KOH solution. When charging, the $Ni(OH)_2$- and $Cd(OH)_2$-plated electrodes are dissociated to restore the original Cd and NiO(OH) electrodes and concentrate the electrolyte. These cells have a higher energy density than lead–acid batteries.
- **Nickel–metal hydride** (**NiMH**) batteries have more or less replaced Ni–Cd batteries because they have higher energy density, are more cost effective, and are significantly less toxic.

- **Surge current** is an above-average current transiently released at the beginning of the discharge phase; it wanes rapidly until a stable current is achieved.

Cell Potentials

- A **reduction potential** quantifies the tendency for a species to gain electrons and be reduced. The higher the reduction potential, the more a given species wants to be reduced.
  - **Standard reduction potentials** (E°_{red}) are calculated by comparison to the **standard hydrogen electrode** (**SHE**) under the standard conditions of 298 K, 1 atm pressure, and 1 *M* concentrations.
  - The standard hydrogen electrode has a standard reduction potential of 0 V.
- **Standard electromotive force** (E°_{cell}) is the difference in standard reduction potential between the two half-cells.
- For galvanic cells, the difference of the reduction potentials of the two half-reactions is positive; for electrolytic cells, the difference of the reduction potentials of the two half-reactions is negative.

Electromotive Force and Thermodynamics

- Electromotive force and change in free energy always have opposite signs.
  - When E°_{cell} is positive, ΔG° is negative. This is the case in galvanic cells.
  - When E°_{cell} is negative, ΔG° is positive. This is the case in electrolytic cells.
  - When E°_{cell} is 0, ΔG° is 0. This is the case in concentration cells.
- The **Nernst equation** describes the relationship between the concentration of species in a solution under nonstandard conditions and the electromotive force.
- There exists a relationship between the equilibrium constant (K_{eq}) and E°_{cell}.
  - When K_{eq} (the ratio of products' concentrations at equilibrium over reactants', raised to their stoichiometric coefficients) is greater than 1, E°_{cell} is positive.
  - When K_{eq} is less than 1, E°_{cell} is negative.
  - When K_{eq} is equal to 1, E°_{cell} is 0.

ANSWERS TO CONCEPT CHECKS

12.1

1. In a galvanic cell, the anode is the site of oxidation, has current flowing toward it, and has a (–) designation. The cathode has electrons flowing toward it and attracts cations.
2. In an electrolytic cell, the anode is the site of oxidation and has current flowing toward it. The cathode has electrons flowing toward it, has a (–) designation, and attracts cations.
3. Pb (*s*) | H_2SO_4 (4 *M*) || H_2SO_4 (4 *M*) | PbO_2 (*s*)
4. Electrolytic cells are nonspontaneous and have a positive ΔG. Galvanic cells are spontaneous and have a negative ΔG; therefore, they have a positive E_{cell}.

5. $$\text{mol M} = \frac{It}{n\text{F}} \rightarrow I = \frac{(\text{mol M})n\text{F}}{t} = \frac{\left(\frac{230\text{ g}}{23\ \frac{\text{g}}{\text{mol}}}\right)\left(1\text{ mol } e^-\right)\left(96{,}485\ \frac{\text{C}}{\text{mol } e^-}\right)}{30\text{ hr}\left(\frac{3600\text{ s}}{1\text{ hr}}\right)} \approx \frac{10 \times 10^5}{10^5}$$

$$= 10\text{ A (actual} = 8.93\text{ A)}$$

6.

Battery	State of Use	Galvanic or Electrolytic	Anode Material	Anode Charge	Cathode Material	Cathode Charge
Ni–Cd	Discharging	Galvanic	Cd	Negative	NiO(OH)	Positive
Ni–Cd	Charging	Electrolytic	$Cd(OH)_2$	Positive	$Ni(OH)_2$	Negative
Molten NaCl	Discharging	Electrolytic	Any	Positive	Any	Negative
Daniell cell	Discharging	Galvanic	Zn	Negative	Cu	Positive
Lead–acid	Charging	Electrolytic	$PbSO_4$	Positive	$PbSO_4$	Negative
Lead–acid	Discharging	Galvanic	Pb	Negative	PbO_2	Positive

12.2

1. A sample is measured by setting up a cell relative to a standard hydrogen electrode, which is given a reduction potential of 0 V by convention.
2. A positive emf means the cell is spontaneous (galvanic); a negative emf means the cell is nonspontaneous (electrolytic).
3. The first cell is electrolytic because it has a negative emf. The second cell is galvanic because it has a positive emf.
4. The reduction potential of triiodide is higher than iron(III), so triiodide will be reduced and iron will be oxidized: 2 Fe + 3 I_3^- → 2 Fe^{3+} + 9 I^- (E°_{cell} = +0.57 V)

12.3

1.

K_{eq}	$\Delta G°$: (+) or (–)?	Reaction: Spontaneous or Nonspontaneous?	$E°_{cell}$: (+) or (–)?
$\mathbf{1.2 \times 10^{-2}}$	+	Nonspontaneous	–
$\mathbf{2 \times 10^{2}}$	–	Spontaneous	+
1	0	Not applicable—applies to any cell at equilibrium	0

Remember that $\Delta G° = -RT \ln K_{eq}$; if $K_{eq} < 1$, $\ln K_{eq} < 0$, and $\Delta G° > 0$. If $K_{eq} > 1$, $\ln K_{eq} > 0$, and $\Delta G° < 0$. If $K_{eq} = 1$, $\ln K_{eq} = 0$, and $\Delta G° = 0$.

2.

Q	K_{eq}	Reaction Direction (Forward, Backward, or Equilibrium)	Sign of E_{cell}
10^{-3}	10^{-2}	Forward	+
10^{2}	1.1	Backward	–
1	1	Equilibrium	0

Note that these calculations do not assume standard conditions, unlike question 1.

EQUATIONS TO REMEMBER

(12.1) **Moles of electrons transferred during reduction:** $M^{n+} + n\,e^- \rightarrow M\,(s)$

(12.2) **Electrodeposition equation:** $\text{mol M} = \dfrac{It}{n\text{F}}$

(12.3) **Standard electromotive force of a cell:** $E^\circ_{\text{cell}} = E^\circ_{\text{red,cathode}} - E^\circ_{\text{red,anode}}$

(12.4) **Standard change in free energy from standard emf:** $\Delta G^\circ = -n\text{F}E^\circ_{\text{cell}}$

(12.5) **Nernst equation (full):** $E_{\text{cell}} = E^\circ_{\text{cell}} - \dfrac{\text{R}T}{n\text{F}} \ln Q$

(12.6) **Nernst equation (simplified):** $E_{\text{cell}} = E^\circ_{\text{cell}} - \dfrac{0.0592}{n} \log Q$

(12.7) **Reaction quotient:** $Q = \dfrac{[\text{C}]^c[\text{D}]^d}{[\text{A}]^a[\text{B}]^b}$

(12.8) **Standard change in free energy from equilibrium constant:** $\Delta G^\circ = -\text{R}T \ln K_{\text{eq}}$

(12.9) **Free energy change (nonstandard conditions):** $\Delta G = \Delta G^\circ + \text{R}T \ln Q$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Rusting occurs due to the oxidation–reduction reaction of iron with environmental oxygen:

$$4\ Fe\ (s) + 3\ O_2\ (g) \rightarrow 2\ Fe_2O_3\ (s)$$

Some metals cannot react with oxygen in this fashion. Which of the following best explains why iron can?

A. Iron has a more positive reduction potential than those metals, making it more likely to donate electrons to oxygen.
B. Iron has a more positive reduction potential than those metals, making it more likely to accept electrons from oxygen.
C. Iron has a less positive reduction potential than those metals, making it more likely to donate electrons to oxygen.
D. Iron has a less positive reduction potential than those metals, making it more likely to accept electrons from oxygen.

2. Given the following standard reduction potentials:

$Zn^{2+} + 2\ e^- \rightarrow Zn$ $\quad E^\circ_{red} = -0.763$ V

$Ag^+ + e^- \rightarrow Ag$ $\quad E^\circ_{red} = +0.337$ V

What is the standard electromotive force of the following reaction?

$$Zn^{2+} + 2\ Ag \rightarrow 2\ Ag^+ + Zn$$

A. –2.2 V
B. –1.1 V
C. +1.1 V
D. +2.2 V

3. Consider the following data:

$Hg^{2+} + 2\ e^- \rightarrow Hg$ $\quad E^\circ_{red} = +0.85$ V

$Cu^+ + e^- \rightarrow Cu$ $\quad E^\circ_{red} = +0.52$ V

$Zn^{2+} + 2\ e^- \rightarrow Zn$ $\quad E^\circ_{red} = -0.76$ V

$Al^{3+} + 3\ e^- \rightarrow Al$ $\quad E^\circ_{red} = -1.66$ V

The anode of a certain galvanic cell is composed of copper. Which of the metals from the data table can be used at the cathode, assuming equal concentrations of the two electrolyte solutions?

A. Hg
B. Cu
C. Zn
D. Al

4. An electrolytic cell is filled with water. Which of the following will move toward the cathode of such a cell?

I. H^+ ions
II. O^{2-} ions
III. Electrons

A. I only
B. II only
C. I and III only
D. II and III only

5. If the value of E°_{cell} is already known, what additional data is sufficient to calculate ΔG°?

A. The gas constant (R)
B. Reaction quotient
C. Temperature of the system
D. Half-reactions of the cells

6. Which of the following compounds is LEAST likely to be found in the salt bridge of a galvanic cell?

A. NaCl
B. SO_3
C. $MgSO_3$
D. NH_4NO_3

7. If the surface area of electrode material in an electrochemical cell is tripled, what else is necessarily tripled?

I. E°_{cell}
II. Current
III. K_{eq}

A. I only
B. II only
C. I and II only
D. II and III only

8. Which of the following can alter the emf of an electrochemical cell?

A. The mass of the electrodes
B. The length of the wire connecting the half-cells
C. The overall size of the battery
D. The temperature of the solutions in the half-cells

9. Which of the following statements could be true about a Na–Cd cell, based on the information below?

$Na^+ + e^- \rightarrow Na$ $\quad E^\circ_{red} = -2.71$ V

$Cd^{2+} + 2\ e^- \rightarrow Cd$ $\quad E^\circ_{red} = -0.40$ V

A. It is a galvanic cell, and sodium is the cathode.
B. It is an electrolytic cell, and cadmium is the anode.
C. It is a galvanic cell, with $E^\circ_{cell} = 3.11$ V.
D. It is an electrolytic cell, with $E^\circ_{cell} = -3.11$ V.

10. Which of the following expressions correctly describes the relationship between standard electromotive force and standard change in free energy?

A. $\Delta G^\circ = -n\mathrm{F}(E^\circ_{red,anode} - E^\circ_{red,cathode})$
B. $E^\circ_{cell} = \frac{n\mathrm{F}}{\mathrm{R}T} \ln K_{eq}$
C. $E^\circ_{cell} = -\frac{\mathrm{R}T}{n\mathrm{F}} \ln K_{eq}$
D. $\Delta G^\circ = n\mathrm{F}(E^\circ_{red,anode} - E^\circ_{red,cathode})$

11. Which of the following choices is indicative of a spontaneous reaction, assuming standard conditions?

A. E°_{cell} is negative
B. $Q = K_{eq}$
C. The cell is a concentration cell
D. $K_{eq} > 1$

12. For a cell with the following half-reactions:

Anode: $SO_2 + 2\ H_2O \rightarrow SO_4^{2-} + 4\ H^+ + 2\ e^-$

Cathode: $Pd^{2+} + 2\ e^- \rightarrow Pd$

How would decreasing the pH of the solution inside the cell affect the electromotive force (emf)?

A. The emf would decrease.
B. The emf would remain the same.
C. The emf would increase.
D. The emf would become zero.

13. An electrolytic cell necessarily has:

A. $\Delta S^\circ > 0$
B. $\Delta G^\circ < 0$
C. $K_{eq} < 1$
D. $E^\circ_{cell} > 0$

14. Which of the following is the best explanation for the fact that a larger mass of electrodes are required for lead–acid batteries, as compared to other batteries, to produce a certain current?

A. The lead–acid electrolyte, sulfuric acid, is diprotic and incompletely dissociates in solution.
B. The energy density of lead–acid electrodes is higher than that of other batteries.
C. The electrolytes in other batteries less readily dissociate than those of lead–acid batteries.
D. The energy density of lead–acid electrodes is lower than that of other batteries.

15. Which of the following best describes why overcharging a Ni–Cd battery is not detrimental?

A. The energy density of a Ni–Cd battery is high, so it can store more charge than other batteries per its mass.
B. The electrodes of a Ni–Cd battery can discharge through the circuit when they are fully charged.
C. The Ni–Cd battery will stop accepting electrons from an outside source when its electrodes are recharged.
D. Ni–Cd batteries have a high surge current and can dissipate the overcharge before damage can occur to electrodes.

Explanations to Discrete Practice Questions

1. C

In the oxidation–reduction reaction of a metal with oxygen, the metal will be oxidized (donate electrons) and oxygen will be reduced (accept electrons). This fact allows us to immediately eliminate **choices (B)** and **(D)**. A species with a higher reduction potential is more likely to be reduced, and a species with a lower reduction potential is more likely to be oxidized. Based on the information in the question, iron is oxidized more readily than those metals; this means that iron has a lower reduction potential.

2. B

To determine the standard electromotive force of a cell, simply subtract the standard reduction potentials of the two electrodes. In this case, the cathode is zinc because it is being reduced; the anode is silver because it is being oxidized. Thus,

$$E^\circ_{\text{cell}} = E^\circ_{\text{red,cathode}} - E^\circ_{\text{red,anode}} = -0.763 - 0.337 = -1.10\ \text{V}$$

While we must multiply the silver half-reaction by two to balance electrons, the actual value for the reduction potential does not change. Remember that the standard reduction potential is determined by the identity of the electrode, not the amount of it present.

3. A

Oxidation occurs at the anode, and reduction occurs at the cathode. Because Cu is the anode, it must be oxidized. The reduction potential of the cathode cannot be less than that of the anode for a galvanic cell. Therefore, mercury, **choice (A)**, must be the cathode. In a concentration cell, the same material is used as both the cathode and anode; however, this question assumes equal concentrations. If both electrolyte solutions have the same concentration, there will be no oxidation–reduction reaction and, therefore, no anode or cathode. This eliminates **choice (B)**.

4. C

In an electrolytic cell, ionic compounds are broken up into their constituents; the cations (positively charged ions) migrate toward the cathode, and the anions (negatively charged ions) migrate toward the anode. In this case, the cations are H^+ ions (protons), so option I is correct. Electrons flow from anode to cathode in all types of cells, meaning that option III is also correct. Option II is incorrect for two reasons. First, it is unlikely that the anions in any cell would be O^{2-} rather than OH^-. Second, and more significantly, these anions would flow to the anode, not the cathode.

5. D

This answer comes directly from the equation relating Gibbs free energy and E°_{cell}. $\Delta G^\circ = -n\text{F}E^\circ_{\text{cell}}$, where n is the number of moles of electrons transferred and F is the Faraday constant, 96,485 $\frac{\text{C}}{\text{mol } e^-}$. To determine n, one must look at the balanced half-reactions occurring in the oxidation–reduction reaction.

6. B

Salt bridges contain inert electrolytes. Ionic compounds, such as **choices (A)**, **(C)**, and **(D)**, are known to be strong electrolytes because they completely dissociate in solution. **Choice (B)** cannot be considered an electrolyte because its atoms are covalently bonded and will not dissociate in aqueous solution. **Choices (B)** and **(C)** may appear similar, but there is an important distinction to be made. **Choice (C)** implies that Mg^{2+} and SO_3^{2-} are the final, dissociated ionic

constituents, while **choice (B)** implies that neutral SO_3 would have to be dissolved in solution.

7. B

Potential, as measured by E°_{cell}, is dependent only on the identity of the electrodes and not the amount present. Similarly, the equilibrium constant depends only on the identity of the electrolyte solutions and the temperature. However, as the electrode material is increased, the surface area participating in oxidation–reduction reactions is increased and more electrons are released, making statement II correct.

8. D

E°_{cell} is dependent upon the change in free energy of the system through the equation $RT \ln K_{eq} = nFE^\circ_{cell}$. The temperature, T, appears in this equation; thus, a change in temperature will impact the E°_{cell}.

9. B

If this were a galvanic cell, the species with the more positive reduction potential (cadmium) would be reduced. The cathode is always reduced in an electrochemical cell, so sodium could not be the cathode in such a galvanic cell, eliminating **choice (A)**. Sodium would be the cathode in an electrolytic cell, however, which would make cadmium the anode. Thus, the answer is **choice (B)**. Note that we do not have to determine E°_{cell} because we already know the answer. However, the E°_{cell} would be –2.71 – (–0.40) = –2.31 V for an electrolytic cell, and +2.31 V for a galvanic cell, eliminating **choices (C)** and **(D)**.

10. D

There are only two equations involving standard change in free energy in electrochemical cells: $\Delta G^\circ = -nFE^\circ_{cell}$ and $\Delta G^\circ = -RT \ln K_{eq}$. Substituting $E^\circ_{cell} = E^\circ_{red,cathode} - E^\circ_{red,anode}$ into the first equation and distributing the negative sign gives **choice (D)**. **Choice (A)** would be the opposite of ΔG°. Setting the two equations equal to each other, we get $RT \ln K_{eq} = nFE^\circ_{cell}$. Solving for E°_{cell}, we get $E^\circ_{cell} = \frac{RT}{nF} \ln K_{eq}$, which is the opposite of **choice (B)**. **Choice (C)** incorrectly solves the algebra.

11. D

A spontaneous electrochemical reaction has a negative ΔG. Using the equation $\Delta G^\circ = -RT \ln K_{eq}$, $K_{eq} > 1$ would result in $\ln K_{eq} > 0$, which means $\Delta G^\circ < 0$. A negative electromotive force, **choice (A)**, or equilibrium state, **choice (B)**, would not correspond to a spontaneous reaction. Concentration cells can be spontaneous; however, if the concentration cell had reached equilibrium, it would cease to be a spontaneous reaction, eliminating **choice (C)**. When an answer choice *may* be true, but does not *have to* be—it is the wrong answer on Test Day.

12. A

A change in pH has a direct correlation to the hydrogen ion (H^+) concentration. Decreasing the pH increases the H^+ concentration, which means the concentration of products has increased in the oxidation of sulfur dioxide. This means it would be harder to liberate electrons, thus decreasing the emf. One could also view this decrease in oxidation potential as an increase in reduction potential. If $E^\circ_{red,anode}$ increases, then E°_{cell} must decrease according to $E^\circ_{cell} = E^\circ_{red,cathode} - E^\circ_{red,anode}$.

13. C

An electrolytic cell is nonspontaneous. Therefore, the ΔG° must be positive and E°_{cell} must be negative, eliminating **choices (B)** and **(D)**. The change in entropy may be positive or negative, depending on the species involved, eliminating **choice (A)**. According to the equation $\Delta G^\circ = -RT \ln K_{eq}$, $K_{eq} < 1$ would result in $\ln K_{eq} < 0$, which means $\Delta G^\circ > 0$.

14. D

Compared to other cell types, lead–acid batteries have a characteristically low energy density, **choice (D)**. While **choice (A)** is a true statement, the incomplete dissociation of sulfuric acid does not fully explain the low energy density of lead–acid batteries. **Choice (C)** is likely to be an opposite; the more easily the electrodes dissociate, the easier it is to carry out oxidation–reduction reactions with them.

15. C

During the recharge cycle, Ni–Cd cells will accept current from an outside source until the Cd and NiO(OH) electrodes are pure; at this point, the reaction will stop because $Cd(OH)_2$ runs out and no more electrons can be accepted. **Choices (A)** and **(B)** are both true statements, but they fail to explain why overcharging the battery (continuing to try to run current into the battery even when the electrodes are reverted to their original state) is not a problem with Ni–Cd batteries. Finally, surge current refers to the initial burst of current seen in some batteries; once charged, the surge current will not increase even if the power source continues to be run because no additional charge will be stored on the electrodes, eliminating **choice (D)**.

Glossary

Absolute zero—The temperature at which all substances have no thermal energy; 0 K or –273.15°C.

Absorption spectrum—The series of discrete lines at characteristic frequencies representing the energy required to excite an electron from the ground state.

Acid—A species that donates hydrogen ions or accepts electrons.

Acid dissociation constant (K_a)—The equilibrium constant that measures the degree of dissociation of an acid under specific conditions.

Acidic solution—An aqueous solution that contains more H^+ ions than OH^- ions; pH < 7 under standard conditions.

Activation energy (E_a)—The minimum amount of energy required for a reaction to reach the transition state.

Actual yield—The experimental quantity of a substance obtained at the end of a reaction.

Adiabatic process—A process that occurs without the transfer of heat into or out of the system.

Alkali metals—Elements found in Group IA of the periodic table; highly reactive, readily losing one valence electron to form ionic compounds with nonmetals.

Alkaline earth metals—Elements found in Group IIA of the periodic table; chemistry is similar to that of the alkali metals, except that they have two valence electrons and, thus, form +2 cations.

Amphiprotic species—A species that may either gain or lose a proton.

Amphoteric species—A species capable of reacting as either an acid or base, depending on the nature of the reactants.

Anion—An ionic species with a negative charge.

Anode—The electrode at which oxidation occurs.

Antibonding orbital—A molecular orbital formed by the overlap of two or more atomic orbitals; energy is greater than the energy of the combining atomic orbitals.

Aqueous solution—A solution in which water is the solvent.

Arrhenius acid—A species that donates protons (H^+) in aqueous solution.

Arrhenius base—A species that donates hydroxide ions (OH^-) in aqueous solution.

Arrhenius equation—A chemical kinetics equation that relates the rate constant (k) of a reaction with the frequency factor (A), the activation energy (E_a), the ideal gas constant (R), and temperature (T) in kelvin.

Atom—The smallest unit of an element that retains the properties of the element; it cannot be further broken down by chemical means.

Atomic mass—The mass of a given isotope of an element; closely related to the mass number.

Atomic mass unit (amu)—A unit of mass defined as $\frac{1}{12}$ the mass of a carbon-12 atom; approximately equal to the mass of one proton or one neutron.

Atomic number—The number of protons in a given element.

Atomic orbital—Describes the region of space where there is a high probability of finding an electron.

Atomic radius—The average distance between a nucleus and its outermost electron; usually measured as one-half the distance between two nuclei of an element in its elemental form.

Atomic weight—The weighted average mass of the atoms of an element, taking into account the relative abundance of all naturally occurring isotopes.

Aufbau principle—The concept that electrons fill energy levels in order of increasing energy, completely filling one sublevel before beginning to fill the next.

Autoionization—The process by which a molecule (usually water) spontaneously dissociates into cations and anions.

Avogadro's number—The number of atoms or molecules in one mole of a substance: 6.02×10^{23} mol^{-1}.

Avogadro's principle—The law stating that under the same conditions of temperature and pressure, equal volumes of different gases will have the same number of molecules.

Azimuthal quantum number (l)—The quantum number denoting the sublevel or subshell in which an electron can be found; reveals the shape of the orbital.

Balanced equation—An equation for a chemical reaction in which the number of atoms for each element in the reaction and the total charge are the same for the reactants and the products.

Balmer series—Part of the emission spectrum for hydrogen, representing transitions of an electron from energy levels $n > 2$ to $n = 2$.

Base—A species that donates hydroxide ions or electron pairs or that accepts protons.

Base dissociation constant (K_b)—The equilibrium constant that measures the degree of dissociation for a base under specific conditions.

Basic solution—An aqueous solution that contains more OH^- ions than H^+ ion; pH > 7 under standard conditions.

Bohr model—The model of the hydrogen atom in which electrons assume certain circular orbits around a positive nucleus.

Boiling point—The temperature at which the vapor pressure of a liquid is equal to the incident pressure; the normal boiling point of any liquid is defined as its boiling point at a pressure of 1 atmosphere.

Boiling point elevation—The amount by which a given quantity of solute raises the boiling point of a liquid; a colligative property.

Bond energy—The energy (enthalpy change) required to break a particular bond under given conditions.

Bond length—The average distance between two nuclei in a bond; as the number of shared electron pairs increases, the bond length decreases.

Bond order—The number of shared electron pairs between two atoms; a single bond has a bond order of 1, a double bond has a bond order of 2, a triple bond has a bond order of 3.

Bonding orbital—A molecular orbital formed by the overlap of two or more atomic orbitals; energy is less than that of the combining orbitals.

Boyle's law—The law stating that at constant temperature, the volume of a gaseous sample is inversely proportional to its pressure.

Broken-order reaction—A reaction with noninteger orders in its rate law.

Brønsted–Lowry acid—A proton donor.

Brønsted–Lowry base—A proton acceptor.

Buffer—A solution containing a weak acid and its salt (or a weak base and its salt) that tends to resist changes in pH.

Buffer region—The portion of a titration curve in which the concentration of an acid is approximately equal to that of its conjugate base; pH remains relatively constant through this region.

Calorie (cal)—A unit of thermal energy.

Calorimeter—An apparatus used to measure the heat absorbed or released by a reaction.

Catalyst—A substance that increases the rates of the forward and reverse directions of a specific reaction by lowering activation energy, but is itself left unchanged.

Cathode—The electrode at which reduction takes place.

Cation—An ionic species with a positive charge.

Celsius (°C)—A temperature scale defined by having 0°C equal to the freezing point of water and 100°C equal to the boiling point of water; otherwise known as the centigrade temperature scale.

Chalcogens—Elements found in Group VIA of the periodic table with diverse chemistry; the group contains metals, nonmetals (like oxygen), and metalloids; typically form –2 anions.

Charging—A state of an electrochemical cell in which an external electromotive force is being used to return a cell to its original state; during this

process, electrons are transferred nonspontaneously from cathode to anode.

Charles's law—The law stating that the volume of a gas at constant pressure is directly proportional to its absolute (kelvin) temperature.

Chelation—The process of binding metal ions to the same ligand at multiple points.

Chemical bond—The interaction between two atoms resulting from the sharing or transfer of electrons.

Chemical equation—An expression used to describe the quantity and identity of the reactants and products of a reaction.

Chemical properties—Those properties of a substance related to the chemical changes that it undergoes, such as ionization energy and electronegativity.

Closed system—A system that can exchange energy but not matter with its surroundings.

Colligative properties—Those properties of solutions that depend only on the number of solute particles present but not on the nature of those particles.

Collision theory of chemical kinetics—A theory that states that the rate of a reaction is proportional to the number of collisions per second between reacting molecules that have sufficient energy to overcome the activation energy barrier; implies that only a fraction of collisions are sufficient.

Combination reaction—A reaction in which two or more reactants form a single product.

Combined gas law—A gas law that combines Boyle's law, Charles's law, and Gay-Lussac's law to state that pressure and volume are inversely proportional to each other, and each is directly proportional to temperature.

Combustion reaction—A reaction in which an oxidant (typically oxygen) reacts with a fuel (typically a hydrocarbon) to yield water and an oxide (such as carbon dioxide if between a hydrocarbon and oxygen).

Common ion effect—A shift in the equilibrium of a solution due to the addition of ions of a species already present in the reaction mixture.

Complex ion—A polyatomic molecule in which a central cation is bonded to electron pair donors called ligands.

Compound—A pure substance that can be decomposed to produce elements, other compounds, or both.

Compression—Reduction in the volume of a gas.

Concentrated solution—A solution with a high concentration value; the cutoff for the term "concentrated" depends on the purpose and identity of the solution.

Concentration—The amount of solute per unit of solvent or the relative amount of one component in a mixture.

Concentration cell—A cell that creates an electromotive force (emf or voltage) using a single chemical species in half-cells of varying concentration.

Condensation—The process in which a gas transitions to the liquid state.

Conductor—A material in which electrons are able to transfer energy in the form of heat or electricity.

Conjugate acid–base pair—The relationship between a Brønsted–Lowry acid and its deprotonated form, or a Brønsted–Lowry base and its protonated form.

Coordinate covalent bond—A covalent bond in which both electrons of the bonding pair are donated by one of the bonded atoms.

Covalent bond—A chemical bond formed by the sharing of an electron pair between two atoms; can be in the form of single bonds, double bonds, or triple bonds.

Critical pressure—The vapor pressure at the critical temperature of a given substance.

Critical temperature—Also known as the critical point. The highest temperature at which the liquid and gas phases of a substance can coexist; above this temperature, the liquid and gas phases are indistinguishable.

Crystal—A solid in which atoms, ions, or molecules are arranged in a regular, three-dimensional lattice structure.

***d* subshell**—Subshell corresponding to the angular momentum quantum number $l = 2$; contains five orbitals and is found in the third and higher principal energy levels.

Dalton's law of partial pressures—The law stating that the sum of the partial pressures of the components of a gaseous mixture must equal the total pressure of the sample.

Daniell cell—An electrochemical cell in which the anode is the site of Zn metal oxidation and the cathode is the site of Cu^{2+} ion reduction.

Decomposition reaction—A reaction in which a single compound breaks down into two or more products.

Delocalized orbitals—Molecular orbitals in which electron density is spread over an entire molecule, or a portion thereof, rather than being localized between two atoms.

Density (ρ)—A physical property of a substance, defined as the mass contained in a unit of volume.

Deposition—In most chemical processes, the direct transition of a substance from the gaseous state to the solid state; in electrochemical reactions, the build up of a solid precipitate onto an electrode.

Diamagnetism—A condition that arises when a substance has no unpaired electrons and is slightly repelled by a magnetic field.

Diffusion—The random motion of gas or solute particles across a concentration gradient, leading to uniform distribution of the gas or solute throughout the container.

Dilute solution—A solution with a low concentration of a given solute.

Dipole—A species containing bonds between elements of different electronegativities, resulting in an unequal distribution of charge.

Dipole–dipole interactions—The attractive forces between two dipoles; magnitude is dependent on both the dipole moments and the distance between the two species.

Dipole moment—A vector quantity with a magnitude that is dependent on the product of the charges and the distance between them; oriented from the positive to the negative pole.

Discharging—The state of a rechargeable electrochemical cell that is providing an electromotive force by allowing electrons to flow spontaneously from anode to cathode.

Disproportionation—An oxidation–reduction reaction in which the same species acts as the oxidizing agent and as the reducing agent; also called dismutation.

Dissociation—The separation of a single species into two separate species; usually used in reference to salts or weak acids or bases.

Double-displacement reaction—A reaction in which ions from two different compounds swap their associated counterions; typically, one of the products of this type of reaction is insoluble in solution and will precipitate.

Ductility—The property of metals that allows a material to be drawn into thinly stretched wires.

Effective nuclear charge (Z_{eff})—The charge perceived by an electron from the nucleus; applies most often to valence electrons and influences periodic trends such as atomic radius and ionization energy.

Effusion—The movement of gas from one compartment to another under pressure through a small opening; follows Graham's law.

Electrochemical cell—A cell within which an oxidation–reduction reaction takes place, containing two electrodes between which there is an electrical potential difference.

Electrode—An electrical conductor through which an electrical current enters or leaves a medium.

Electrolysis—The process in which an electrical current is used to power an otherwise nonspontaneous decomposition reaction.

Electrolyte—A compound that ionizes in water and increases the conductance of the solution.

Electrolytic cell—An electrochemical cell that uses an external voltage source to drive a nonspontaneous oxidation–reduction reaction.

Electromagnetic radiation—A wave composed of electric and magnetic fields oscillating perpendicular to each other and to the direction of propagation.

Electromagnetic spectrum—The range of all possible frequencies or wavelengths of electromagnetic radiation.

Electromotive force (emf)—The potential difference developed between the cathode and the anode of an electrochemical cell; also called voltage.

Electron (e^-)—A subatomic particle that remains outside the nucleus and carries a single negative charge; in most cases, its mass is considered to be negligible.

Electron configuration—The symbolic representation used to describe the electron arrangement within the energy sublevels in a given atom.

Electron spin—The intrinsic angular momentum of an electron, represented by m_s; has arbitrary values of $+\frac{1}{2}$ and $-\frac{1}{2}$.

Electronegativity—A measure of the ability of an atom to attract the electrons in a bond; commonly measured with the Pauling scale.

Element—A substance that cannot be further broken down by chemical means; defined by its number of protons (atomic number).

Emission spectrum—A series of discrete lines at characteristic frequencies, each representing the energy emitted when electrons in an atom return from an excited state to their ground state.

Empirical formula—The simplest whole-number ratio of the different elements in a compound.

Endothermic reaction—A reaction that absorbs heat from the surroundings as the reaction proceeds (positive ΔH).

Endpoint—The point in a titration at which the indicator changes to its final color.

Energy density—An equivalence unit regarding the amount of electrochemical energy capable of being stored per unit weight; a battery with a large energy density can produce a large amount of energy with a small amount of material.

Enthalpy (H)—The heat content of a system at constant pressure; the change in enthalpy (ΔH) in the course of a reaction is the difference between the enthalpies of the products and the reactants.

Entropy (S)—A property related to dispersion of energy through a system or the degree of disorder in that system; the change in entropy (ΔS) in the course of a reaction is the difference between the entropies of the products and the reactants.

Equilibrium—The state of balance in which the forward and reverse reaction rates of a reversible reaction are equal; the concentrations of all species will remain constant over time unless there is a change in the reaction conditions.

Equilibrium constant (K_{eq})—The ratio of the concentrations of the products to the concentrations of the reactants for a certain reaction at equilibrium, all raised to their stoichiometric coefficients.

Equivalence point—The point in a titration at which the moles of acid present equal the moles of base added, or vice-versa.

Equivalent—A mole of charge in the form of electrons, protons, ions, or other measurable quantities that are produced by a substance.

Evaporation—The transition from a liquid to a gaseous state.

Excess reagent—In a chemical reaction, any reagent that does not limit the amount of product that can be formed.

Excitation—The promotion of an electron to a higher energy level by absorption of an energy quantum.

Excited state—An electronic state having a higher energy than the ground state; typically attained by the absorption of a photon of a certain energy.

Exothermic reaction—A reaction that gives off heat to the surroundings (negative ΔH) as the reaction proceeds.

***f* subshell**—The subshell corresponding to the angular momentum quantum number $l = 3$; contains seven orbitals and is found in the fourth and higher principal energy levels.

Faraday constant (F)—The total charge on 1 mole of electrons ($F = 96{,}485 \frac{C}{\text{mol } e^-}$); not to be confused with the farad (also denoted F), a unit of capacitance.

First law of thermodynamics—The law stating that the total energy of a system and its surroundings remains constant.

First-order reaction—A reaction in which the rate is directly proportional to the concentration of only one reactant.

Fluid—A substance that flows due to weak intermolecular attractions between molecules and that takes the shape of its container; liquids and gases are considered fluids.

Formal charge—The conventional assignment of charges to individual atoms of a Lewis structure for a molecule; the total number of valence electrons in the free atom minus the total number of electrons when the atom is bonded (assuming equal splitting of the electrons in bonds).

Formula weight—The sum of the atomic weights of constituent ions according an ionic compound's empirical formula.

Freezing—The process in which a liquid transitions to the solid state; also known as solidification or crystallization.

Freezing point—At a given pressure, the temperature at which the solid and liquid phases of a substance coexist in equilibrium; identical to the melting point.

Freezing point depression—Amount by which a given quantity of solute lowers the freezing point of a liquid; a colligative property.

Galvanic cell—An electrochemical cell that uses a spontaneous oxidation–reduction reaction to generate an electromotive force; also called a voltaic cell.

Gas—The physical state of matter possessing the most disorder, in which molecules interact through very weak attractions; found at relatively low pressure and high temperatures.

Gas constant (R)—A proportionality constant that appears in the ideal gas law equation, $PV = nRT$. Its value depends on the units of pressure, temperature, and volume used in a given situation.

Gay-Lussac's law—The law stating that the pressure of a gaseous sample at constant volume is directly proportional to its absolute temperature.

Gibbs free energy (G)—The energy of a system available to do work. The change in Gibbs free energy, ΔG, can be determined for a given reaction equation from the enthalpy change, temperature, and entropy change; a negative ΔG denotes a spontaneous reaction, while a positive ΔG denotes a nonspontaneous reaction.

Graham's law—The law stating that the rate of effusion or diffusion for a gas is inversely proportional to the square root of the gas's molar mass.

Gram equivalent weight (GEW)—The amount of a compound that contains 1 mole of reacting capacity when fully dissociated; one GEW equals the molar mass divided by the reactive capacity (how many of the species of interest is obtained) per formula unit.

Ground state—The unexcited state of an electron.

Group—A vertical column of the periodic table containing elements that are similar in their chemical properties; also called a family.

Half-cell—The separated compartments housing the electrodes and solutions in an electrochemical reaction.

Half-reaction—Either the reduction half or oxidation half of an oxidation–reduction reaction; in an electrochemical cell, each half-reaction occurs at one of the electrodes.

Halogens—The active nonmetals in Group VIIA of the periodic table, which have high electronegativities and high electron affinities.

Heat—The energy transferred spontaneously from a warmer sample to a cooler sample.

Heat of formation (ΔH_f)—The heat absorbed or released during the formation of a pure substance from its elements at a constant pressure.

Heat of fusion (ΔH_{fus})—The enthalpy change for the conversion of 1 gram or 1 mole of a solid to a liquid at constant temperature and pressure.

Heat of sublimation (ΔH_{sub})—The enthalpy change for the conversion of 1 gram or 1 mole of a solid to a gas at constant temperature and pressure.

Heat of vaporization (ΔH_{vap})—The enthalpy change for the conversion of 1 gram or 1 mole of a liquid to a gas at constant temperature and pressure.

Heisenberg uncertainty principle—The concept that states that it is impossible to determine both the momentum and position of an electron simultaneously with perfect accuracy.

Henderson–Hasselbalch equation—Equation showing the relationship of the pH or pOH of a solution to the pK_a or pK_b and the ratio of the concentrations of the dissociated species.

Henry's law—The law stating that the mass of a gas that dissolves in a solution is directly proportional to the partial pressure of the gas above the solution.

Hess's law—The law stating that the energy change in an overall reaction is equal to the sum of the energy changes in the individual reactions that comprise it.

Heterogeneous—Nonuniform in composition.

Heterogeneous catalyst—A catalyst that is not in the same phase of matter as the reactants (for example, a solid platinum catalyst reacting with hydrogen gas).

Homogeneous—Uniform in composition.

Homogeneous catalyst—A catalyst that is in the same phase of matter as the reactants (for example, an aqueous enzyme in the cytoplasm of a cell).

Hund's rule—The rule that electrons will fill into separate orbitals with parallel spins before pairing within an orbital.

Hybridization—The combination of two or more atomic orbitals to form new orbitals with properties that are intermediate between those of the original orbitals.

Hydrogen bonding—The strong attraction between a hydrogen atom bonded to a highly electronegative atom (such as nitrogen, oxygen, or fluorine) in one molecule and a highly electronegative atom in another molecule.

Hydrolysis—A reaction in which water is consumed during the breakdown of another molecule.

Hydronium ion—The H_3O^+ ion.

Hydroxide ion—The OH^- ion.

Ideal bond angle—An angle between nonbonding or bonding electron pairs that minimizes the repulsion between them.

Ideal gas—A hypothetical gas with behavior that is described by the ideal gas law under all conditions; assumes that its particles have zero volume and do not exhibit interactive forces.

Ideal gas law—The equation stating $PV = nRT$, where R is the gas constant; can be used to describe the behavior of many real gases at moderate pressures and temperatures significantly above absolute zero.

Indicator—A substance used in low concentrations during a titration that changes color over a certain pH range (acid–base titrations) or at a particular electromotive force (oxidation–reduction titrations); the final color change of an indicator occurs at the endpoint of a titration.

Inert gases—The elements in Group VIIIA, which contain a full octet of valence electrons in their outermost shells and are therefore very unreactive; also called noble gases.

Intermediate—A molecule that transiently exists in a multistep reaction; does not appear in the overall balanced equation.

Intermolecular forces—The attractive and repulsive forces between molecules.

Intramolecular forces—The attractive forces between atoms within a single molecule (ionic and covalent bonds).

Ion—A charged atom or molecule that results from the loss or gain of electrons.

Ion product (*IP*)—The general term for the reaction quotient of a dissolving ionic compound; compared to K_{sp} to determine the saturation status of a solution.

Ionic bond—A chemical bond formed through electrostatic interaction between positive and negative ions.

Ionic radius—The average distance from the center of the nucleus to the edge of its electron cloud; cationic radii are generally smaller than their parent metal, whereas anionic radii are generally larger than their parent nonmetal.

Ionic solid—A solid consisting of positive and negative ions arranged into crystals that are made up of regularly repeated units held together by ionic bonds.

Ionization energy—The energy required to remove an electron from the valence shell of a gaseous atom.

Isobaric process—A process that occurs at constant pressure.

Isolated system—A system that can exchange neither matter nor energy with its surroundings.

Isothermal process—A process that occurs at constant temperature.

Isotopes—Atoms containing the same number of protons but different numbers of neutrons.

Isovolumetric process—A process that occurs at constant volume in which the system performs no work; also called an isochoric process.

Joule (J)—The unit of energy; $1\ J = 1\ \frac{kg \bullet m^2}{s^2}$.

Kelvin (K)—A temperature scale with units equal to the units of the Celsius scale and absolute zero defined as 0 K; also called the absolute temperature scale.

Kinetic molecular theory—The theory proposed to account for the observed behavior of gases; considers gas molecules to be pointlike, volumeless particles exhibiting no intermolecular forces that are in constant random motion and undergo only completely elastic collisions with the container or other gas particles.

Kinetic product—The product of a reaction that is formed favorably at a lower temperature because thermal energy is not available to form the transition state required to create a more stable thermodynamic product; has a smaller overall difference in free energy between the products and reactants than the thermodynamic product.

Law of conservation of charge—The law stating that, in a given reaction, the charge of ions in the products is equal to the charge of ions in the reactants.

Law of conservation of mass—The law stating that, in a given reaction, the mass of the products is equal to the mass of the reactants.

Law of constant composition—The law stating that the elements in a pure compound are found in specific mass ratios.

Law of mass action—The form of the equilibrium constant; has the concentrations of products over concentrations of reactants, each raised to their stoichiometric coefficients.

Le Châtelier's principle—The observation that when a system at equilibrium is disturbed or stressed, the system will react in such a way as to relieve the stress and restore equilibrium.

Lead–acid battery—An electrochemical cell in which the anode is the site of Pb metal oxidation and the cathode is the site of Pb^{4+} ion reduction. The electrolyte is a strong acid, usually sulfuric acid.

Lewis acid—A species capable of accepting an electron pair.

Lewis base—A species capable of donating an electron pair.

Lewis structure—A method of representing the shared and unshared electrons of an atom, molecule, or ion; also called a Lewis dot diagram.

Ligand—A molecule bonded to a metal ion in a coordination compound; ligands are Lewis bases that form coordinate covalent bonds with the central metal ion.

Limiting reagent—In a chemical reaction, the reactant present in such quantity as to limit the amount of product that can be formed.

Liquid—The state of matter in which intermolecular attractions are intermediate between those in gases and in solids, distinguished from the gas phase by having a definite volume and from the solid phase because molecules may mix freely.

Lyman series—A portion of the emission spectrum for hydrogen representing electronic transitions from energy levels $n > 1$ to $n = 1$.

Magnetic quantum number (m_l)—The third quantum number, defining the particular orbital of a subshell in which an electron resides; conveys information about the orientation of the orbital in space.

Malleability—A physical property of metals that defines how well an element can be shaped using a hammer.

Mass—A physical property representing the amount of matter in a given sample.

Maxwell–Boltzmann distribution curve—The distribution of the molecular speeds of gas particles at a given temperature; as temperature increases, average speed increases and the distribution becomes wider and flatter.

Melting point—The temperature at which the solid and liquid phases of a substance coexist in equilibrium; identical to the freezing point.

Metal—One of a class of elements on the left side of the periodic table possessing low ionization energies and electronegativities; readily give up electrons to form cations and possess relatively high electrical conductivity.

Metalloid—An element possessing properties intermediate between those

of a metal and those of a nonmetal; also called a semimetal.

Millimeters of mercury (mmHg)—A unit of pressure defined as the number of millimeters that mercury in a barometer is raised above its surface in a capillary tube by an external pressure; 1 torr is equal to 1 mmHg by definition, and 1 atmosphere is equal to 760 mmHg.

Mixed-order reaction—A reaction in which the reaction order changes over time in the rate law.

Molality (*m*)—A concentration unit equal to the number of moles of solute per kilogram of solvent.

Molar mass—The mass in grams of one mole of an element or compound.

Molarity (*M*)—A concentration unit equal to the number of moles of solute per liter of solution.

Mole—An amount of substance equal to Avogadro's number of molecules or atoms; the mass of 1 mole of substance in grams is the same as the mass of one molecule or atom in atomic mass units.

Mole fraction (*X*)—A unit of concentration equal to the ratio of the number of moles of a particular component to the total number of moles for all species in the system.

Molecular formula—A formula showing the actual number and identity of all atoms in each molecule of a compound; always a whole-number multiple of the empirical formula.

Molecular orbital—The region of electron density in chemical bonding that results from the overlap of two or more atomic orbitals.

Molecular weight—The sum of the atomic weights of all the atoms in a molecule.

Molecule—The smallest polyatomic unit of an element or compound that exists with distinct chemical and physical properties.

Nernst equation—An equation that relates the voltage of an electrochemical cell to the concentrations of the reactants and products within that cell.

Net ionic equation—A reaction equation showing only the species actually participating in the reaction.

Neutral solution—An aqueous solution in which the concentration of H^+ and OH^- ions are equal (pH = 7 at 298 K).

Neutralization reaction—A reaction between an acid and base in which a salt is formed (and sometimes water).

Neutron—A subatomic particle contained within the nucleus of an atom; carries no charge and has a mass very slightly larger than that of a proton.

Nickel–cadmium battery—A rechargeable electrochemical cell in which the anode is the site of Cd metal oxidation and the cathode is the site of Ni^{2+} ion reduction.

Nickel–metal hydride battery—A rechargeable electrochemical cell in which the anode is the site of metal hydride oxidation and the cathode is the site of nickel ion reduction; the nickel may be in one of many oxidation states.

Nonelectrolyte—A compound that does not ionize in water.

Nonmetal—One of a class of elements with high ionization energies and electron affinities that generally gain electrons to form anions; located in the upper right corner of the periodic table.

Nonpolar covalent bond—A covalent bond between elements of similar electronegativity; contains no charge separation.

Nonpolar molecule—A molecule that exhibits no net separation of charge and, therefore, no net dipole moment.

Nonrepresentative element—Elements with an expanded valence shell that includes *d*- and *f*-block electrons; also called Group B or transition elements.

Nonspontaneous process—A process that will not occur on its own without energy input from the surroundings; has a positive change in free energy.

Normality (*N*)—A concentration unit equal to the number of equivalents per liter of solution.

Nucleus—The small central region of an atom; a dense, positively charged area containing protons and neutrons.

Octet—Eight valence electrons in a subshell around a nucleus; imparts great stability to an atom.

Octet rule—A rule stating that bonded atoms tend to undergo reactions that will produce a complete octet of va-

lence electrons; applies without exception only to C, N, O, and F.

Open system—A system that can exchange both energy and matter with its surroundings.

Orbital—A region of electron density around an atom or molecule containing no more than two electrons of opposite spin.

Osmosis—The movement of water through a semipermeable membrane down its concentration gradient, from low solute concentration to high solute concentration.

Osmotic pressure—The pressure that must be applied to a solution to prevent the passage of water through a semipermeable membrane down its concentration gradient; best thought of as a "sucking" pressure drawing water into solution.

Oxidation—A reaction involving the net loss of electrons, increasing oxidation number.

Oxidation number—The number assigned to an atom in an ion or molecule that denotes its real or hypothetical charge, assuming that the most electronegative element in a bond is awarded all of the electrons in that bond.

Oxidation potential—The ability of a substance to be spontaneously oxidized; a more positive oxidation potential (measured in volts) is indicative of a substance that is easier to oxidize and will therefore more likely act as an anode in an electrochemical cell.

Oxidizing agent—In an oxidation–reduction reaction, the atom that facilitates the oxidation of another species; the oxidizing agent gains electrons and is thereby reduced.

***p* subshell**—The subshell corresponding to the angular momentum quantum number $l = 1$; contains three dumbbell-shaped orbitals oriented perpendicular to each other (p_x, p_y, and p_z) and is found in the second and higher principal energy levels.

Paired electrons—Two electrons in the same orbital with assigned spins of $+\frac{1}{2}$ and $-\frac{1}{2}$.

Paramagnetism—A condition that arises when a substance has unpaired electrons and is slightly attracted to a magnetic field.

Partial pressure—The pressure that one component of a gaseous mixture would exert if it were alone in the container.

Pascal (Pa)—The SI unit for pressure, equivalent to $\frac{N}{m^2}$; 1 atm = 101,325 Pa.

Pauli exclusion principle—The principle stating that no two electrons within an atom may have an identical set of quantum numbers.

Percent composition—The percentage of the total formula weight of a compound attributable to a given element.

Percent yield—The percentage of the theoretical product yield that is actually recovered when a chemical reaction occurs; obtained by dividing the actual yield by the theoretical yield and multiplying by 100%.

Period—A horizontal row of the periodic table containing elements with the same number of electron shells.

Periodic law—The law stating that the chemical properties of elements depend on the atomic number of the elements and change in a periodic fashion.

Periodic table—The visual display of all known chemical elements arranged in rows (periods) and columns (groups) according to their atomic number and electron structure.

pH—A measure of the hydrogen ion content of an aqueous solution, defined as the negative log of the H^+ (H_3O^+) concentration.

pH meter—A device used to measure the concentration of hydrogen ions in solution and report it as a pH value.

Phase—One of the three forms of matter: solid, liquid, or gas; also called state.

Phase diagram—A plot, usually of pressure *vs.* temperature, showing which phases of a compound will exist under any set of conditions.

Photon—The form of light which displays particulate and quantal behavior.

Physical property—A property of a substance unrelated to its chemical behavior, such as melting point, boiling point, density, or odor.

Pi (π) bond—A bond with two parallel electron cloud densities formed between two *p*-orbitals that limits the

possibility of free rotation; π bonds are the second bond in a double bond and both the second and third bonds in a triple bond.

pOH—A measure of the hydroxide (OH^-) ion content of an aqueous solution, defined as the negative log of the OH^- concentration.

Polar covalent bond—A covalent bond between atoms with different electronegativities in which electron density is unevenly distributed, giving the bond positive and negative ends.

Polar molecule—A molecule possessing one or more polar covalent bonds and a geometry that allows the bond dipole moments to sum to a net dipole moment.

Polyvalent acid—An acid capable of donating more than one proton; also known as a polyprotic acid.

Polyvalent base—A base capable of donating more than one hydroxide or accepting more than one proton.

Potential energy diagram—A graph that shows the potential energies of the reactants and products of a reaction during the course of the reaction; by convention, the *x*-axis shows the progress of the reaction and the *y*-axis shows potential energy.

Potentiometer—A device used to measure electromotive force (voltage).

Precipitate—An insoluble solid that separates from a solution; generally the result of mixing two or more solutions or of a temperature change.

Pressure—Average force per unit area measured in atmospheres (atm), torr or mmHg, or pascals (Pa); 1 atm = 760 torr $\equiv$ 760 mmHg = 101.325 kPa.

Principal quantum number (n)—The first quantum number, which defines the energy level or shell occupied by an electron.

Proton (p^+)—A subatomic particle that carries a single positive charge and has a mass slightly less than 1 amu.

Quantum number—A number used to describe the energy levels in which electrons reside; all electrons in an element are described by a unique set of four quantum numbers.

Radioactivity—A phenomenon exhibited by certain unstable isotopes in which they undergo spontaneous nuclear transformation via emission of one or more particles.

Raoult's law—A law stating that the partial pressure of a component in a solution is proportional to the mole fraction of that component in the solution; provides an explanation for vapor pressure depression seen in solutions.

Rate constant—The proportionality constant in the rate law of a reaction; specific to a particular reaction at a given temperature.

Rate-determining step—The slowest step of a reaction mechanism; this step serves as a bottleneck on the progress of the reaction.

Rate law—A mathematical expression giving the rate of a reaction as a function of the concentrations of the reactants; must be determined experimentally.

Rate order—The exponential effect of a change in concentration of a reactant on the change of rate in a reaction; the overall rate order is the sum of all the individual reactant rate orders.

Reaction mechanism—The series of steps that occurs in the course of a chemical reaction, often including the formation and destruction of reaction intermediates.

Reaction order—In a calculation of the rate law for a reaction, the sum of the exponents to which the concentrations of reactants must be raised.

Reaction quotient (Q)—Has the same form as the equilibrium constant, but the concentrations of products and reactants may not be at equilibrium; when compared to K_{eq}, it dictates the direction a reaction will proceed spontaneously.

Reaction rate—The speed at which a substance is produced or consumed by a reaction.

Real gas—A gas that exhibits deviations from the ideal gas law due to molecular attractions and the actual volume of the gas molecules themselves.

Rechargeable battery—An electrochemical cell that can undergo a reversible oxidation–reduction process; when discharging, it functions as a galvanic (voltaic) cell, and when charging, it functions as an electrolytic cell.

Redox titration—A specific method used to determine the concentration of an unknown solution using reducible titrants or titrands, typically by measuring voltage changes.

Reducing agent—In an oxidation–reduction reaction, the atom that facilitates the reduction of another species; the reducing agent loses electrons and is thereby oxidized.

Reduction—A reaction involving the net gain of electrons, decreasing the oxidation number.

Reduction potential—The ability of a substance to be spontaneously reduced; a more positive reduction potential (measured in volts) is indicative of a substance that is easier to reduce and will therefore more likely act as a cathode in an electrochemical cell.

Representative elements—Elements in Groups 1, 2, and 13 through 18 in the modern IUPAC table (the *s*- and *p*-blocks of the table, also called A group elements); these elements tend to have valence shells that follow the octet rule.

Resonance—A difference in the arrangement of electron pairs but not the bond connectivity or overall charge within a Lewis structure.

Resonance hybrid—A Lewis structure that represents the weighted average (by stability) of all possible resonance structures.

Root-mean-square speed (u_{rms})—The average speed of a gas molecule at a given temperature; as a scalar, it does not take direction into account.

***s* subshell**—Subshell corresponding to the angular momentum quantum number $l = 0$ and containing one spherical orbital; found in all energy levels.

Salt—An ionic substance consisting of cations and anions.

Salt bridge—A component of an electrochemical cell composed of an inert electrolyte that allows the charge gradient that builds up in the half-cells to be dissipated as a reaction occurs; contains ions that will not react with electrodes or ions in solution and that can move to balance charge.

Saturated solution—A solution containing the maximum amount of solute that can be dissolved in a particular solvent at a given temperature.

Second law of thermodynamics—The law stating that all spontaneous processes lead to an increase in the entropy of the universe.

Second-order reaction—A reaction in which the rate is directly proportional to the concentration of two reactants, or to the square of one single reactant.

Semipermeable—A quality of a membrane allowing only some components of a solution to pass through, usually including the solvent, while limiting the passage of other species.

Sigma (σ) bond—A head-to-head bond between two orbitals of different atoms that allows free rotation about its axis.

Single-displacement reaction—A reaction in which an ion of one compound is replaced with another ion; also known as a single-replacement reaction.

Solid—The phase of matter possessing the greatest order; molecules are fixed in a rigid structure.

Solubility—A measure of the amount of solute that can be dissolved in a solvent at a certain temperature.

Solubility product (K_{sp})—The equilibrium constant for the ionization reaction of a sparingly soluble salt.

Solute—The component of a solution that is present in a lesser concentration than the solvent.

Solution—A homogeneous mixture of two or more substances. It may be solid (brass), liquid (HCl (*aq*)), or gas (air).

Solvate—The tendency of water to dissociate ionic compounds into constituent ions; the dipole moments of water molecules create electrostatic interactions with cations or anions in solution.

Solvent—The component of a solution present in the greatest amount; the substance in which the solute is dissolved.

Sparingly soluble salt—An ionic compound that has a low solubility at a given temperature.

Specific heat—The amount of heat required to raise the temperature of one gram of a substance by 1°C.

Spectator ions—Ions involved in a reaction that do not change formula, charge, or phase; normally omitted from the net ionic equation.

Spectrum—The characteristic wavelengths of electromagnetic radiation emitted or absorbed by an object, atom, or molecule.

Spin quantum number (m_s)—The fourth quantum number, which indicates the orientation of the intrinsic spin of an electron in an atom; can only assume values of $+\frac{1}{2}$ and $-\frac{1}{2}$.

Spontaneous process—A process that will occur on its own without energy input from the surroundings; defined by a negative change in free energy.

Standard conditions—Conditions defined as 25°C, 1 atm pressure, and 1 *M* concentrations; used for measuring the standard Gibbs free energy, enthalpy, entropy, and cell electromotive force.

Standard free energy ($G°$)—The Gibbs free energy for a reaction under standard conditions.

Standard hydrogen electrode (SHE)—The electrode defined as having a potential of zero under standard conditions; all oxidation and reduction potentials are measured relative to the standard hydrogen electrode at 25°C and with 1 *M* concentrations of each ion in solution.

Standard potential—The voltage associated with a half-reaction of a specific oxidation–reduction reaction; generally tabulated as reduction potentials, compared to the standard hydrogen electrode.

Standard state—The phase of matter for a certain element under standard conditions.

Standard temperature and pressure (STP)—Defined as 0°C (273 K) and 1 atm; used for measuring characteristics of an ideal gas.

State function—A function that depends on the state of a system but not on the path used to arrive at that state; includes pressure, density, temperature, volume, enthalpy, internal energy, Gibbs free energy, and entropy.

Stoichiometry—A form of dimensional analysis focusing on the relationships between amounts of reactants and products in a reaction.

Strong acid—An acid that undergoes complete dissociation in an aqueous solution.

Strong base—A base that undergoes complete dissociation in an aqueous solution.

Sublimation—A change of phase from solid to gas without passing through the liquid phase.

Subshell—The division of electron shells or energy levels into different values of the azimuthal quantum number (*s*, *p*, *d*, and *f*); composed of orbitals.

Surroundings—All matter and energy in the universe not included in the particular system under consideration.

System—The matter and energy under consideration.

Temperature—A measure of the average kinetic energy of the particles in a system.

Theoretical yield—The maximal amount of product that can be obtained in a reaction; determined by stoichiometric analysis of the limiting reagent.

Thermodynamic product—The product of a reaction that is formed favorably at a higher temperature because thermal energy is available to form the transition state of the more stable product; has a larger overall difference in free energy between the products and reactants than the kinetic product.

Titrand—A solution of unknown concentration to which a solution of known concentration is added to determine its concentration.

Titrant—A solution of known concentration that is slowly added to a solution of unknown concentration to determine its concentration.

Titration—A method used to determine the concentration of an unknown solution by gradual reaction with a solution of known concentration.

Titration curve—A plot of the pH of a solution *vs.* the volume of acid or base added in an acid–base titration, or a plot of the electromotive force of a solution *vs.* the volume of oxidizing or reducing agent added in an oxidation–reduction titration.

Transition metal—Any of the elements in the B groups of the periodic table, all of which have partially filled *d* subshells.

Transition state—The point during a reaction in which old bonds are partially broken and new bonds are partially formed; has a higher energy than the reactants or products of the

reaction and is also called the activated complex.

Triple point—The pressure and temperature at which the solid, liquid, and gas phases of a particular substance coexist in equilibrium.

Unsaturated solution—A solution into which more solute may be dissolved before reaching saturation.

Valence electron—An electron in the highest occupied energy level of an atom; the tendency of a given valence electron to be retained or lost determines the chemical properties of an element.

Valence shell electron pair repulsion (VSEPR) theory—A system that reflects the geometric arrangement of a molecule based on its Lewis dot structure; the three-dimensional structure is determined by the repulsions between bonding and nonbonding electron pairs in the valence shells of atoms.

van der Waals equation of state—One of several real gas laws, which corrects for attractive forces and the volumes of gas particles, which are assumed to be negligible in the ideal gas law.

Vapor pressure—The partial pressure of a gaseous substance in the atmosphere above the liquid or solid with which it is in equilibrium.

Vapor pressure depression—The decrease in the vapor pressure of a liquid caused by the presence of dissolved solute; a colligative property.

Vaporization—The transformation of a liquid into a gas.

Water dissociation constant (K_w)—The equilibrium constant of the water dissociation reaction at a given temperature; equal to 10^{-14} at 25°C (298 K).

Weak acid—An acid that undergoes partial dissociation in an aqueous solution.

Weak base—A base that undergoes partial dissociation in an aqueous solution.

Yield—The amount of product obtained from a reaction.

Zero-order reaction—A reaction in which the concentrations of reactants have no effect on the overall rate.

Preface

And now it starts: your long, yet fruitful journey toward wearing a white coat. Proudly wearing that white coat, though, is hopefully only part of your motivation. You are reading this book because you want to be a healer.

If you're serious about going to medical school, then you are likely already familiar with the importance of the MCAT in medical school admissions. While the holistic review process puts additional weight on your experiences, extracurricular activities, and personal attributes, the fact remains: along with your GPA, your MCAT score remains one of the two most important components of your application portfolio—at least early in the admissions process. Each additional point you score on the MCAT pushes you in front of thousands of other students and makes you an even more attractive applicant. But the MCAT is not simply an obstacle to overcome; it is an opportunity to show schools that you will be a strong student and a future leader in medicine.

We at Kaplan take our jobs very seriously and aim to help students see success not only on the MCAT, but as future physicians. We work with our Learning Science experts to ensure that we're using the most up-to-date teaching techniques in our resources. Multiple members of our team hold advanced degrees in medicine or associated biomedical sciences, and are committed to the highest level of medical education. Kaplan has been working with the MCAT for over 50 years and our commitment to premed students is unflagging; in fact, Stanley Kaplan created this company when he had difficulty being accepted to medical school due to unfair quota systems that existed at the time.

We stand now at the beginning of a new era in medical education. As citizens of this 21st-century world of healthcare, we are charged with creating a patient-oriented, culturally competent, cost-conscious, universally available, technically advanced and research-focused healthcare system, run by compassionate providers. Suffice it to say, this is no easy task. Problem-based learning, integrated curricula, and classes in interpersonal skills are some of the responses to this demand for an excellent workforce—a workforce of which you'll soon be a part.

We're thrilled that you've chosen us to help you on this journey. Please reach out to us to share your challenges, concerns, and successes. Together, we will shape the future of medicine in the United States and abroad; we look forward to helping you become the doctor you deserve to be.

Good luck!

About *Scientific American*

Founded in 1845, *Scientific American* is the award-winning authoritative source for the science discoveries and technology innovations that matter. The longest continuously published magazine in the United States, it is translated into 14 languages and reaches a global audience of more than 6 million. Other titles include *Scientific American Mind* and *Spektrum der Wissenschaft* in Germany. In its history, 152 Nobel Prize scientists have contributed 246 articles to *Scientific American*, including Albert Einstein, Francis Crick, Stanley Prusiner, and Richard Axel.

Scientific American is at the heart of Nature Publishing Group's consumer media division, meeting the needs of the general public. For more information, please visit www.scientificamerican.com.

About the MCAT

ANATOMY OF THE MCAT

Here is a general overview of the structure of Test Day:

Section	Number of Questions	Time Allotted
Examinee Agreement		8 minutes
Tutorial (optional)		10 minutes
Chemical and Physical Foundations of Biological Systems	59	95 minutes
Break (optional)		10 minutes
Critical Analysis and Reasoning Skills (CARS)	53	90 minutes
Lunch Break (optional)		30 minutes
Biological and Biochemical Foundations of Living Systems	59	95 minutes
Break (optional)		10 minutes
Psychological, Social, and Biological Foundations of Behavior	59	95 minutes
Void Question		5 minutes
Satisfaction Survey (optional)		5 minutes

The structure of the four sections of the MCAT is further detailed below.

Chemical and Physical Foundations of Biological Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 5% • General Chemistry: 30% • Organic Chemistry: 15% • Physics: 25%
Critical Analysis and Reasoning Skills (CARS)	
Time	90 minutes
Format	• 53 questions • 9 passages • All questions are passage-based. There are no discrete (stand-alone) questions. • Score between 118 and 132

What It Tests	Disciplines: • Humanities: 50% • Social Sciences: 50% Skills: • *Foundations of Comprehension*: 30% • *Reasoning Within the Text*: 30% • *Reasoning Beyond the Text*: 40%
Biological and Biochemical Foundations of Living Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 65% • General Chemistry: 5% • Organic Chemistry: 5%
Psychological, Social, and Biological Foundations of Behavior	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biology: 5% • Psychology: 65% • Sociology: 30%
Total	
Testing Time	375 minutes (6 hours, 15 minutes)
Total Seat Time	453 minutes (7 hours, 33 minutes)
Questions	230
Score	472 to 528

SCIENTIFIC INQUIRY AND REASONING SKILLS (SIRS)

The AAMC has defined four *Scientific Inquiry and Reasoning Skills* (SIRS) that will be tested in the three science sections of the MCAT:

1. *Knowledge of Scientific Concepts and Principles* (35% of questions)
2. *Scientific Reasoning and Problem-Solving* (45% of questions)
3. *Reasoning About the Design and Execution of Research* (10% of questions)
4. *Data-Based and Statistical Reasoning* (10% of questions)

Let's see how each one breaks down into more specific Test Day behaviors. Note that the bullet points of specific objectives for each of the SIRS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Skill 1: *Knowledge of Scientific Concepts and Principles*

This is probably the least surprising of the four SIRS; the testing of science knowledge is, after all, one of the signature qualities of the MCAT. Skill 1 questions will require you to do the following:

- Recognize correct scientific principles
- Identify the relationships among closely-related concepts
- Identify the relationships between different representations of concepts (verbal, symbolic, graphic)
- Identify examples of observations that illustrate scientific principles
- Use mathematical equations to solve problems

At Kaplan, we simply call these Science Knowledge or Skill 1 questions. Another way to think of Skill 1 questions is as "one-step" problems. The single step is either to realize which scientific concept the question stem is suggesting or to take the concept stated in the question stem and identify which answer choice is an accurate application of it. Skill 1 questions are particularly prominent among discrete questions (those not associated with a passage). These questions are an opportunity to gain quick points on Test Day—if you know the science concept attached to the question, then that's it! On Test Day, 35% of the questions in each science section will be Skill 1 questions.

Here are some sample Skill 1 question stems:

- How would a proponent of the James–Lange theory of emotion interpret the findings of the study cited the passage?
- Which of the following most accurately describes the function of FSH in the human female menstrual cycle?
- If the products of Reaction 1 and Reaction 2 were combined in solution, the resulting reaction would form:
- Ionic bonds are maintained by which of the following forces?

Skill 2: *Scientific Reasoning and Problem-Solving*

The MCAT science sections do, of course, move beyond testing straightforward science knowledge; Skill 2 questions are the most common way in which it does so. At Kaplan, we also call these Critical Thinking questions. Skill 2 questions will require you to do the following:

- Reason about scientific principles, theories, and models
- Analyze and evaluate scientific explanations and predictions
- Evaluate arguments about causes and consequences
- Bring together theory, observations, and evidence to draw conclusions
- Recognize scientific findings that challenge or invalidate a scientific theory or model
- Determine and use scientific formulas to solve problems

Just as Skill 1 questions can be thought of as "one-step" problems, many Skill 2 questions are "two-step" problems, and more difficult Skill 2 questions may require three or more steps. These questions can require a wide spectrum of reasoning skills, including integration of multiple facts from a passage, combination of multiple science content areas, and prediction of an experiment's results. Skill 2 questions also tend to ask about science content without actually mentioning it by name. For example, a question might describe the results of one experiment and ask you to predict the results of a second experiment without actually telling you what underlying scientific principles are at work—part of the question's difficulty will be figuring out which principles to apply in order to get the correct answer. On Test Day, 45% of the questions in each science section will be Skill 2 questions.

Here are some sample Skill 2 question stems:

- Which of the following experimental conditions would most likely yield results similar to those in Figure 2?
- All of the following conclusions are supported by the information in the passage EXCEPT:
- The most likely cause of the anomalous results found by the experimenter is:
- An impact to a man's chest quickly reduces the volume of one of his lungs to 70% of its initial value while not allowing any air to escape from the man's mouth. By what percentage is the force of outward air pressure increased on a 2 cm^2 portion of the inner surface of the compressed lung?

Skill 3: *Reasoning About the Design and Execution of Research*

The MCAT is interested in your ability to critically appraise and analyze research, as this is an important day-to-day task of a physician. We call these questions Skill 3 or Experimental and Research Design questions for short. Skill 3 questions will require you to do the following:

- Identify the role of theory, past findings, and observations in scientific questioning
- Identify testable research questions and hypotheses
- Distinguish between samples and populations and distinguish results that support generalizations about populations
- Identify independent and dependent variables
- Reason about the features of research studies that suggest associations between variables or causal relationships between them (such as temporality and random assignment)
- Identify conclusions that are supported by research results
- Determine the implications of results for real-world situations
- Reason about ethical issues in scientific research

Over the years, the AAMC has received input from medical schools to require more practical research skills of MCAT test-takers, and Skill 3 questions are the response to these demands. This skill is unique in that the outside knowledge you need to answer Skill 3 questions is not taught in any one undergraduate course; instead, the research design principles needed to answer these questions are learned gradually throughout your science classes and especially through any laboratory work you have completed. It should be noted that Skill 3 comprises 10% of the questions in each science section on Test Day.

Here are some sample Skill 3 question stems:

- What is the dependent variable in the study described in the passage?
- The major flaw in the method used to measure disease susceptibility in Experiment 1 is:
- Which of the following procedures is most important for the experimenters to follow in order for their study to maintain a proper, randomized sample of research subjects?
- A researcher would like to test the hypothesis that individuals who move to an urban area during adulthood are more likely to own a car than are those who have lived in an urban area since birth. Which of the following studies would best test this hypothesis?

Skill 4: *Data-Based and Statistical Reasoning*

Lastly, the science sections of the MCAT test your ability to analyze the visual and numerical results of experiments and studies. We call these Data and Statistical Analysis questions. Skill 4 questions will require you to do the following:

- Use, analyze, and interpret data in figures, graphs, and tables
- Evaluate whether representations make sense for particular scientific observations and data

- Use measures of central tendency (mean, median, and mode) and measures of dispersion (range, interquartile range, and standard deviation) to describe data
- Reason about random and systematic error
- Reason about statistical significance and uncertainty (interpreting statistical significance levels and interpreting a confidence interval)
- Use data to explain relationships between variables or make predictions
- Use data to answer research questions and draw conclusions

Skill 4 is included in the MCAT because physicians and researchers spend much of their time examining the results of their own studies and the studies of others, and it's very important for them to make legitimate conclusions and sound judgments based on that data. The MCAT tests Skill 4 on all three science sections with graphical representations of data (charts and bar graphs) as well as numerical ones (tables, lists, and results summarized in sentence or paragraph form). On Test Day, 10% of the questions in each science section will be Skill 4 questions.

Here are some sample Skill 4 question stems:

- According to the information in the passage, there is an inverse correlation between:
- What conclusion is best supported by the findings displayed in Figure 2?
- A medical test for a rare type of heavy metal poisoning returns a positive result for 98% of affected individuals and 13% of unaffected individuals. Which of the following types of error is most prevalent in this test?
- If a fourth trial of Experiment 1 was run and yielded a result of 54% compliance, which of the following would be true?

SIRS Summary

Discussing the SIRS tested on the MCAT is a daunting prospect given that the very nature of the skills tends to make the conversation rather abstract. Nevertheless, with enough practice, you'll be able to identify each of the four skills quickly, and you'll also be able to apply the proper strategies to solve those problems on Test Day. If you need a quick reference to remind you of the four SIRS, these guidelines may help:

Skill 1 (**Science Knowledge**) questions ask:

- Do you remember this science content?

Skill 2 (**Critical Thinking**) questions ask:

- Do you remember this science content? And if you do, could you please apply it to this novel situation?
- Could you answer this question that cleverly combines multiple content areas at the same time?

Skill 3 (**Experimental and Research Design**) questions ask:

- Let's forget about the science content for a while. Could you give some insight into the experimental or research methods involved in this situation?

Skill 4 (**Data and Statistical Analysis**) questions ask:

- Let's forget about the science content for a while. Could you accurately read some graphs and tables for a moment? Could you make some conclusions or extrapolations based on the information presented?

CRITICAL ANALYSIS AND REASONING SKILLS (CARS)

The *Critical Analysis and Reasoning Skills* (CARS) section of the MCAT tests three discrete families of textual reasoning skills; each of these families requires a higher level of reasoning than the last. Those three skills are as follows:

1. *Foundations of Comprehension* (30% of questions)
2. *Reasoning Within the Text* (30% of questions)
3. *Reasoning Beyond the Text* (40% of questions)

These three skills are tested through nine humanities- and social sciences-themed passages, with approximately 5 to 7 questions per passage. Let's take a more in-depth look into these three skills. Again, the bullet points of specific objectives for each of the CARS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Foundations of Comprehension

Questions in this skill will ask for basic facts and simple inferences about the passage; the questions themselves will be similar to those seen on reading comprehension sections of other standardized exams like the SAT® and ACT®. *Foundations of Comprehension* questions will require you to do the following:

- Understand the basic components of the text
- Infer meaning from rhetorical devices, word choice, and text structure

This admittedly covers a wide range of potential question types including Main Idea, Detail, Function, and Definition-in-Context questions, but finding the correct answer to all *Foundations of Comprehension* questions will follow from a basic understanding of the passage and the point of view of its author (and occasionally that of other voices in the passage).

Here are some sample *Foundations of Comprehension* question stems:

- **Main Idea**—The author's primary purpose in this passage is:
- **Detail**—Based on the information in the second paragraph, which of the following is the most accurate summary of the opinion held by Schubert's critics?
- **(Scattered) Detail**—According to the passage, which of the following is FALSE about literary reviews in the 1920s?
- **Function**—The author's discussion of the effect of socioeconomic status on social mobility primarily serves which of the following functions?
- **Definition-in-Context**—The word "obscure" (paragraph 3), when used in reference to the historian's actions, most nearly means:

Reasoning Within the Text

While *Foundations of Comprehension* questions will usually depend on interpreting a single piece of information in the passage or understanding the passage as a whole, *Reasoning Within the Text* questions will typically require you to infer unstated parts of arguments or bring together two disparate pieces of the passage. *Reasoning Within the Text* questions will require you to:

- Integrate different components of the text to increase comprehension

In other words, questions in this skill often ask either *How do these two details relate to one another?* or *What else must be true that the author didn't say?* The CARS section will also ask you to judge certain parts of the passage or even judge the author. These questions, which fall under the *Reasoning Within the Text* skill, can ask you to identify authorial bias, evaluate the credibility of cited sources, determine the logical soundness of an argument, or search for relevant evidence in the passage to support a given conclusion. In all, this category includes Inference and Strengthen–Weaken (Within the Passage) questions, as well as a smattering of related—but rare—question types.

Here are some sample *Reasoning Within the Text* question stems:

- **Inference (Implication)**—Which of the following phrases, as used in the passage, is most suggestive that the author has a personal bias toward narrative records of history?
- **Inference (Assumption)**—In putting together her argument in the passage, the author most likely assumes:
- **Strengthen–Weaken (Within the Passage)**—Which of the following facts is used in the passage as the most prominent piece of evidence in favor of the author's conclusions?
- **Strengthen–Weaken (Within the Passage)**—Based on the role it plays in the author's argument, *The Possessed* can be considered:

Reasoning Beyond the Text

The distinguishing factor of *Reasoning Beyond the Text* questions is in the title of the skill: the word *Beyond*. Questions that test this skill, which make up a larger share of the CARS section than questions from either of the other two skills, will always introduce a completely new situation that was not present in the passage itself; these questions will ask you to determine how one influences the other. *Reasoning Beyond the Text* questions will require you to:

- Apply or extrapolate ideas from the passage to new contexts
- Assess the impact of introducing new factors, information, or conditions to ideas from the passage

The *Reasoning Beyond the Text* skill is further divided into Apply and Strengthen–Weaken (Beyond the Passage) questions, and a few other rarely appearing question types.

Here are some sample *Reasoning Beyond the Text* question stems:

- **Apply**—If a document were located that demonstrated Berlioz intended to include a chorus of at least 700 in his *Grande Messe des Mortes*, how would the author likely respond?
- **Apply**—Which of the following is the best example of a "virtuous rebellion," as it is defined in the passage?
- **Strengthen–Weaken (Beyond the Text)**—Suppose Jane Austen had written in a letter to her sister, "My strongest characters were those forced by circumstance to confront basic questions about the society in which they lived." What relevance would this have to the passage?
- **Strengthen–Weaken (Beyond the Text)**—Which of the following sentences, if added to the end of the passage, would most WEAKEN the author's conclusions in the last paragraph?

CARS Summary

Through the *Foundations of Comprehension* skill, the CARS section tests many of the reading skills you have been building on since grade school, albeit in the context of very challenging doctorate-level passages. But through the two other skills (*Reasoning Within the Text* and *Reasoning Beyond the Text*), the MCAT demands that you understand the deep structure of passages and the arguments within them at a very advanced level. And, of course, all of this is tested under very tight timing restrictions: only 102 seconds per question—and that doesn't even include the time spent reading the passages.

Here's a quick reference guide to the three CARS skills:

Foundations of Comprehension questions ask:

- Did you understand the passage and its main ideas?
- What does the passage have to say about this particular detail?

Reasoning Within the Text questions ask:

- What must be true that the author did not say?
- What's the logical relationship between these two ideas from the passage?
- How well argued is the author's thesis?

Reasoning Beyond the Text questions ask:

- How does this principle from the passage apply to this new situation?
- How does this new piece of information influence the arguments in the passage?

SCORING

Each of the four sections of the MCAT is scored between 118 and 132, with the median at 125. This means the total score ranges from 472 to 528, with the median at 500. Why such peculiar numbers? The AAMC stresses that this scale emphasizes the importance of the central portion of the score distribution, where most students score (around 125 per section, or 500 total), rather than putting undue focus on the high end of the scale.

Note that there is no wrong answer penalty on the MCAT, so you should select an answer for every question—even if it is only a guess.

The AAMC has released the official correlation between scaled score and percentile, as shown here. It should be noted that the percentile scale is adjusted and renormalized over time and thus should not be overinterpreted.

Total Score	Percentile	Total Score	Percentile
528	100	499	47
527	100	498	43
526	100	497	40
525	100	496	37
524	100	495	34
523	100	494	31
522	99	493	28
521	99	492	25
520	98	491	22
519	98	490	20
518	97	489	18
517	96	488	15
516	95	487	13

Total Score	Percentile	Total Score	Percentile
515	93	486	11
514	91	485	10
513	89	484	8
512	87	483	7
511	85	482	6
510	83	481	5
509	80	480	4
508	77	479	3

506	71	477	1
505	68	476	1
504	64	475	1
503	61	474	0
502	57	473	0
501	54	472	0
500	51		

Source: AAMC. 2015. *Summary of Total and Section Scores from the MCAT Exam Based on Results for Tests Administered in April and May 2015.* Accessed February 2016. https://students-residents.aamc.org/search/?q=percentilenewmcat.pdf.

Further information on score reporting is included at the end of the next section (see *After Your Test*).

MCAT POLICIES AND PROCEDURES

We strongly encourage you to download the latest copy of *MCAT® Essentials*, available on the AAMC's website, to ensure that you have the latest information about registration and Test Day policies and procedures; this document is updated annually. A brief summary of some of the most important rules is provided here.

MCAT Registration

The only way to register for the MCAT is online. You can access AAMC's registration system at: www.aamc.org/mcat.

You will be able to access the site approximately six months before Test Day. The AAMC designates three registration "Zones"—Gold, Silver, and Bronze. Registering during the Gold Zone (from the opening of registration until approximately one month before Test Day) provides the most flexibility and lowest test fees. The Silver Zone runs until approximately two to three weeks before Test Day and has less flexibility and higher fees; the Bronze Zone runs until approximately one to two weeks before Test Day and has the least flexibility and highest fees.

Fees and the Fee Assistance Program (FAP)

Payment for test registration must be made by MasterCard or VISA. As described earlier, the fees for registering for the MCAT—as well as rescheduling the exam or changing your testing center—increase as one approaches Test Day. In addition, it is not uncommon for test centers to fill up well in advance of the registration deadline. For these reasons, we recommend identifying your preferred Test Day as soon as possible and registering. There are ancillary benefits to having a set Test Day, as well: when you know the date you're working toward, you'll study harder and are less likely to keep pushing back the exam. The AAMC offers a Fee Assistance Program (FAP) for students with financial hardship to help reduce the cost of taking the MCAT, as well as for the American Medical College Application Service (AMCAS®) application. Further information on the FAP can be found at: www.aamc.org/students/applying/fap.

Testing Security

On Test Day, you will be required to present a government-issued ID. When registering, take care to spell your name precisely the same as it appears on this ID; failure to provide this ID at the test center or differences in spelling between your registration and ID will be considered a "no-show," and you will not receive a refund for the exam.

You will also be required to provide an electronic thumbprint and electronic signature verification to take the exam. Some testing centers may use a metal detection wand to ensure that no prohibited items are brought into the testing room. Prohibited items include all electronic devices, including watches and timers, calculators, cell phones, and any and all forms of recording equipment; food, drinks (including water), and cigarettes or other smoking paraphernalia; hats and scarves (except for religious purposes); and books, notes, or other study materials. If you require a medical device, such as an insulin pump or pacemaker, you must apply for accommodated testing. During breaks, you are allowed to access food and drink, but not electronic devices, including cell phones.

Testing centers are under video surveillance and the AAMC does not take potential violations of testing security lightly. The bottom line: *know the rules and don't break them*.

Accommodations

Students with disabilities or medical conditions can apply for accommodated testing. Documentation of the disability or condition is required, and requests may take two months—or more—to be approved. For this reason, it is recommended that you begin the process of applying for accommodated testing as early as possible. More information on applying for accommodated testing can be found at: www.aamc.org/students/applying/mcat/accommodations

After Your Test

When your MCAT is all over, no matter how you feel you did, be good to yourself when you leave the test center. Celebrate! Take a nap. Watch a movie. Ride your bike. Plan a trip. Call up all of your neglected friends or stalk them on Facebook. Totally consume a cheesesteak and drink dirty martinis at night (assuming you're over 21). Whatever you do, make sure that it has absolutely nothing to do with thinking too hard—you deserve some rest and relaxation.

Perhaps most importantly, do not discuss specific details about the test with anyone. For one, it is important to let go of the stress of Test Day, and reliving your exam only inhibits you from being able to do so. But more significantly, the Examinee Agreement you sign at the beginning of your exam specifically prohibits you from discussing or disclosing exam content. The AAMC is known to seek out individuals who violate this agreement and retains the right to prosecute these individuals at their discretion. This means that you should not, under any circumstances, discuss the exam in person or over the phone with other individuals—including us at Kaplan—or post information or questions about exam content to Facebook, Student Doctor Network, or other online social media. You are permitted to comment on your "general exam experience," including how you felt about the exam overall or an individual section, but this is a fine line. In summary: *if you're not certain whether you can discuss an aspect of the test or not, just don't do it!* Do not let a silly Facebook post stop you from becoming the doctor you deserve to be.

Scores are released approximately one month after Test Day. The release is staggered during the afternoon and evening, starting at 5 p.m. Eastern. This means that not all examinees receive their scores at exactly the same time. Your score report will include a scaled score for each section between 118 and 132, as well as your total combined score between 472 and 528. These scores are given as confidence intervals. For each section, the confidence interval is approximately the given score ±1; for the total score, it is approximately the given score ±2. You will also be given the corresponding percentile rank for each of these section scores and the total score.

How This Book Was Created

The *Kaplan MCAT Review* project began shortly after the release of the *Preview Guide for the MCAT 2015 Exam*, 2nd edition. Through thorough analysis by our staff psychometricians, we were able to analyze the relative yield of the different topics on the MCAT, and we began constructing tables of contents for the books of the *Kaplan MCAT Review* series. A dedicated staff of 30 writers, 7 editors, and 32 proofreaders worked over 5,000 combined hours to produce these books. The format of the books was heavily influenced by weekly meetings with Kaplan's learning-science team.

These books were submitted for publication in February 2016. For any updates after this date, please visit www.kaplanmcat.com/pages/retail-book-corrections-and-updates.

If you have any questions about the content presented here, email KaplanMCATfeedback@kaplan.com. For other questions not related to content, email booksupport@kaplan.com.

Each book has been vetted through at least eight rounds of review. To that end, the information presented is these books is true and accurate to the best of our knowledge. Still, your feedback helps us improve our prep materials. Please notify us of any inaccuracies or errors in the books by sending an email to KaplanMCATfeedback@kaplan.com.

Using This Book

Kaplan MCAT Organic Chemistry Review, along with the other seven books in your student kit, is the cornerstone of your prep for the MCAT. This book offers the content review, strategies, and practice that make Kaplan the #1 choice for MCAT prep.

This book is designed to help you review the organic chemistry topics covered on the MCAT. Please understand that content review—no matter how thorough—is not sufficient preparation for the MCAT! The MCAT tests not only your science knowledge but also your critical reading, reasoning, and problem-solving skills. Do not assume that simply memorizing the contents of this book will earn you high scores on Test Day; to maximize your scores, you must also improve your reading and test-taking skills through MCAT-style questions and practice tests.

MCAT CONCEPT CHECKS

At the end of each section, you'll find a few open-ended questions that you can use to assess your mastery of the material. These MCAT Concept Checks were introduced after multiple conversations with Kaplan's learning-science team. Research has demonstrated repeatedly that introspection and self-analysis improve mastery, retention, and recall of material. Complete these MCAT Concept Checks to ensure that you've got the key points from each section before moving on!

PRACTICE QUESTIONS

At the end of each chapter, you'll find 15 MCAT-style practice questions. These are designed to help you assess your understanding of the chapter you just read. Most of these questions focus on the first of the *Scientific Inquiry and Reasoning Skills* (*Knowledge of Scientific Concepts and Principles*), although there are occasional questions that fall into the second or fourth SIRS (*Scientific Reasoning and Problem-Solving*, and *Data-Based and Statistical Reasoning*, respectively).

SIDEBARS

The following is a guide to the five types of sidebars you'll find in *Kaplan MCAT Organic Chemistry Review*:

- **Bridge:** These sidebars create connections between science topics that appear in multiple chapters throughout the *Kaplan MCAT Review* series.
- **Key Concept:** These sidebars draw attention to the most important takeaways in a given topic, and they sometimes offer synopses or overviews of complex information. If you understand nothing else, make sure you grasp the Key Concepts for any given subject.
- **MCAT Expertise:** These sidebars point out how information may be tested on the MCAT or offer key strategy points and test-taking tips that you should apply on Test Day.
- **Mnemonic:** These sidebars present memory devices to help recall certain facts.
- **Real World:** These sidebars illustrate how a concept in the text relates to the practice of medicine or the world at large. While this is not information you need to know for Test Day, many of the topics in Real World sidebars are excellent examples of how a concept may appear in a passage or discrete (stand-alone) question on the MCAT.

WHAT THIS BOOK COVERS

The information presented in the *Kaplan MCAT Review* series covers everything listed on the official MCAT content lists. Every topic in these lists is covered in the same level of detail as is common to the undergraduate and postbaccalaureate classes that are considered prerequisites for the MCAT. Note that your premedical classes may include topics not discussed in these books, or they may go into more depth than these books do. Additional exposure to science content is never a bad thing, but recognize that all of the content knowledge you are expected to have walking in on Test Day is covered in these books.

New to the Third Edition of the *Kaplan MCAT Review* series are **Star Ratings**. You'll see these stars throughout the book, and they are meant as a guide to the number and density of test-worthy facts in each chapter and sub-chapter.

★★★★ Four-star chapters and topics are packed with testable facts. Make sure you have all of these down before Test Day. Even if you find these topics difficult to grasp, you should put in the extra effort to fully understand them.

★★★ Three-star chapters and topics contain content that is tested an above-average amount. If you plan to score above average–and you probably do!–then you should master all or nearly all of these before Test Day.

★★ Two-star sections will demand varied focus, depending on your personal studying needs. These topics have been proven to be MCAT-worthy, but if you have limited study time or already feel confident with these topics, you can move more quickly through this material.

★ One-star chapters and topics are unlikely to be directly tested, but many of these topics provide foundations for, and connections between, higher-yield material.

These Star Ratings were created based on material released by the AAMC. In other words, according to the testmaker and all our experience with their resources, more stars means more questions on Test Day.

This book also contains a thorough glossary and index for easy navigation of the text.

In the end, this is your book, so write in the margins, draw diagrams, highlight the key points—do whatever is necessary to help you get that higher score. We look forward to working with you as you achieve your dreams and become the doctor you deserve to be!

1.5 Summary of Functional Groups ☆☆☆☆

Concept Summary 18

MCAT Expertise

According to the AAMC, the MCAT will not include standalone, nomenclature-only organic chemistry questions (such as "name this compound" questions). But as you probably remember from your own classes, nomenclature is the very foundation of the entire subject of organic chemistry, and you will lose points on Test Day if you don't have nomenclature down cold.

Introduction

You walk into the pharmacy looking for something to take for a headache and find an entire aisle of drugs just for that purpose: Advil, Aleve, Motrin, Tylenol, ibuprofen, naproxen, acetaminophen, and aspirin. In this list, however, there are only four distinct drugs. In the United States, it is not uncommon for drugs to be known by both generic and brand names—and sometimes, multiple brands market the same medications. As a medical student, you'll have to know both: while a doctor may order *atorvastatin 40 mg qd*, patients will tell you they're taking *Lipitor daily*.

For doctors, a generic name is sufficiently unambiguous to specify a given compound, but this is not true within the pharmaceutical industry. Medications are usually large organic compounds with many functional groups and numerous chiral centers. Chemists needed to be able to describe such compounds, as well as innumerably many others. Thus, within chemistry, a specific set of rules for naming and describing compounds was designed. In this chapter, we'll examine the steps for naming a compound and then practice applying them to example compounds. By the end of the chapter, we'll have discussed the most common functional groups for Test Day and how they relate to each other in the nomenclature hierarchy. Note that you may have learned nomenclature for a number of other compounds, including ethers, epoxides, amines, imines, sulfonic acids, and others in your organic chemistry courses; we have restricted the content of this chapter to only the functional groups you are expected to identify on Test Day.

MCAT Expertise

Nomenclature is often tested on the MCAT by providing the question stem and the answer choices in different formats. For example, the question stem will give you the IUPAC name of the reactant, and the answer choices will show product structures—leaving you to figure out both the structure of the reactant and the reaction taking place.

1.1 IUPAC Naming Conventions ★★

Nomenclature is one of the most important prerequisites for answering organic chemistry questions on Test Day; if you don't know which chemical compound the question is asking about, it's hard to get the answer right! That's why it's so important to understand both IUPAC and common nomenclature. Once you have a handle on these naming systems, you can easily translate question stems and focus on finding the correct answer. Let's begin by examining IUPAC naming conventions before we highlight specific compounds and functional groups.

NAMING STEPS

The primary goal of the **International Union of Pure and Applied Chemistry** (**IUPAC**) naming system is to create an unambiguous relationship between the name and structure of a compound. With the conventions established by IUPAC, no two distinct compounds have the same name. The IUPAC naming system greatly simplifies chemical naming. Once we understand the rules, we can match names to structures with ease.

1. Identify the Longest Carbon Chain Containing the Highest-Order Functional Group

This will be called the **parent chain** and will be used to determine the root of the name. Keep in mind that if there are double or triple bonds between carbons, they must be considered when identifying the highest-order functional group. We'll examine priorities of functional groups throughout this chapter, but keep in mind that the highest-priority functional group (with the most oxidized carbon) will provide the suffix. This step may sound easy, but be careful! The molecule may be drawn in such a way that the longest carbon chain is not immediately obvious. If there are two or more chains of equal length, then the more substituted chain gets priority as the parent chain. Figure 1.1 shows a hydrocarbon with the longest chain labeled.

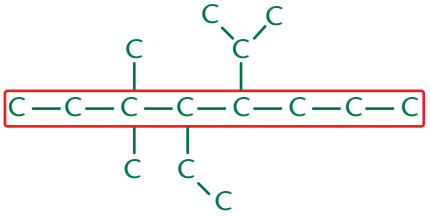

Figure 1.1. Finding the Longest Carbon Chain

2. Number the Chain

In order to appropriately name a compound, we need to number the carbon chain, as shown in Figure 1.2. As a convention, the carbon numbered 1 will be the one closest to the highest-priority functional group. If the functional groups all have the same priority, numbering the chain should make the numbers of the substituted carbons as low as possible.

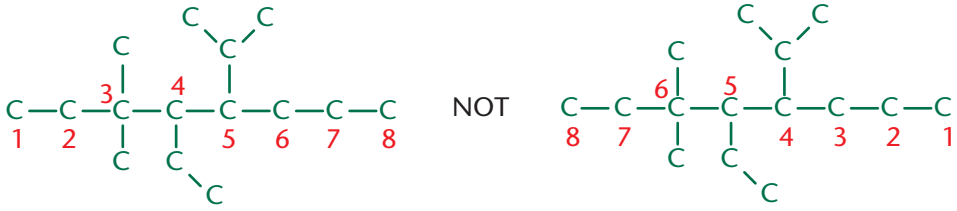

Figure 1.2. Numbering the Longest Carbon Chain
The highest-priority functional group should have the lowest possible number; if all substituents have the same priority, make their numbers as low as possible.

After we have discussed the functional groups most commonly tested on the MCAT, we'll review a table of those functional groups in order of priority. For now, keep in mind that the more oxidized the carbon is, the higher priority it has in the molecule. Oxidation state increases with more bonds to **heteroatoms** (atoms besides carbon and hydrogen, like oxygen, nitrogen, phosphorus, or halogens) and decreases with more bonds to hydrogen.

Just like straight chains, rings are numbered starting at the point of greatest substitution, continuing in the direction that gives the lowest numbers to the highest-priority functional groups. Somewhat counterintuitively, if there is a tie between assigning priority in a molecule with double and triple bonds, the double bond takes precedence.

3. Name the Substituents

Substituents are functional groups that are not part of the parent chain. A substituent's name will be placed at the beginning of the compound name as a prefix, followed by the name of the longest chain. Remember that only the highest-priority functional group will determine the suffix for the compound and must be part of the parent chain.

Carbon chain substituents are named like alkanes, with the suffix ***–yl*** replacing ***–ane***. The prefix ***n–*** that we see in Figure 1.3 on *n*-propyl simply indicates that this is "normal"—in other words, a straight-chain alkane. Because this prefix will not always be present, it is safe to assume that alkane substituents will be normal unless otherwise specified.

$CH_3–$	$CH_3CH_2–$	$CH_3CH_2CH_2–$
methyl	ethyl	*n*-propyl

Figure 1.3. Common Normal Alkyl Substituents
The bond on the right side of each substituent connects to the parent molecule.

In Figure 1.4, we see some examples of what alternative alkyl substituents may look like.

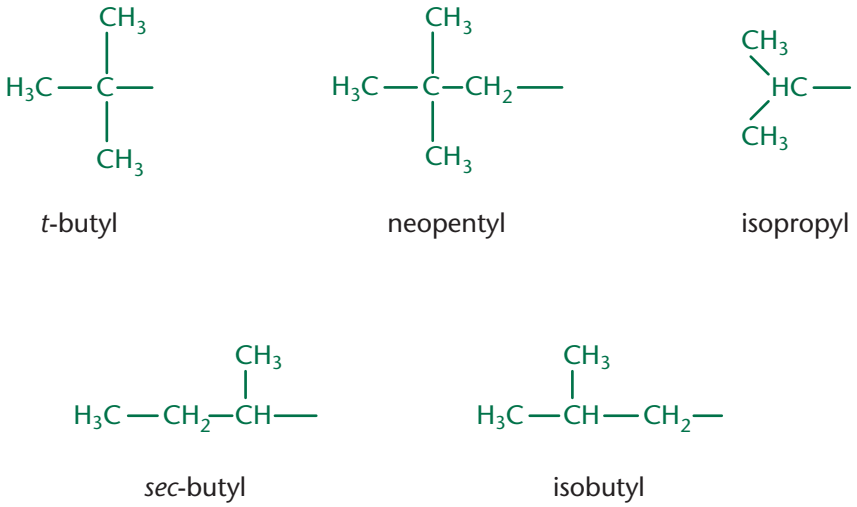

Figure 1.4. Common Alternative Alkyl Substituents
The bond on the right side of each substituent connects to the parent molecule.

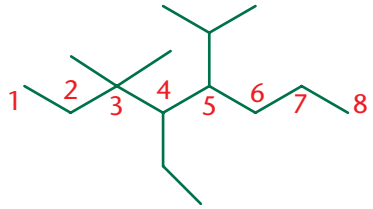
If there are multiple substituents of the same type, we use the prefixes ***di***–, ***tri***–, ***tetra***–, and so on to indicate this fact. These prefixes are included directly before the substituent's name.

4. Assign a Number to Each Substituent

Pair the substituents that you have named to the corresponding numbers in the parent chain. Multiple substituents of the same type will get both the *di*–, *tri*–, and *tetra*– prefixes that we have previously noted and also a carbon number designation—even if they are on the same carbon.

5. Complete the Name

Names always begin with the names of the substituents in alphabetical order, with each substituent preceded by its number. Note, however, that prefixes like *di*–, *tri*–, and *tetra*– as well as the hyphenated prefixes like ***n***– and ***tert***– (or ***t***–) are ignored while alphabetizing. Nonhyphenated roots that *are* part of the name, however, are included; these are modifiers like ***iso***–, ***neo***–, or ***cyclo***–. Then, the numbers are separated from each other with commas, and from words with hyphens. Finally, we finish the name with the name of the backbone chain, including the suffix for the functional group of highest priority. Figure 1.5 shows an example of an entire hydrocarbon named with IUPAC nomenclature.



4-ethyl-5-isopropyl-3,3-dimethyloctane

Figure 1.5. An Example of a Complete IUPAC Name

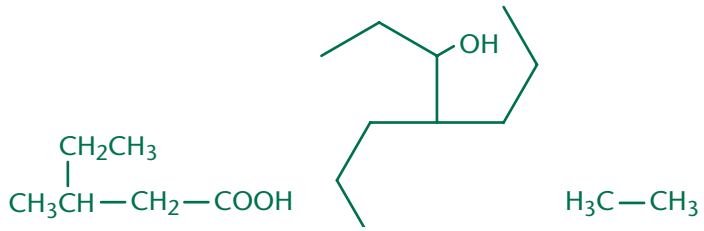
MCAT Concept Check 1.1:

Before you move on, assess your understanding of the material with these questions.

1. List the steps of IUPAC nomenclature:

   1. _____
   2. _____
   3. _____
   4. _____
   5. _____

2. Circle or highlight the parent chain in each of the following compounds:



3. How are numbers separated from each other and from words in a compound's name?

_____

1.2 Hydrocarbons and Alcohols ★

Hydrocarbons are compounds that contain only carbon and hydrogen atoms. Alcohols, on the other hand, contain at least one –OH group, which lends them additional reactivity. In this section, we'll explore the naming of hydrocarbons and alcohols.

ALKANES

Alkanes are simple hydrocarbon molecules with the formula $C_nH_{(2n+2)}$. The names for the first four of these compounds are methane (one carbon), ethane (two carbons), propane (three carbons), and butane (four carbons). Alkanes with more than four carbons have a simpler naming pattern in which the name is the Greek root describing the number of carbons followed by ***–ane***. These Greek roots from 5 to 12 are: ***pent–***, ***hex–***, ***hept–***, ***oct–***, ***non–***, ***dec–***, ***undec–***, and ***dodec–***. Some examples of alkanes are shown in Table 1.1.

Number of Carbons	Name	Structure
1	methane	2	ethane	3	propane	4	butane	5	pentane	6	hexane	7	heptane	8	octane	
Table 1.1. Examples of Alkanes

Halogens are common substituents on alkanes. Alkyl halides are indicated by a prefix: ***fluoro***–, ***chloro***–, ***bromo***–, or ***iodo***–.

ALKENES AND ALKYNES

The MCAT does not explicitly test reactions of **alkenes** or **alkynes**, but you may still see the suffixes –***ene*** and –***yne***, which signify double and triple bonds, respectively. Keep in mind that many of these compounds will also have common names, and it is vital to know these common names as well. On Test Day, you are most likely to encounter double bonds in the context of unsaturated fatty acids or other biochemical compounds. The double or triple bond is named like a substituent and is indicated by the lower-numbered carbon involved in the bond. The number may precede the molecule name, as in 2-butene, or it may be placed near the suffix, as in but-2-ene; both are correct. If there are *multiple* multiple bonds, the numbering is generally separated from the suffix, as in 1,3-butadiene.

ALCOHOLS

Alcohols are named by replacing –***e*** in the name of the corresponding alkane with –***ol***. The chain is numbered so that the carbon attached to the hydroxyl group (–OH) gets the lowest possible number—even when there is a multiple bond present. The hydroxyl group takes precedence over multiple bonds because of the higher oxidation state of the carbon. If the alcohol is not the highest-priority functional group, then it is named as a hydroxyl substituent (***hydroxy***–). Figure 1.6 demonstrates a few alcohols and their IUPAC names.

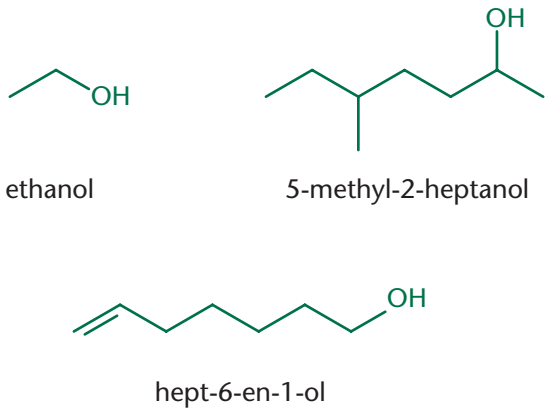

Figure 1.6. Naming Alcohols
Alcohols are more oxidized than multiple bonds, so they take priority in nomenclature and are indicated with the suffix –*ol*.

Alcohols are often referred to by their common names, rather than their IUPAC names. In this version of naming, the name of the alkyl group is followed by the word *alcohol*. Examples include *ethyl alcohol* (rather than ethanol) and *isopropyl alcohol* (rather than 2-propanol.)

MCAT Expertise

The MCAT may use the common names for some alcohols, as well as some of the molecules we will see later. For alcohols, these include ethyl alcohol and isopropyl alcohol—know what these common names refer to!

Mnemonic

Vicinal diols are in the **vicin**ity of each other, on nearby carbons. **Gemin**al diols—like the **Gemin**i twins—are paired, or in this case, on the same carbon.

Alcohols with two hydroxyl groups are called **diols** or **glycols** and are indicated with the suffix ***–diol***. The entire hydrocarbon name is preserved, and ***–diol*** is added. When naming diols, one must number each hydroxyl group. For example, ethane-1,2-diol is an ethane molecule that has a hydroxyl group on each carbon. This molecule is also known by its common name, ethylene glycol. Diols with hydroxyl groups on the same carbon are called **geminal diols**; diols with hydroxyl groups on adjacent carbons are called **vicinal diols**. Geminal diols, or **hydrates**, are not commonly seen because they spontaneously dehydrate (lose a water molecule) to produce carbonyl compounds with the functional group C=O.

MCAT Concept Check 1.2:

Before you move on, assess your understanding of the material with these questions.

1. Fill in the correct names for the alkanes listed below. If more than one compound can be described with a given molecular formula, name the straight-chain alkane to which the formula refers, and draw one alternative.

Molecular Formula	IUPAC Name (Straight-Chain Alkane)	Alternative Structure
CH_4		
C_2H_6		
C_3H_8		
C_4H_{10}		
C_5H_{12}		
C_6H_{14}		
C_7H_{16}		
C_8H_{18}		
C_9H_{20}		
$C_{10}H_{22}$		

2. In a molecule with two double bonds adjacent to each other and an alcohol, which functional group would take precedence in naming?

_____

3. What is the difference between a geminal and a vicinal diol?
   - Geminal diol:

     _____
   - Vicinal diol:

     _____

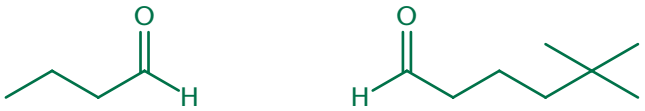
4. What are the common names for 2-propanol and ethanol?
   - 2-Propanol: _____
   - Ethanol: _____

1.3 Aldehydes and Ketones ★★

Aldehydes and ketones are two classes of molecules that contain a **carbonyl group**, which is a carbon double-bonded to an oxygen. Aldehydes and ketones differ in the placement of the carbonyl group: aldehydes are **chain-terminating**, meaning that they appear at the end of a parent chain, while ketones are found in the middle of carbon chains. Aldehydes and ketones do not have any leaving groups connected to the carbonyl carbon; they are only connected to alkyl chains or, in the case of aldehydes, hydrogen atoms. As we'll examine later, carboxylic acids and their derivatives do contain leaving groups connected to the carbonyl carbon.

ALDEHYDES

Aldehydes have a carbonyl group found at the end of the carbon chain. Because this is a terminal functional group that takes precedence over many others, it is generally attached to carbon number 1. Aldehydes are named by replacing the ***–e*** of the parent alkane with the suffix ***–al***. When the aldehyde is at position 1, as is usually the case, we do not need to include this number in the chemical name. Figure 1.7 shows the IUPAC nomenclature for two aldehydes.



butanal 5,5-dimethylhexanal

Figure 1.7. Naming Aldehydes
The carbonyl group of the aldehyde usually does not receive a number in the name because it is a terminal functional group.

Methanal, ethanal, and propanal are referred to almost exclusively by their common names, *formaldehyde*, *acetaldehyde*, and *propionaldehyde*, rather than their IUPAC names. These molecules are shown in Figure 1.8.

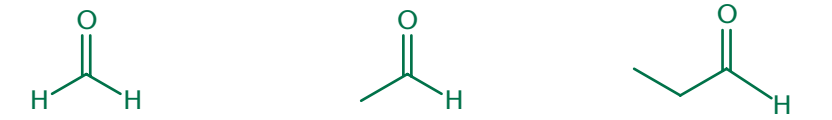


Figure 1.8. Common Names of Aldehydes

Bridge

Sugars are classified as either aldoses (aldehyde sugars) or ketoses (ketone sugars). Understanding nomenclature can help you to identify the structure of a sugar as well as some of its physical properties. Carbohydrate structure is discussed in Chapter 4 of *MCAT Biochemistry Review*.

KETONES

Ketones contain a carbonyl group somewhere in the middle of the carbon chain. Because this is the case, we will always have to assign a number to the carbonyl carbon when naming ketones (except propanone, which must have the ketone on carbon 2 by default). Ketones are named by replacing ***–e*** in the name of the parent alkane with the suffix ***–one***. Just as when naming other compounds, be sure to give the carbonyl the lowest possible number if it is the highest-priority group.

Ketones are commonly named by listing the alkyl groups in alphabetical order, followed by *ketone*, such as *ethylmethylketone*. *Acetone* is the smallest possible ketone molecule, and it defies traditional naming conventions because it has three rather than two carbons (***acet–***, like ***eth–*** generally refers to two carbons). Figure 1.9 includes IUPAC and common names for a number of ketones.

MCAT Expertise

As is the case for alcohols, it is important to know both the common names and IUPAC names for common aldehydes and ketones. Make sure that you know what formaldehyde, acetaldehyde, and acetone are!

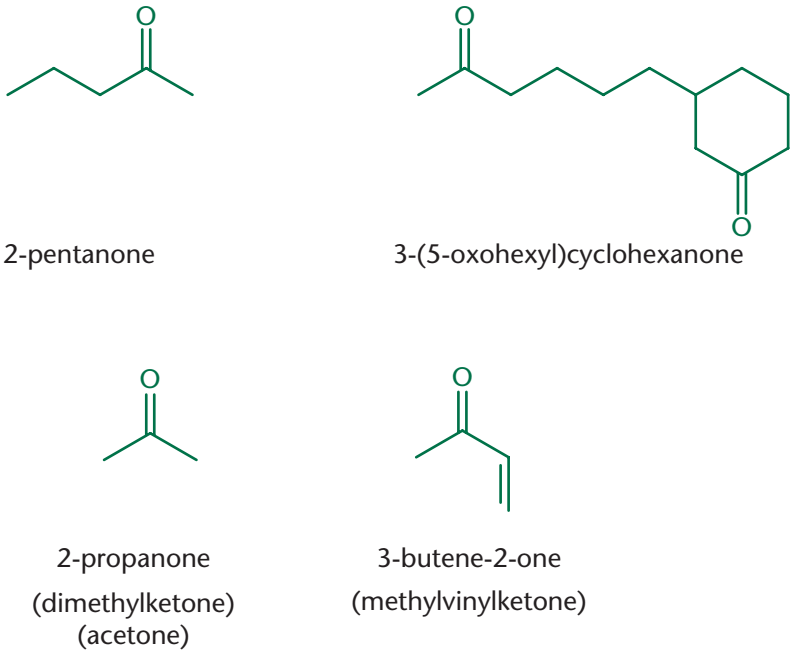

Figure 1.9. Naming Ketones
Common names are included in parentheses.

In a more complex molecule with a higher-priority group that takes precedence over the carbonyl, we name aldehydes and ketones as substituents, using the prefix ***oxo***–. This is in reference to the carbonyl oxygen and applies for both ketones and aldehydes. Sometimes ketones may also be indicated with the prefix ***keto***–.

Another convention that you may see on the MCAT is naming carbons relative to the carbonyl group. By this convention, the carbon *adjacent* to the carbonyl carbon is indicated by alpha (α). Moving away from the carbonyl, the successive carbons are referred to as beta (β), gamma (γ), and delta (δ) carbons. This applies on both sides of the carbonyl in the same fashion, so the carbons on both sides of a ketone are considered alpha carbons. This will become important when we discuss α-hydrogen acidity in Chapter 7 of *MCAT Organic Chemistry Review*.

MCAT Concept Check 1.3:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between an aldehyde and a ketone?
   - Aldehyde:

     _____
   - Ketone:

     _____
2. What suffixes are used for aldehydes and ketones; how are carbonyl groups named as a substituent?
   - Aldehyde suffix: _____; substituent prefix: _____
   - Ketone suffix: _____; substituent prefix: _____
3. Fill in the common names in the following chart.

IUPAC Name	Common Name
Methanal	
Ethanal	
Propanal	
Propanone	

4. For a molecule with a double bond, an aldehyde, and an alcohol, which functional group would determine the suffix when naming?

   _____

1.4 Carboxylic Acids and Derivatives ★★

CARBOXYLIC ACIDS

Carboxylic acids contain both a carbonyl group (C=O) and a hydroxyl group (–OH) on a terminal carbon. Carboxylic acids, like aldehydes, are terminal functional groups; therefore, their associated carbon is usually numbered 1. This is the most oxidized functional group that appears on the MCAT, with three bonds to oxygen; only carbon dioxide, with four bonds to oxygen, contains a more oxidized carbon. Carboxylic acids are thus the highest-priority functional group in MCAT-tested nomenclature, and all other groups are named as substituents using prefixes. Carboxylic acids are named by replacing ***–e*** in the name of the parent alkane with the suffix ***–oic acid***.

Once again, the common names for carboxylic acids show up fairly often on the MCAT. *Formic acid* is the common name for methanoic acid; *acetic acid* is ethanoic acid; and *propionic acid* is propanoic acid. These compounds are shown in Figure 1.10. Be sure that you know both these common names and IUPAC names for Test Day.

MCAT Expertise

Did you notice that some of the common names are similar between aldehydes and carboxylic acids? Remembering that formaldehyde and formic acid both refer to molecules with methane as a parent alkane—and that acetaldehyde and acetic acid contain ethane as a parent alkane—will help consolidate this information.

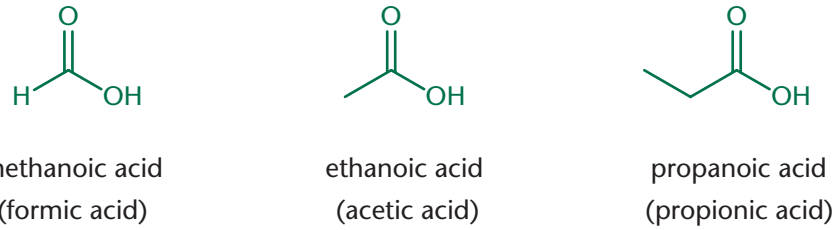

Figure 1.10. Naming Carboxylic Acids
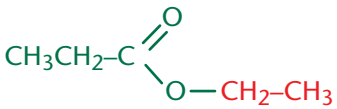
The carboxylic acid group does not receive a number in the name because it is a terminal functional group; common names are included in parentheses.

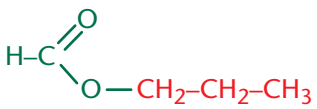
The carboxylic acid derivatives are the final category of functional groups. These include esters, amides, and anhydrides.

ESTERS

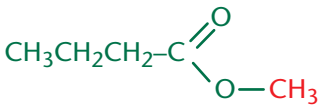
Esters are common carboxylic acid derivatives. In these compounds, the hydroxyl group (–OH) is replaced with an **alkoxy group** (–OR, where R is a hydrocarbon chain). Ester nomenclature is based on the naming conventions for carboxylic acids. The first term is the alkyl name of the esterifying group. Think of this first term as an adjective describing the ester, based on the identity of the alkyl (R) group. The second term is the name of the parent acid, with ***–oate*** replacing the ***–oic acid*** suffix. For example, methanoic acid (formic acid) would form butyl methanoate with exposure to butanol under appropriate reaction conditions. Examples of ester nomenclature are shown in Figure 1.11.



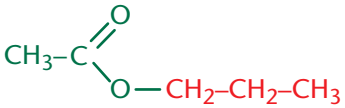
ethyl propanoate



propyl methanoate



methyl butanoate

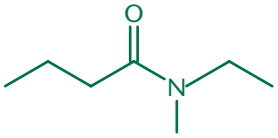


propyl ethanoate

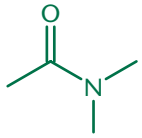
Figure 1.11. Naming Esters
Groups bonded directly to the ester oxygen are named as substituents and are not numbered.

AMIDES

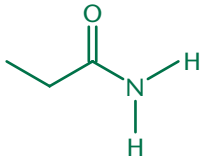
Another group of carboxylic acid derivatives includes **amides**. In an amide, the hydroxyl group is replaced by an **amino group** (nitrogen-containing group). These compounds can be more complex—the amino nitrogen can be bonded to zero, one, or two alkyl groups. Amides are named similarly to esters, except that the suffix becomes ***–amide***. Substituents attached to the nitrogen atom are labeled with a capital *N*–, indicating that this group is bonded to the parent molecule via a nitrogen. These substituents are included as prefixes in the compound name and are not numbered. Several examples of amide nomenclature are included in Figure 1.12.



N-ethyl-*N*-methylbutanamide



N,*N*-dimethylethanamide



propanamide

Figure 1.12. Naming Amides
Groups bonded directly to the amide nitrogen are named as substituents with the prefix *N*–, and are not numbered.

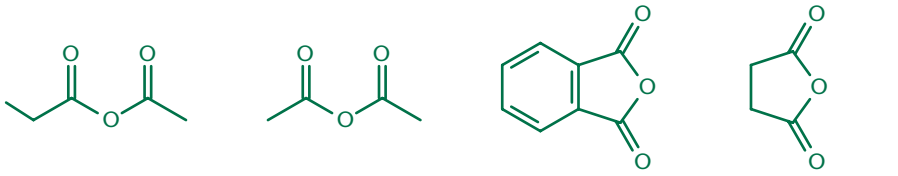
ANHYDRIDES

One final group of carboxylic acid derivatives is the **anhydrides**. In the formation of an anhydride from two carboxylic acid molecules, one water molecule is removed. Many anhydrides are cyclic, which may result from the intramolecular dehydration of a dicarboxylic acid. Anhydrides are named by replacing ***acid*** with ***anhydride*** in the name of the corresponding carboxylic acid if

Mnemonic

Because *hydro–* is a prefix meaning water and *an–* is a prefix meaning *not* or *without*, we can remember that anhydrides have had water molecules removed during formation.

the anhydride is formed from only one type of carboxylic acid. If the anhydride is not symmetrical, both carboxylic acids are named (without the suffix *acid*) before *anhydride* is added to the name. Some examples of anhydrides are shown in Figure 1.13.



ethanoic propanoic anhydride | ethanoic anhydride (acetic anhydride) | phthalic anhydride | succinic anhydride

Figure 1.13. Naming Anhydrides
Phthalic anhydride and succinic anhydride are given as examples of cyclic anhydrides; their names need not be memorized.

MCAT Concept Check 1.4:

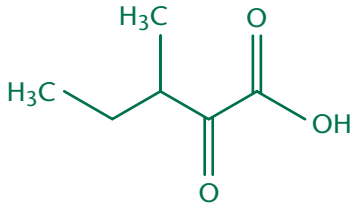
Before you move on, assess your understanding of the material with these questions.

1. What would be the names of the ester, amide, and anhydride derivatives of pentanoic acid? Assume that the R group on the ester is $–CH_3$ and that the amide is unsubstituted.
   - Ester:

     _____
   - Amide:

     _____
   - Anhydride:

     _____
2. Name the following compound:



_____

1.5 Summary of Functional Groups ★★★★

Table 1.2 lists the functional groups that you will need to know for the MCAT in order of priority, with prefixes and suffixes. Carboxylic acids are the highest-priority functional group on the MCAT. In nomenclature, use the suffix if the functional group is the highest-priority group in the molecule; otherwise, name the group as a substituent using its prefix.

Functional Group	Prefix	Suffix
Carboxylic acid	carboxy–	–oic acid
Anhydride	alkanoyloxycarbonyl–	anhydride
Ester	alkoxycarbonyl–	–oate
Amide	carbamoyl– or amido–	–amide
Aldehyde	oxo–	–al
Ketone	oxo– or keto–	–one
Alcohol	hydroxy–	–ol
Alkene*	alkenyl–	–ene
Alkyne*	alkynyl–	–yne
Alkane	alkyl–	–ane

*Note: Alkenes and alkynes are considered to be tied for priority except in cyclic compounds, where alkenes have higher priority.

Table 1.2. Major Functional Groups

Key Concept

Functional group priority is correlated with oxidation state. Carboxylic acids have the highest priority while alkanes have the lowest.

Conclusion

Now that we've worked through nomenclature, we should be able to navigate MCAT organic chemistry questions with ease and confidence. Remember that even if an MCAT question is asking about a reaction or laboratory technique, translating the name of a compound in the question stem may be a necessary step to get to the answer. We have also covered the important functional groups that will show up and have taken note of the order of priority for these groups when it comes to naming compounds. Remember, the common names can be just as important on the MCAT as the IUPAC names—so knowing both is key. Now that we know the language of organic chemistry, we will learn more about the properties of molecules in the next two chapters, and then will focus on reactions of functional groups and laboratory techniques in subsequent chapters of *MCAT Organic Chemistry Review*.

CONCEPT SUMMARY

IUPAC Naming Conventions

- The **International Union of Pure and Applied Chemistry** (**IUPAC**) has designated standards for naming chemical compounds. There are five steps in the process:
  - First, find the longest carbon chain in the compound that contains the highest-priority functional group. This is called the **parent chain**.
  - Second, number the chain in such a way that the highest-priority functional group receives the lowest possible number. This group will determine the **suffix** of the molecule.
  - Third, name the **substituents** with a **prefix**. Multiple substituents of a single type receive another prefix denoting how many are present (***di***–, ***tri***–, ***tetra***–, and so on).
  - Fourth, assign a number to each of the substituents depending on the carbon to which it is bonded.
  - Finally, complete the name by alphabetizing the substituents and separating numbers from each other by commas and from words by hyphens.

Hydrocarbons and Alcohols

- **Alkanes** are **hydrocarbons** without any double or triple bonds. They have the general formula $C_nH_{(2n+2)}$.
- Alkanes are named according to the number of carbons present followed by the suffix –***ane***.
  - The first four alkanes are methane (CH_4), ethane (C_2H_6), propane (C_3H_8), and butane (C_4H_{10}).
  - Larger alkanes use the Greek root for the number (pentane, hexane, heptane, octane, and so on).
- **Alkenes** and **alkynes** contain double and triple bonds, respectively.
  - Alkenes are named by substituting –***ene*** for the suffix and numbering the double bond by its lower-numbered carbon. Alkynes substitute –***yne*** with the same numbering.
- **Alcohols** contain a hydroxyl (–OH) group, which substitutes for one or more of the hydrogens in the hydrocarbon chain.
  - Alcohols are named by substituting the suffix –***ol*** or by using the prefix ***hydroxy***– if a higher-priority group is present.
  - Alcohols have higher priority than double or triple bonds and alkanes.

- Common names of alcohols include the name of the carbon chain followed by the word *alcohol*. For example, ethyl alcohol is the same compound as ethanol.
- **Diols** contain two hydroxyl groups. They are termed **geminal** if on the same carbon or **vicinal** if on adjacent carbons.

Aldehydes and Ketones

- Aldehydes and ketones contain a **carbonyl group**—a carbon double-bonded to an oxygen.
- **Aldehydes** have the carbonyl group on a terminal carbon that is also attached to a hydrogen atom.
  - Aldehydes are named with the suffix ***–al***, or by using the prefix ***oxo***– if a higher-priority group is present.
  - Common names of aldehydes include formaldehyde for methanal, acetaldehyde for ethanal, and propionaldehyde for propanal.
- **Ketones** have the carbonyl group on a nonterminal carbon.
  - Ketones are named with the suffix ***–one*** and share the prefix ***oxo***– if a higher-priority group is present. Ketones can also be indicated by the prefix ***keto***–.
  - The common names of ketones are constructed by naming the alkyl groups on either side alphabetically and adding ketone. For example, 2-butanone is called ethylmethylketone.
  - Acetone is significant as the smallest ketone. Its IUPAC name is propanone.
- Carbonyl-containing compounds (aldehydes, ketones, carboxylic acids, and derivatives) also create a lettering scheme for carbons. The carbon adjacent to the carbonyl carbon is the **α-carbon**.

Carboxylic Acids and Derivatives

- **Carboxylic acids** are the highest-priority functional group because they contain three bonds to oxygen: one from a hydroxyl group and two from a carbonyl group.
- Carboxylic acids are always terminal, although their **derivatives** may occur within a molecule.
  - Carboxylic acids are named with the suffix ***–oic acid***. They are very rarely named as a prefix.
  - Common names for carboxylic acids follow the trend for aldehydes. Formic acid is methanoic acid, acetic acid is ethanoic acid, and propionic acid is propanoic acid.

- **Esters** are carboxylic acid derivatives where –OH is replaced with –OR, an **alkoxy group**.
  - Esters use the suffix ***–oate*** or the prefix ***alkoxycarbonyl***–.
  - Common names for esters are derived from the alcohol and the carboxylic acid used during synthesis.
- **Amides** replace the hydroxyl group of a carboxylic acid with an amino group that may or may not be substituted.
  - Amides use the suffix –***amide*** or the prefix ***carbamoyl***– or ***amido***–. Substituents attached to the amide nitrogen are designated with a capital ***N***–.
- **Anhydrides** are formed from two carboxylic acids by dehydration. They may be symmetric (two of the same acid), asymmetric (two different acids), or cyclic (intramolecular reaction of a dicarboxylic acid)
  - Anhydrides are named using the suffix ***anhydride*** in place of *acid*. If the anhydride is formed from more than one carboxylic acid, both are named in alphabetical order in the name before the word anhydride.

Summary of Functional Groups

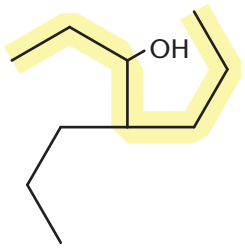
- Functional groups are arranged in order of priority as follows: Carboxylic acid > anhydride > ester > amide > aldehyde > ketone > alcohol > alkene or alkyne > alkane

ANSWERS TO CONCEPT CHECKS

1.1

1. 1. Find the longest carbon chain in the compound with the highest-order functional group; 2. Number the chain; 3. Name the substituents; 4. Assign a number to each substituent; 5. Complete the name

2. 



Note: There are two possible answers; however, the longest chain must include the hydroxyl group.

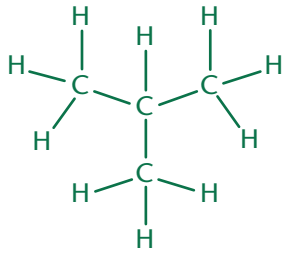
3. Numbers are separated from each other by commas with no spaces. Numbers are separated from words within the compound name by hyphens.

1.2

1.

Molecular Formula	IUPAC Name (Straight-Chain Alkane)	Alternative Structure
CH_4	Methane	No alternative structures
C_2H_6	Ethane	No alternative structures
C_3H_8	Propane	No alternative structures
C_4H_{10}	Butane	See below
C_5H_{12}	Pentane	See below
C_6H_{14}	Hexane	See below
C_7H_{16}	Heptane	See below
C_8H_{18}	Octane	See below
C_9H_{20}	Nonane	See below
$C_{10}H_{22}$	Decane	See below

Butane and all hydrocarbons that are larger than butane may have a branched appearance, which shortens the parent chain. An example is *isobutane*, properly named *methylpropane*, shown here. Any branched hydrocarbon with the correct number of carbons and no multiple bonds or rings is correct.



2. The alcohol would take precedence because the carbon to which it is attached has a higher oxidation state.
3. Diols are alcohols with two hydroxyl groups. For geminal diols, these are on the same carbon. For vicinal diols, they are in the vicinity of one another—on adjacent carbons.
4. Isopropyl alcohol and ethyl alcohol, respectively.

1.3

1. An aldehyde has a carbonyl group at the end of the chain. A ketone has a carbonyl group somewhere in the middle of the carbon chain. Another way to think of this is that the carbonyl carbon of an aldehyde has at least one bond to a hydrogen atom, whereas the carbonyl carbon of a ketone is always bonded to two other carbons.
2. Aldehydes are referred to with the suffix *–al*, while ketones are given the suffix *–one*. Carbonyl groups of both aldehydes and ketones are labeled as *oxo–* substituents (ketones may also be called *keto–* substituents).
3.

IUPAC Name	Common Name
Methanal	Formaldehyde
Ethanal	Acetaldehyde
Propanal	Propionaldehyde
Propanone	Acetone

4. Ketones and aldehydes both take precedence over both alcohols and hydrocarbon chains, and the functional group that is the highest priority determines the suffix. Because the aldehyde is chain-terminating and therefore on carbon number 1, the aldehyde would determine the suffix when naming this compound.

1.4

1. The ester derivative would be methyl pentanoate. The amide would be pentanamide. The anhydride would be pentanoic anhydride.
2. 3-methyl-2-oxopentanoic acid

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following lists the correct common names for ethanal, methanal, and ethanol, respectively?

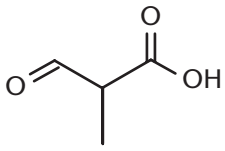
A. Acetaldehyde, formaldehyde, ethyl alcohol
B. Ethyl alcohol, propionaldehyde, isopropyl alcohol
C. Ethyl alcohol, formaldehyde, acetaldehyde
D. Isopropyl alcohol, ethyl alcohol, formaldehyde

2. Which of the following are considered terminal functional groups?

I. Aldehydes
II. Ketones
III. Carboxylic acids

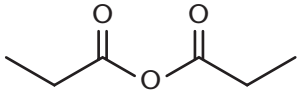
A. I only
B. III only
C. I and III only
D. I, II, and III

3. If all prefixes were dropped, what would be the name of the parent root of this molecule?



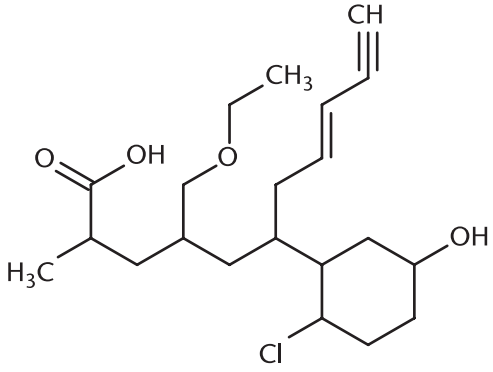
A. Propanoate
B. Propanol
C. Propanoic acid
D. Propanoic anhydride

4. What is the highest-priority functional group in this molecule?



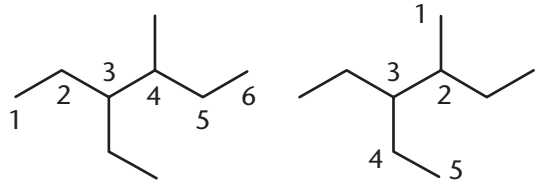
A. Anhydride
B. Carbonyl
C. Ketone
D. Alkyl chain

5. The IUPAC name for the following structure ends in what suffix?



A. –ol
B. –one
C. –oic acid
D. –yne

6. Which of the two possibilities below correctly numbers the carbon backbone of this molecule?

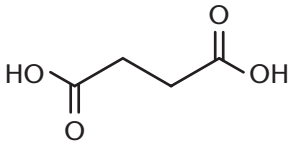


Numbering Scheme 1 Numbering Scheme 2

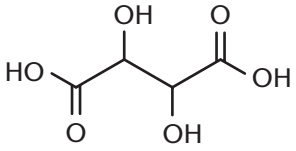
A. Numbering Scheme 1
B. Numbering Scheme 2
C. Numbering Schemes 1 and 2 are equivalent and correct.
D. Numbering Schemes 1 and 2 are equivalent and incorrect.

7. What is the proper structure for 2,3-dihydroxybutan-edioic acid (tartaric acid)?

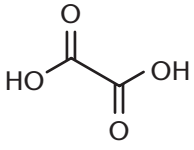
A.



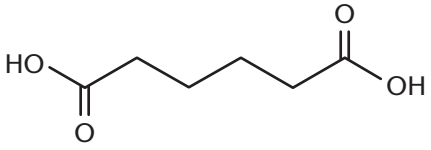
B.



C.



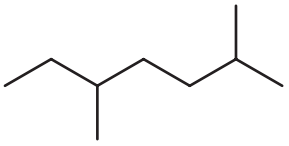
D.



8. The common names for the aldehydes and carboxylic acids that contain only one carbon start with which prefix?

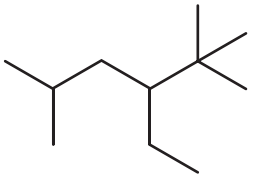
A. Para–
B. Form–
C. Meth–
D. Acet–

9. What is the IUPAC name for the following structure?



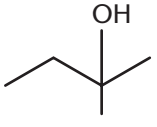
A. 2,5-dimethylheptane
B. 2-ethyl-5-methylhexane
C. 3,6-dimethylheptane
D. 5-ethyl-2-methylhexane

10. What is the IUPAC name for the following structure?



A. 4-isopropyl-2-methylhexane
B. 3-isopropyl-5-methylhexane
C. 2,2,5-trimethyl-3-ethylhexane
D. 3-ethyl-2,2,5-trimethylhexane

11. The IUPAC name for the following structure starts with what prefix?



A. 3-methyl-
B. 2-methyl-
C. 2-hydroxy-
D. 3-hydroxy-

12. NADH is a coenzyme that releases high-energy electrons into the electron transport chain. It is known as nicotinamide adenine dinucleotide or diphospho-pyridine nucleotide. What functional groups exist in this molecule?

I. Phosphate

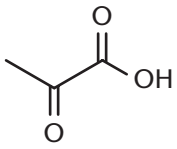
II. Amide

III. Anhydride

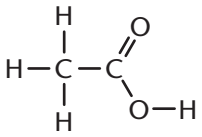
A. I only
B. II only
C. I and II only
D. I, II, and III

13. Pyruvic acid, one of the end products of glycolysis, is commonly called acetylformic acid. Based on its common name, the structure of pyruvic acid must be:

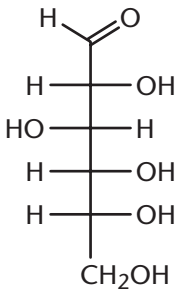
A.



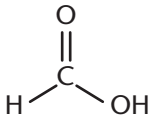
B.



C.



D.



14. Which of the following are common names for carboxylic acid derivatives?

I. Acetic anhydride

II. Formic acid

III. Methyl formate

A. I and II only
B. I and III only
C. II and III only
D. I, II, and III

15. Consider the name 2,3-diethylpentane. Based on the structure implied by this name, the correct IUPAC name for this molecule is:

A. 2,3-diethylpentane.
B. 1,2-diethylbutane.
C. 3-ethyl-4-methylhexane.
D. 3-methyl-4-ethylhexane.

Explanations to Discrete Practice Questions

1. A

The common name of ethanal is acetaldehyde, the common name of methanal is formaldehyde, and the common name of ethanol is ethyl alcohol. Isopropyl alcohol is the common name of 2-propanol. Propionaldehyde is the common name of propanal.

2. C

Aldehydes and carboxylic acids are characterized by their positions at the ends of carbon backbones and are thus considered terminal groups. As a result, the carbons to which they are attached are usually designated carbon 1. Ketones are internal by definition because there must be a carbon on either side of the carbonyl.

3. C

The highest-priority functional group in this molecule is the carboxylic acid, so this will be a component of the backbone and provides the suffix of the molecule. This molecule is 2-methyl-3-oxopropanoic acid.

4. A

This molecule features an anhydride. The only other groups are hydrocarbon chains, which will provide part of the name of the parent root. Keep in mind that when a carbonyl group is present with a leaving group, the larger functional group (carboxylic acid, anhydride, ester, amide) takes priority over the carbonyl group alone. This molecule is propanoic anhydride.

5. C

Among the functional groups presented, carboxylic acids have the highest priority, and their compounds end with an *–oic acid* suffix. **Choice (A)** denotes an alcohol, **choice (B)** a ketone, and **choice (D)** an alkyne, all of which have lower priorities than carboxylic acids. The MCAT does not test nomenclature of halides or ethers, but note that these must have lower priority than a carboxylic acid because they are less oxidized groups.

6. A

This molecule is 3-ethyl-4-methylhexane, not 2,3-diethylpentane. When naming alkanes, one must locate the longest carbon chain (6 carbons, rather than 5 carbons), and the numbering system should give the alkyl groups the lowest possible numbers.

7. B

We know from the IUPAC name that we have a butanedioic acid backbone—in other words, a four-carbon backbone with carboxylic acids at either end. Adding the hydroxyl groups at carbons 2 and 3 then yields the correct structure.

8. B

Form– is a prefix shared by the common names of methanoic acid (formic acid) and methanal (formaldehyde).

9. A

The first task in naming a compound is identifying the longest carbon chain. In this case, the longest chain has seven carbons, so the parent alkane ends in *–heptane*. **Choices (B)** and **(D)** can therefore be eliminated. Then, we must make sure that the carbons are numbered so that the substituents' position numbers are as small as possible. This compound has two methyl groups; minimizing their position numbers requires us to number the chain from right to left. These methyl groups are attached to carbons 2 and 5, so the correct IUPAC name is 2,5-dimethylheptane. **Choice (C)** is incorrect because the position numbers of the substituents are not minimized.

10. D

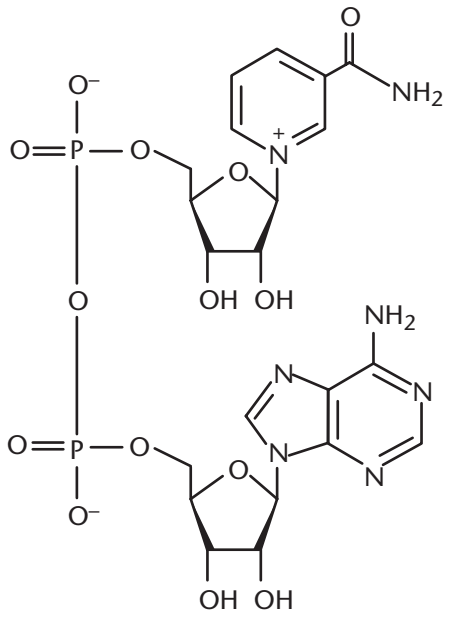
We begin by finding the longest carbon chain; because there are no non-alkyl groups, we don't need to worry about any other groups' priorities. We then number our carbons such that the lowest possible combination of numbers is given to the various substituents. Then substituents are organized alphabetically, not numerically—eliminating **choice (C)**.

11. B

We know right away that **choices (C)** and **(D)** will be incorrect because a hydroxyl group is of higher priority than a methyl group. We also know that we will number the carbon chain so that the hydroxyl group receives the lowest possible position. Therefore, this molecule is 2-methyl-2-butanol, which starts with the prefix 2-methyl.

12. C

The suffix *–amide* in nicotinamide indicates that this compound contains an amide functional group. The prefix *diphospho–* indicates that there are two phosphate groups, as well. Even if we did not know the prefix *phospho–* from this chapter, we should recognize that nucleotides, mentioned in the name of the compound, contain a sugar, a phosphate group, and a nitrogenous base. The structure of NAD^+, the oxidized form of NADH, is shown below.



13. A

We can use the name acetylformic acid to figure out what our functional groups are. The prefix *acet–* refers to a two-carbon unit with one carbon in a carbonyl group—think of acetic acid, acetic anhydride, or acetaldehyde. The carbonyl carbon is the point of attachment to another functional group. Formic acid is a single-carbon carboxylic acid. Therefore, acetylformic acid is an acetyl group directly attached to formic acid, as shown in **choice (A)**. **Choice (B)** shows acetic acid, or vinegar; **choice (C)** shows glucose; and **choice (D)** shows formic acid.

14. B

Acetic anhydride is the common name for ethanoic anhydride. Methyl formate is the common name for methyl methanoate; we can infer this from the common root *form–* and the ester suffix *–oate* (which is sometimes shortened to *–ate* for pronunciation purposes). Formic acid is the common name for methanoic acid, but this is a carboxylic acid—not a derivative.

15. C

Draw out the molecule, and you will see that the longest carbon chain with the substituents at the lowest possible carbon numbers is actually different from the one chosen in the original name. The correct IUPAC name for this molecule is 3-ethyl-4-methylhexane.

Concept Summary 50

Introduction

An important way that we distinguish between molecules is by identifying **isomers** of the same compound—those that have the same molecular formula but different structures. Keep in mind that isomerism describes a relationship; just as there must be at least two children to have siblings, two molecules can be isomers to each other, but no molecule can be an isomer by itself. Throughout this chapter, we will learn how to identify these relationships and describe the similarities and differences between isomers. Figure 2.1 shows the isomer classes that we will learn more about and how they are related—feel free to come back to this figure as a reference after you have read through the more detailed explanations.

Key Concept

Isomers have the same molecular formula, but different structures.

2.1 Structural Isomers ★

Structural isomers are the least similar of all isomers. In fact, the only thing that **structural isomers** (also called **constitutional isomers**) share is their molecular formula, meaning that their molecular weights must be the same. Aside from this similarity, structural isomers are widely varied, with different chemical and physical properties. For example, five different structural isomers of C_6H_{14} are shown in Figure 2.2. Each of these molecules looks completely different but has the same number of carbon and hydrogen atoms.

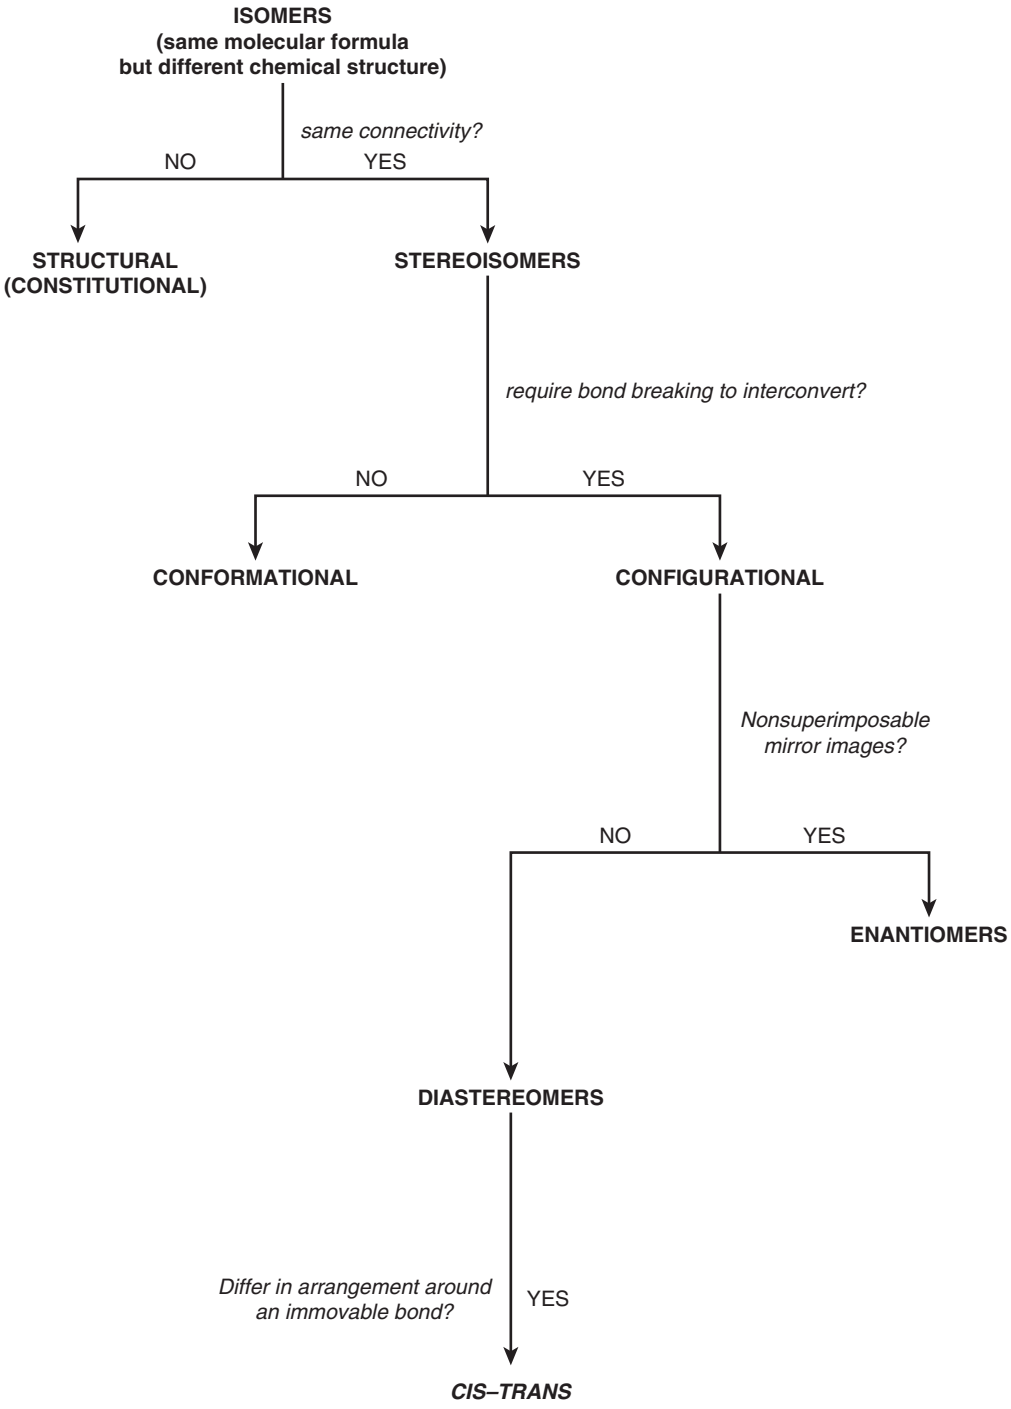

Figure 2.1. Flowchart of Isomer Relationships

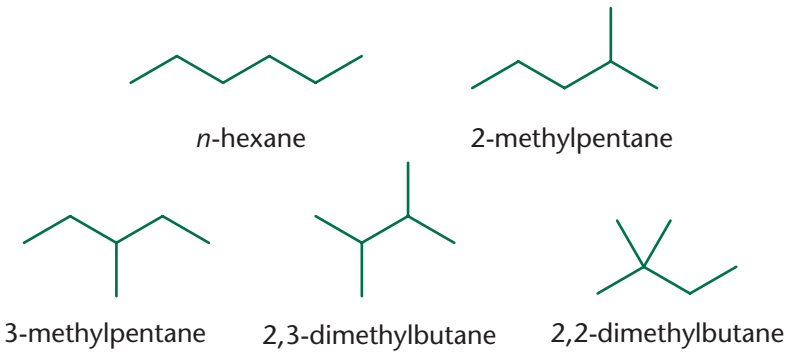

Figure 2.2. Structural (Constitutional) Isomers of C_6H_{14}

Physical and chemical properties are prime MCAT material and are often tested in the context of isomerism. **Physical properties** are characteristics of processes that don't change the composition of matter, such as melting point, boiling point, solubility, odor, color, and density. **Chemical properties** have to do with the reactivity of the molecule with other molecules and result in changes in chemical composition. In organic chemistry, the chemical properties of a compound are generally dictated by the functional groups in the molecule.

Key Concept

Physical properties: no change in composition of matter; examples include melting point, boiling point, solubility, odor, color, density.

Chemical properties: reactivity of molecule, resulting in change in composition; generally attributable to functional groups in the molecule.

MCAT Concept Check 2.1:

Before you move on, assess your understanding of the material with these questions.

1. What property or properties do structural isomers have in common?

_____

2. Of the compounds cyclopropanol, 2-propanol, acetone, and prop-2-ene-1-ol, which are structural isomers of each other?

_____

3. What are physical properties? Give three examples of physical properties.

_____

- _____
- _____
- _____

4. What are chemical properties?

_____

_____

2.2 Stereoisomers

Like structural isomers—and all isomers, for that matter—stereoisomers have the same chemical formula. Unlike structural isomers, however, **stereoisomers** also share the same atomic connectivity. In other words, they have the same structural backbone. Stereoisomers differ in how these atoms are arranged in space (their wedge-and-dash pattern), and all isomers that are not structural isomers fall under this category. The largest distinction within this class is between conformational and configurational isomers. **Conformational** isomers differ in rotation around single (σ) bonds; **configurational isomers** can be interconverted only by breaking bonds.

CONFORMATIONAL ISOMERS

Of all of the isomers, **conformational isomers** or **conformers** are the most similar. Conformational isomers are, in fact, the same molecule, only at different points in their natural rotation around single (σ) bonds.

While double bonds hold molecules in a specific position (as explained with *cis–trans* isomers later), single bonds are free to rotate. Conformational isomers arise from the fact that varying degrees of rotation around single bonds can create different levels of strain. These conformations are easy to see when the molecule is depicted in a **Newman projection**, in which the molecule is visualized along a line extending through a carbon–carbon bond axis. The classic example for demonstrating conformational isomerism in a straight chain is butane, which is shown in Figure 2.3.

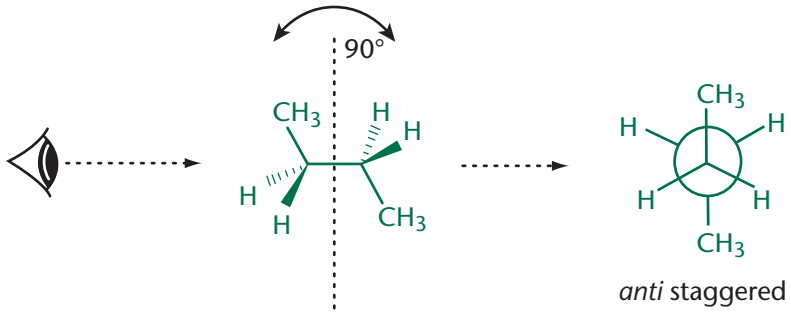

Figure 2.3. Newman Projection of Butane
Depiction of different atoms' positions from the point of view of the C-2 to C-3 bond axis.

Straight-Chain Conformations

For butane, the most stable conformation occurs when the two methyl groups (containing C-1 and C-4) are oriented 180° away from each other. In this position, there is minimal steric repulsion between the atoms' electron clouds

because they are as far apart as they can possibly be. Thus, the atoms are "happiest" and in their lowest-energy state. Because there is no overlap of atoms along the line of sight (besides C-2 and C-3), the molecule is said to be in a **staggered** conformation. Specifically, it is called the ***anti*** conformation because the two largest groups are antiperiplanar (in the same plane, but on opposite sides) to each other. This is the most energetically favorable type of staggered conformation. The other type of staggered conformation, called ***gauche***, occurs when the two largest groups are 60° apart.

To convert from the *anti* to the *gauche* conformation, the molecule must pass through an **eclipsed** conformation in which the two methyl groups are 120° apart and overlap with the hydrogen atoms on the adjacent carbon. When the two methyl groups directly overlap each other with 0° separation, the molecule is said to be **totally eclipsed** and is in its highest-energy state. Totally eclipsed conformations are the least favorable energetically because the two largest groups are synperiplanar (in the same plane, on the same side). The different staggered and eclipsed conformations are demonstrated in Figures 2.3 and 2.4. For compounds larger than butane, the name of the conformation is decided by the relative positions of the two largest substituents about a given carbon–carbon bond.

Mnemonic

It's ***gauche*** (unsophisticated or awkward) for one methyl group to stand too close to another group. Groups are **eclipsed** when they are completely in line with one another—just like a solar or lunar eclipse.

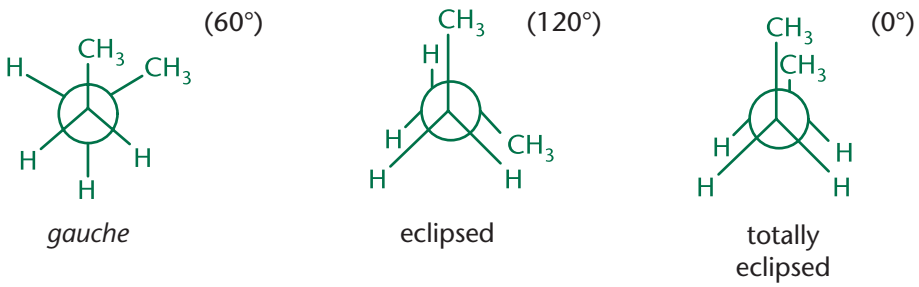

Figure 2.4. Stability of Straight-Chain Conformational Isomers
Degree measurements indicate the angle between the two largest substituents about the carbon–carbon bond.

Figure 2.5 shows the plot of potential energy *vs*. degree of rotation about the bond between C-2 and C-3 in butane. It shows the relative minima and maxima of potential energy of the molecule throughout its various conformations. Remember that every molecule wants to be in the lowest energy state possible, so the higher the energy, the less time the molecule will spend in that energetically unfavorable state.

Key Concept

Notice that the *anti* staggered isomer (A and G) has the lowest energy, whereas the totally eclipsed isomer (D) has the highest energy.

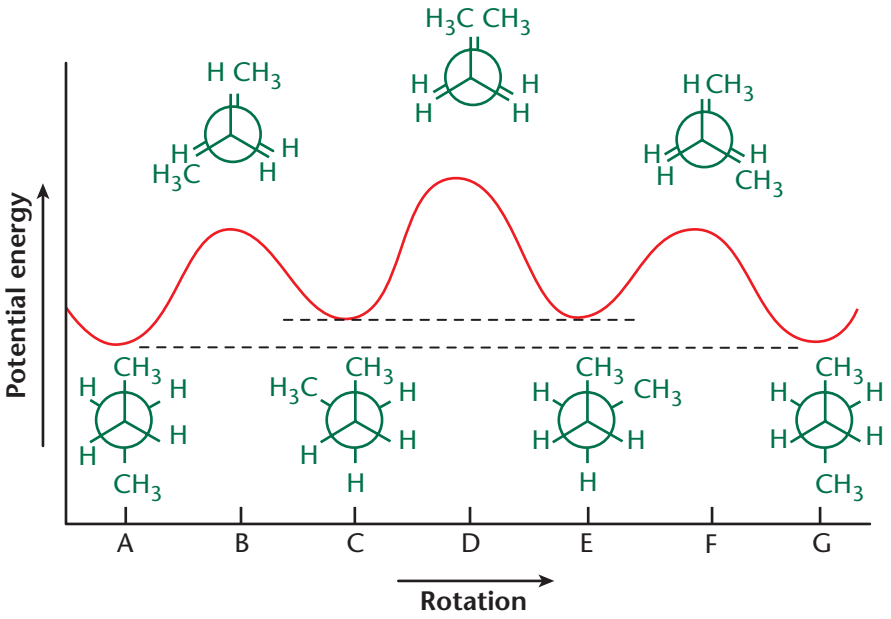

Figure 2.5. Potential Energy *vs.* Degree of Rotation about the C-2 to C-3 Bond in Butane

These conformational interconversion barriers are small (19 $\frac{\text{kcal}}{\text{mol}}$ between *anti* staggered butane and totally eclipsed butane) and are easily overcome at room temperature. Nevertheless, at very low temperatures, conformational interconversions will dramatically slow. If the molecules do not possess sufficient energy to cross the energy barrier, they may not rotate at all (as happens to all molecules at absolute zero).

Cyclic Conformations

Cycloalkanes can be either fairly stable compounds or fairly unstable—depending on **ring strain**. Ring strain arises from three factors: angle strain, torsional strain, and nonbonded strain (sometimes referred to as steric strain). **Angle strain** results when bond angles deviate from their ideal values by being stretched or compressed. **Torsional strain** results when cyclic molecules must assume conformations that have eclipsed or *gauche* interactions. **Nonbonded strain** (**van der Waals repulsion**) results when *nonadjacent* atoms or groups compete for the same space. Nonbonded strain is the dominant source of steric strain in the **flagpole interactions** of the cyclohexane boat conformation. To alleviate the strain, cycloalkanes attempt to adopt various nonplanar conformations. Cyclobutane puckers into a slight "V" shape; cyclopentane adopts what is called an *envelope* conformation; and cyclohexane (the one you will undoubtedly see the most on the MCAT) exists mainly in three conformations called the **chair**, **boat**, and **twist-** or **skew-boat** forms. These cycloalkanes are shown in Figure 2.6.

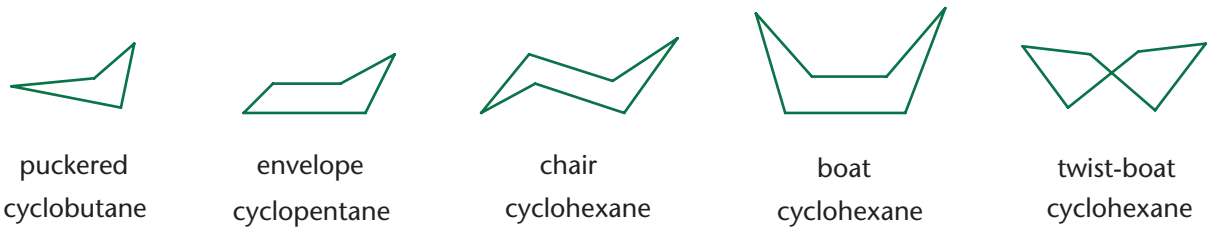

Figure 2.6. Conformations of Cycloalkanes

The most stable conformation of cyclohexane is the chair conformation, which minimizes all three types of strain. The hydrogen atoms that are perpendicular to the plane of the ring (sticking up or down) are called **axial**, and those parallel (sticking out) are called **equatorial**. The axial–equatorial orientations alternate around the ring; that is, if the wedge on C-1 is an axial group, the dash on C-2 will also be axial, the wedge on C-3 will be axial, and so on.

Cyclohexane can undergo a **chair flip** in which one chair form is converted to the other. In this process, the cyclohexane molecule briefly passes through a fourth conformation called the **half-chair** conformation. After the chair flip, all axial groups become equatorial and all equatorial groups become axial. All dashes remain dashes, and all wedges remain wedges. This interconversion can be slowed if a bulky group is attached to the ring; *tert*-butyl groups are classic examples of bulky groups on the MCAT. For substituted rings, the bulkiest group will favor the equatorial position to reduce nonbonded strain (flagpole interactions) with axial groups in the molecule, as shown in Figure 2.7.

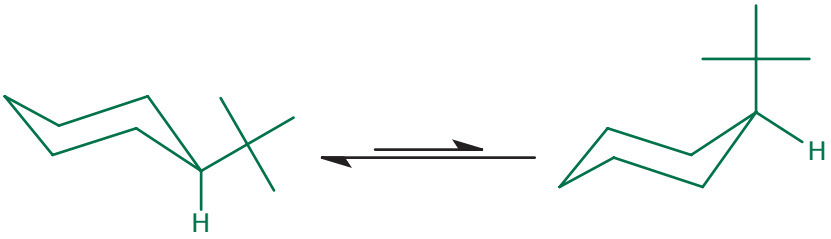

Figure 2.7. Axial and Equatorial Positions in Cyclohexane
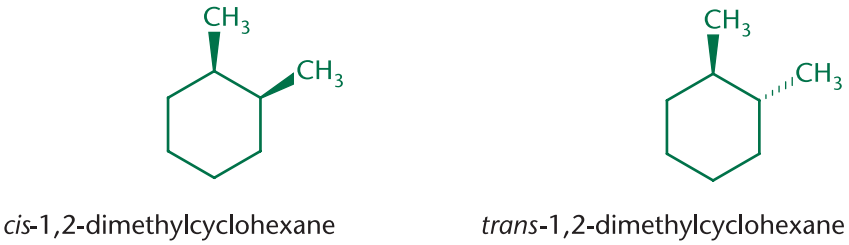
During a chair flip, axial components become equatorial and vice-versa. However, components pointing "up" (wedge) remain up and components pointing "down" (dash) remain down.

In rings with more than one substituent, the preferred chair form is determined by the larger group, which will prefer the equatorial position. These rings also have associated nomenclature. If both groups are located on the same side of the ring, the molecule is called *cis*; if they are on opposite sides of the ring, it is called *trans*, as shown in Figure 2.8. These same terms are used for molecules with double bonds, as explained later in this chapter.



cis-1,2-dimethylcyclohexane *trans*-1,2-dimethylcyclohexane

Figure 2.8. Nomenclature of Rings with Multiple Substituents

CONFIGURATIONAL ISOMERS

Unlike conformational isomers that interconvert by simple bond rotation, **configurational isomers** can only change from one form to another by breaking and reforming covalent bonds. The two categories of configurational isomers are enantiomers and diastereomers. Both enantiomers and diastereomers can also be considered **optical isomers** because the different spatial arrangement of groups in these molecules affects the rotation of plane-polarized light.

Chirality

Key Concept
Chirality = handedness

An object is considered **chiral** if its mirror image cannot be superimposed on the original object; this implies that the molecule lacks an internal plane of symmetry. Chirality can also be thought of as handedness. In fact, one of the easiest visualizations of chirality is to think of your own hands, as shown in Figure 2.9. Although essentially identical, your left hand will not be able to fit into a right-handed glove. **Achiral** objects have mirror images that *can* be superimposed; for example, a fork is identical to its mirror image and is therefore achiral.

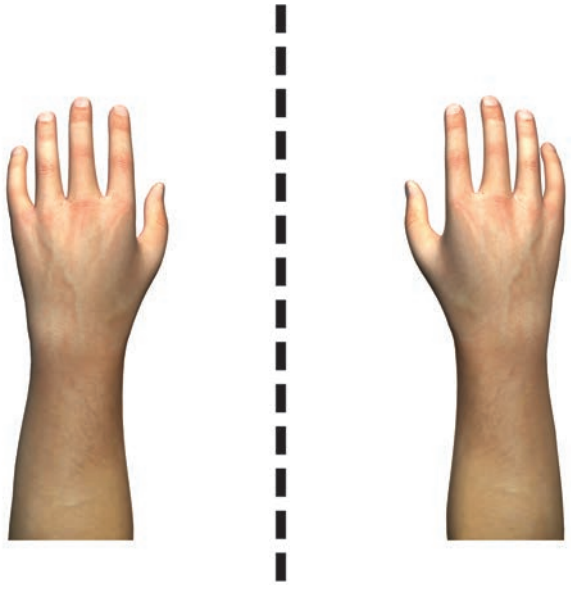


Figure 2.9. Hands as Examples of Chiral Structures
Each hand has a nonsuperimposable mirror image.

On the MCAT, we will often see this concept tested when there is a carbon atom with four different substituents. This carbon will be an asymmetrical core of optical activity and is known as a **chiral center**. As mentioned earlier, chiral centers lack a plane of symmetry. For example, the C-1 carbon atom in 1-bromo-1-chloroethane has four different substituents. As shown in Figure 2.10, this molecule is chiral because it is not superimposable on its mirror image.

MCAT Expertise

Whenever you see a carbon with four different substituents, think chirality.

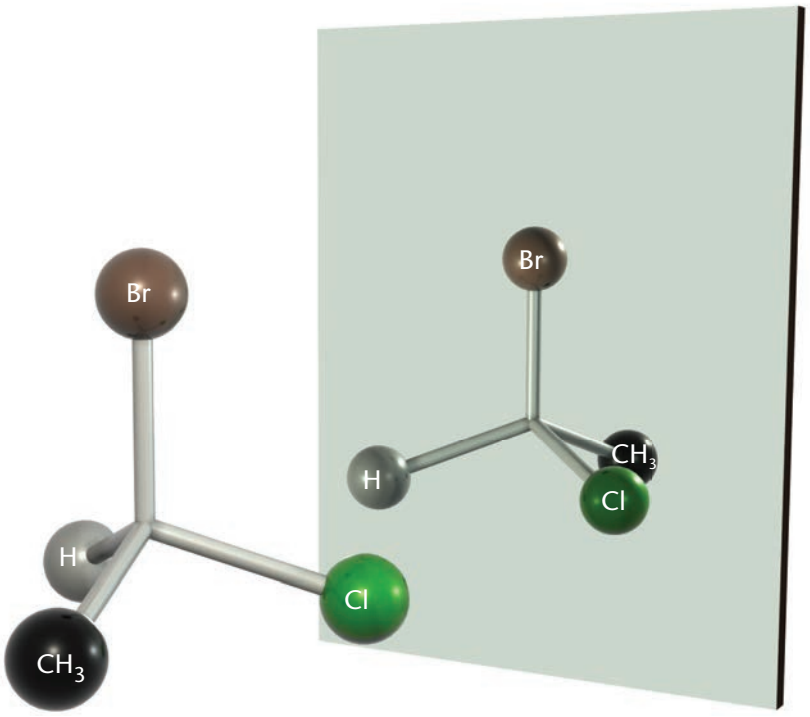

Figure 2.10. Enantiomers of 1-Bromo-1-Chloroethane

Two molecules that are nonsuperimposable mirror images of each other are called **enantiomers**. Molecules may also be related as **diastereomers**. These molecules are chiral and share the same connectivity, but are not mirror images of each other. This is because they differ at some (but not all) of their multiple chiral centers.

Alternatively, a carbon atom with only *three different* substituents, such as 1,1-dibromoethane, has a plane of symmetry and is therefore **achiral**. A simple 180° rotation around a vertical axis, as shown in Figure 2.11, allows the compound to be superimposed upon its mirror image.

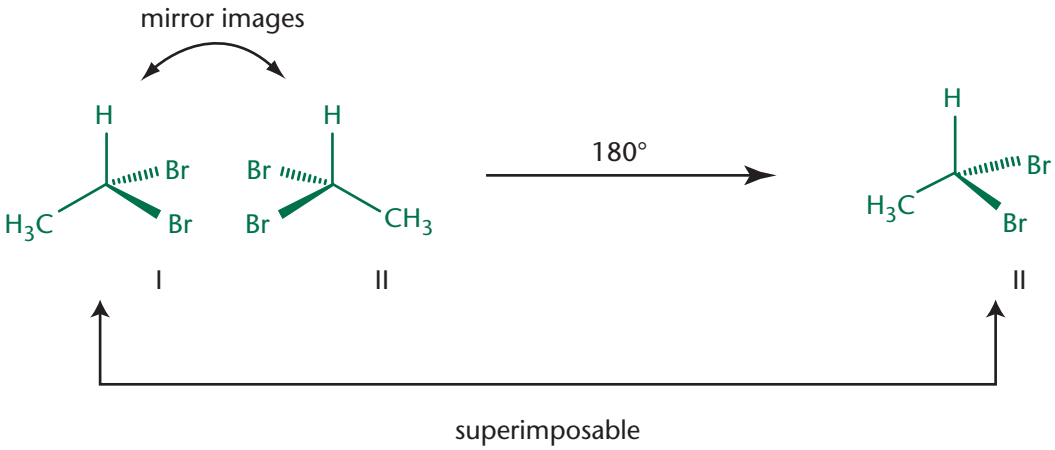

Figure 2.11. Rotation of an Achiral Molecule

Key Concept

Enantiomers have nearly identical physical properties and chemical properties, but they rotate plane-polarized light in opposite directions and react differently in chiral environments.

Enantiomers

Enantiomers (nonsuperimposable mirror images) have the same connectivity but opposite configurations at every chiral center in the molecule. Enantiomers have identical physical and chemical properties with two notable exceptions: optical activity and reactions in chiral environments.

A compound is optically active if it has the ability to rotate plane-polarized light. Ordinary light is unpolarized, which means that it consists of waves vibrating in all possible planes perpendicular to its direction of propagation. A polarizer allows light waves oscillating only in a particular direction to pass through, producing plane-polarized light, as shown in Figure 2.12.

Bridge

While rotation of plane-polarized light can be tested in organic chemistry questions, the polarization of light *itself* is fair game as a physics question. Be sure to review light polarization, discussed in Chapter 8 of *MCAT Physics and Math Review.*

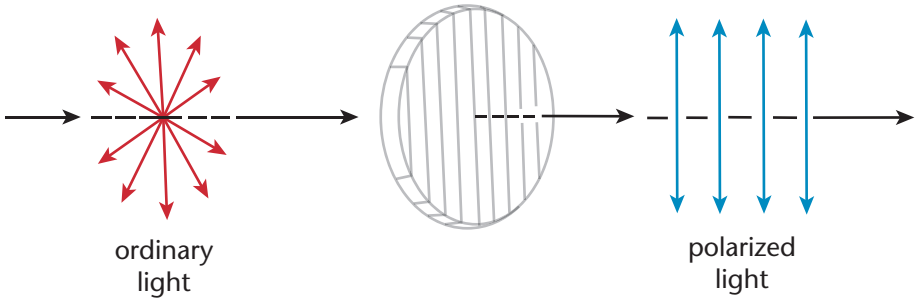

Figure 2.12. Polarizer

Optical activity refers to the rotation of this plane-polarized light by a chiral molecule. At the molecular level, one enantiomer will rotate plane-polarized light to the same magnitude but in the opposite direction of its mirror image (assuming concentration and path lengths are equal). A compound that rotates

the plane of polarized light to the right, or clockwise, is dextrorotatory (d-) and is labeled (+). A compound that rotates light toward the left, or counterclockwise, is levorotatory (l-) and is labeled (–). The direction of rotation cannot be determined from the structure of a molecule and must be determined experimentally. That is, it is not related to the absolute configuration of the molecule.

The amount of rotation depends on the number of molecules that a light wave encounters. This depends on two factors: the concentration of the optically active compound and the length of the tube through which the light passes. Chemists have set standard conditions of 1 $\frac{\text{g}}{\text{ml}}$ for concentration and 1 dm (10 cm) for length to compare the optical activities of different compounds. Rotations measured at different concentrations and tube lengths can be converted to a standardized **specific rotation** using the following equation:

$$[\alpha] = \frac{\alpha_{\text{obs}}}{c \times l}$$

Equation 2.1

where $[\alpha]$ is specific rotation in degrees, α_{obs} is the observed rotation in degrees, c is the concentration in $\frac{\text{g}}{\text{ml}}$, and l is the path length in dm.

When both (+) and (–) enantiomers are present in equal concentrations, they form a **racemic mixture**. In these solutions, the rotations cancel each other out, and no optical activity is observed. If enantiomerism is analogous to handedness, racemic mixtures are the equivalent of ambidexterity. These solutions possess no handedness overall and will not rotate plane-polarized light.

The fact that enantiomers have identical physical and chemical properties prompts a question about racemic mixtures: how can one separate the mixture into its two constituent isomers? The answer lies in the relationship between enantiomers and diastereomers. Reacting two enantiomers with a single enantiomer of another compound will, by definition, lead to two diastereomers. Imagine, for example, two enantiomers that contain only one chiral carbon; these compounds could be labeled (+) and (–). If each is reacted with only the (+) enantiomer of another compound, two products would result: (+,+) and (–,+). Because these two products differ at some—but not all—chiral centers, they are necessarily diastereomers. Diastereomers have different physical properties, as we will explore momentarily. These differences enable one to separate these products by common laboratory techniques such as crystallization, filtration, distillation, and others. Once separated, these diastereomers can be reacted to regenerate the original enantiomers.

Key Concept

The system for labeling optical activity always uses d- or (+) to refer to clockwise rotation of plane-polarized light, while l- and (–) always go together and refer to counterclockwise rotation of plane-polarized light. Do not confuse this with D- or L- labels on carbohydrates or amino acids, which are based on the absolute configuration of glyceraldehyde. (*R*) and (*S*) also refer to absolute configuration, which is determined by structure. Optical activity does not consistently align with the other systems.

Key Concept

A racemic mixture displays no optical activity.

Diastereomers

Diastereomers are non-mirror-image configurational isomers. Diastereomers occur when a molecule has two or more stereogenic centers and differs at some, but not all, of these centers. This means that diastereomers are required to have multiple chiral centers. For any molecule with n chiral centers, there are 2^n possible stereoisomers. Thus, if a compound has two chiral carbon atoms, it has a maximum of four possible stereoisomers, as shown in Figure 2.13.

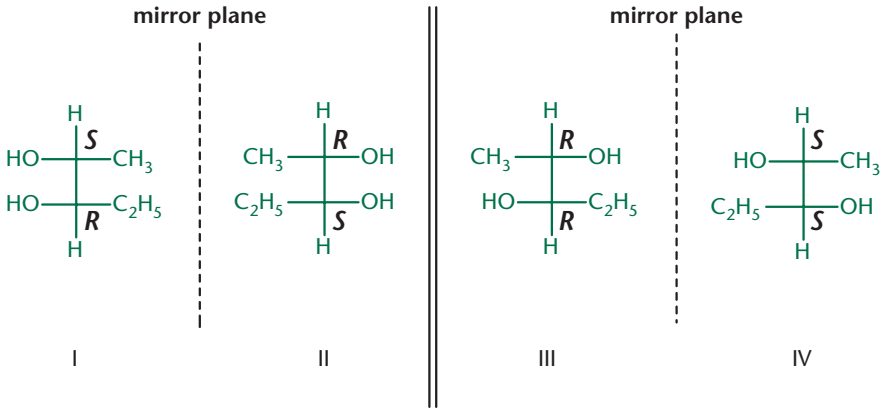

Figure 2.13. 2^n Possible Stereoisomers (n = chiral centers)
Four stereoisomers with two chiral centers; enantiomers = I/II and III/IV pairs, and all other combinations are diastereomers.

In this image, one can see that I and II are mirror images of each other and are therefore enantiomers of each other. Similarly, III and IV are enantiomers. However, I and III are not. These are stereoisomers that are not mirror images and are thus diastereomers. Notice that other combinations of non-mirror-image stereoisomers are also diastereomers: I and IV, II and III, and II and IV.

Diastereomers have different chemical properties. However, they might behave similarly in particular reactions because they have the same functional groups. Because they have different arrangements in space, they will consistently have different physical properties. Diastereomers will also rotate plane-polarized light; however, knowing the specific rotation of one diastereomer gives no indication of the specific rotation of another diastereomer. This is a stark contrast from enantiomers, which will always have equal-magnitude rotations in opposite directions.

Cis–Trans Isomers

Cis–trans* isomers** (formerly called **geometric isomers**) are a specific subtype of diastereomers in which substituents differ in their position around an immovable bond, such as a double bond, or around a ring structure, such as a cycloalkane in which the rotation of bonds is greatly restricted. In simple compounds with only one substituent on either side of the immovable bond, we use the terms ***cis and ***trans***. If two substituents are on the same side of the immovable bond, the molecule is considered *cis*. If they are on opposite sides, it is considered *trans*, as shown in Figure 2.8 earlier. For more complicated compounds with polysubstituted double bonds, (*E*)/(*Z*) nomenclature is used instead, as described in the next section.

Meso Compounds

For a molecule to have optical activity, it must not only have chiral centers within it, but must also lack a plane of symmetry. Thus, if a plane of symmetry exists, the molecule is not optically active even if it possesses chiral centers. This plane of symmetry can occur either through the chiral center or between chiral centers. A molecule with chiral centers that has an internal plane of symmetry is called a ***meso* compound**, an example of which is shown in Figure 2.14.

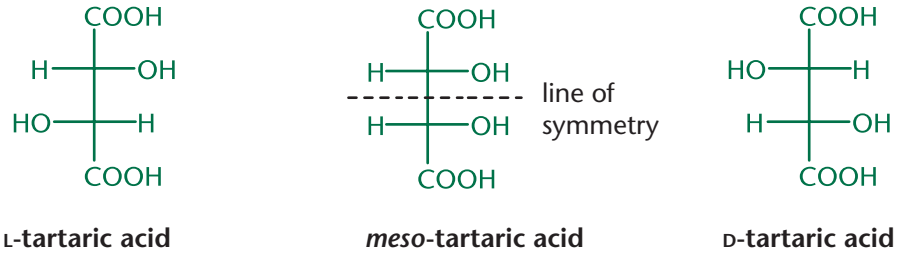

Figure 2.14. Example of a *Meso* Compound

As shown in this image, D- and L-tartaric acid are both optically active, but *meso*-tartaric acid has a plane of symmetry and is not optically active. This means that even though *meso*-tartaric acid has two chiral carbon atoms, the molecule as a whole does not display optical activity. *Meso* compounds are essentially the molecular equivalent of a racemic mixture.

MCAT Expertise

While the MCAT is up-to-date with science, it is still possible to see older terms for some concepts on Test Day. Thus, it's important to know not only the current name *cis–trans* isomers, but also the older name, geometric isomers.

Key Concept

Meso compounds are made up of two halves that are mirror images. Thus, as a whole they are not optically active.

MCAT Concept Check 2.2:
Before you move on, assess your understanding of the material with these questions.

1. What is the difference between a conformational and a configurational isomer?
   - Conformational:

     _____

   - Configurational:

     _____

2. Briefly summarize the differences between enantiomers and diastereomers:

	Definition	Same Physical Properties?	Same Chemical Properties?
Enantiomers			
Diastereomers			

3. What is a *meso* compound?

_____

_____

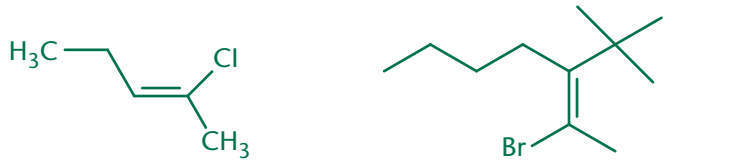
2.3 Relative and Absolute Configurations

The **configuration** of a stereoisomer refers to the spatial arrangement of the atoms or groups in the molecule. The **relative configuration** of a chiral molecule is its configuration in relation to another chiral molecule (often through chemical interconversion). We can use the relative configuration to determine whether molecules are enantiomers, diastereomers, or the same molecule. On the other hand, the **absolute conformation** of a chiral molecule describes the exact spatial arrangement of these atoms or groups, independent of other molecules.

(*E*) AND (*Z*) FORMS

(*E*) and (*Z*) nomenclature is used for compounds with polysubstituted double bonds. Recall that simpler double-bond-containing compounds can use the *cis–trans*

system. To determine the (*E*)/(*Z*) designation, one starts by identifying the highest-priority substituent attached to each double-bonded carbon. Using the **Cahn–Ingold–Prelog priority rules**, priority is assigned based on the atom bonded to the double-bonded carbons: the higher the atomic number, the higher the priority. If the atomic numbers are equal, priority is determined by the next atoms outward; again, whichever group contains the atom with the highest atomic number is given top priority. If a tie remains, the atoms in this group are compared one-by-one in descending atomic number order until the tie is broken. The alkene is named (***Z***) (German: *zusammen*, "together") if the two highest-priority substituents on each carbon are on the same side of the double bond and (***E***) (*entgegen*, "opposite") if they are on opposite sides, as shown in Figure 2.15.



(*Z*)-2-chloro-2-pentene (*E*)-2-bromo-3-*t*-butyl-2-heptene

Figure 2.15. (*E*) and (*Z*) Designations of Alkenes

Mnemonic

Z = "**z**"ame side; ***E*** = "**e**"pposite side

(*R*) AND (*S*) FORMS

(*R*) and (*S*) nomenclature is used for chiral (stereogenic) centers in molecules. We go through a set sequence to determine this absolute configuration:

Step 1: Assign Priority

Using the Cahn–Ingold–Prelog priority rules described earlier, assign priority to the four substituents, looking only at the atoms directly attached to the chiral center. Once again, higher atomic number takes priority over lower atomic number. If the atomic numbers are equal, priority is determined by the combination of the atoms attached to these atoms; if there is a double bond, it is counted as two individual bonds to that atom. If a tie is encountered, work outward from the stereocenter until the tie is broken. An example is shown in Figure 2.16.

Key Concept

When assigning priority, look only at the first atom attached to the chiral carbon, not at the group as a whole. The higher the atomic number of this first atom, the higher the priority—this same system is used to determine priority for both (*E*) and (*Z*) forms as well as (*R*) and (*S*) forms.

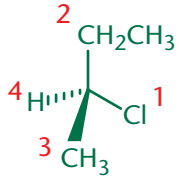


Figure 2.16. Applying the Cahn–Ingold–Prelog Priority Rules to Determine Absolute Configuration
Assign priority by the highest atomic number.

Step 2 (Classic Version): Arrange in Space

Orient the molecule in three-dimensional space so that the atom with the lowest priority (usually a hydrogen atom) is at the back of the molecule. Another way to think of this is to arrange the point of view so that the line of sight proceeds down the bond from the asymmetrical carbon atom (the chiral center) to the substituent with lowest priority. The three substituents with higher priority should then radiate out from the central carbon, coming out of the page, as shown in Figure 2.17.

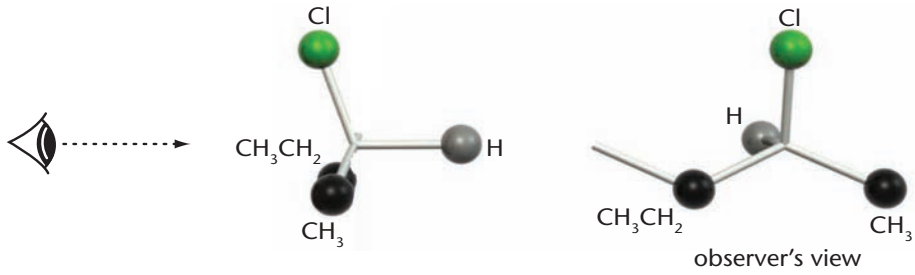

Figure 2.17. Placing the Lowest-Priority Group in the Back

Step 2 (Modified Version): Invert the Stereochemistry

If it is difficult to visualize rotating three-dimensional structures, one can simplify this process by remembering one simple rule: *any time two groups are switched on a chiral carbon, the stereochemistry is inverted*. By this logic, we can simply switch the lowest-priority group with the group at the back of the molecule (the substituent projecting into the page). We can then proceed to Step 3, keeping in mind that we have now changed the molecule to the opposite configuration. Therefore, if we use this modified step, we need to remember to switch our final answer (either (*R*) to (*S*), or (*S*) to (*R*)). This is a strategy we'll commonly use on Fischer diagrams, as described below.

Step 3: Draw a Circle

Now, imagine drawing a circle connecting the substituents from number 1 to 2 to 3. Pay no attention to the lowest-priority group; it can be skipped because it projects directly into the page. If the circle is drawn counterclockwise, the asymmetric atom is called (***S***) (Latin: *sinister*, "left"). If it is clockwise, it is called (***R***) (*rectus*, "right"), as shown in Figure 2.18.

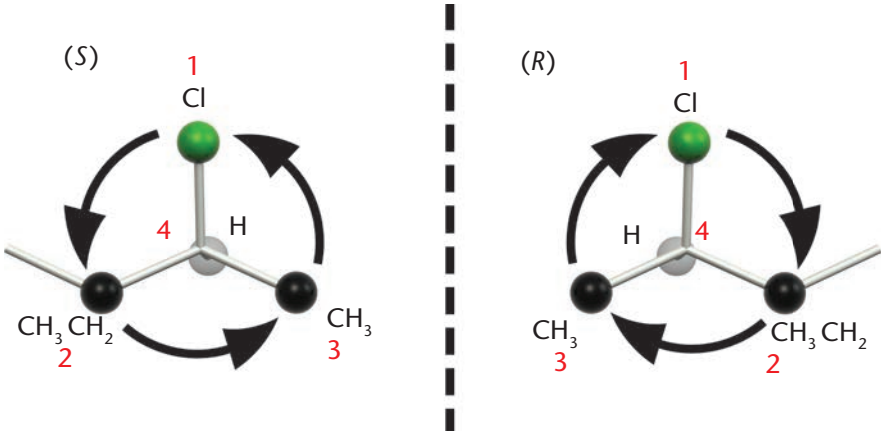

Figure 2.18. Drawing a Circle to Determine Absolute Configuration
Counterclockwise = (*S*); clockwise = (*R*)

Remember to correct the stereochemistry if the modified version of Step 2 was used.

Step 4: Write the Name

Once the (*R*)/(*S*) designation has been determined, the name can be written out. (*R*) and (*S*) are put in parentheses and separated from the rest of the name by a hyphen. If we have a compound with more than one chiral center, location is specified by a number preceding the *R* or *S* within the parentheses and without a hyphen.

FISCHER PROJECTIONS

On the MCAT, one way to represent three-dimensional molecules is by a **Fischer projection**. In this system, horizontal lines indicate bonds that project out from the plane of the page (wedges), whereas vertical lines indicate bonds going into the plane of the page (dashes). The point of intersection of the lines represents a carbon atom.

To determine configurations using Fischer projections, we follow the same rules listed above. Once again, we have to make sure that the lowest-priority group projects into the page. A benefit of Fischer projections is that the lowest-priority group can be on the top or bottom of the molecule and still project into the page.

Another advantage is that we can manipulate Fischer projections without changing the compound. As mentioned before, switching two substituents around a chiral carbon will invert the stereochemistry ((*R*) to (*S*), or (*S*) to (*R*)). Rotating a Fischer projection in the plane of the page by 90° will also invert the stereochemistry of the molecule. By extension, interchanging any *two* pairs of substituents will revert the compound back to its original stereochemistry, and rotating a Fischer projection in the plane of the page by 180° will also retain the stereochemistry of the molecule. These manipulations are shown in Figure 2.19.

Mnemonic

A clockwise arrangement is like turning a steering wheel clockwise, which makes a car turn **R**ight—so the chirality at that center is (***R***).

Key Concept

To determine the absolute configuration at a chiral center:
1. Assign priority by atomic number
2. Arrange the molecule with the lowest-priority substituent in the back (or invert the stereochemistry by switching two substituents)
3. Draw a circle around the molecule from highest to lowest priority (1 to 2 to 3)
4. Clockwise = (*R*); counterclockwise = (*S*)

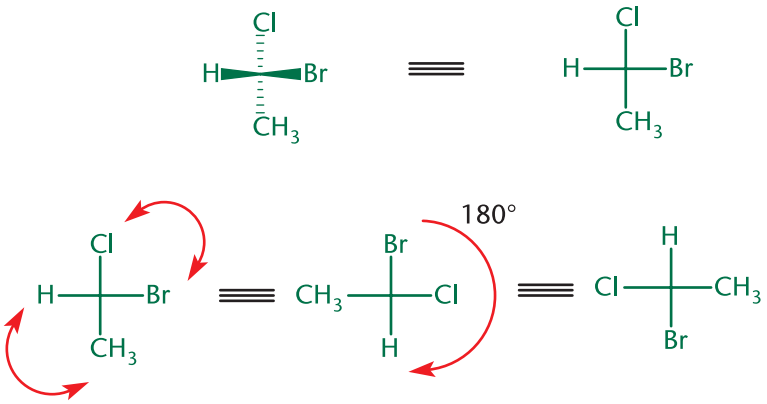

Figure 2.19. Manipulations of Fischer Projections

Again, determining the (*R*)/(*S*) designation of a Fischer projection of a compound follows the same rules as described previously. But what if our lowest-priority group is pointing to the side and, as such, pointing out of the page? Just as before, we've got a couple of different tricks to help determine the right stereochemistry.

Option 1: Make 0 Switches

Go ahead and determine the order of substituents as normal, drawing a circle from 1 to 2 to 3. Remember, number 4 doesn't count, so just skip right over it when determining the order. Then, obtain the (*R*)/(*S*) designation. The *true* designation will be the opposite of what you just obtained.

Option 2: Make 1 Switch

Swap the lowest-priority group with one of the groups on the vertical axis. Obtain the (*R*)/(*S*) designation and, once again, the *true* designation will be the opposite of what you just found.

Option 3: Make 2 Switches

In this method, start with option 2, moving the lowest-priority group into the correct position. Then, switch the other two groups as well. Because we made two switches, this molecule will have the *same* designation as the initial molecule. This is the same as holding one substituent in place and rotating the other three in order.

MCAT Expertise

Determine which option you prefer for Fischer projection (*R*)/(*S*) designation and stick with it. It's more efficient to have a consistent method than to use all three interchangeably.

MCAT Concept Check 2.3:

Before you move on, assess your understanding of the material with these questions.

1. What is the difference between an (*E*) isomer and a (*Z*) isomer?
   - (*E*):

     _____
   - (*Z*):

     _____
2. How is priority assigned under the Cahn–Ingold–Prelog priority rules?

   _____

   _____

   _____
3. For each of the Fischer projection manipulations listed below, is stereochemistry retained or inverted?
   - Switching a pair of substituents: _____
   - Switching two pairs of substituents: _____
   - Rotating the molecule 90°: _____
   - Rotating the molecule 180°: _____

Conclusion

Throughout this chapter, we've seen just how many different molecules can be derived from the same molecular formula. This information is going to be essential on the MCAT—not only for questions on isomerism itself but on every single organic chemistry question you encounter. Most of the compounds we come across will have different possible isomers, and you need to be prepared to differentiate among them to find the one and only correct answer. In the next chapter, we'll explore how organic molecules are held together through discussions of hybridized orbitals and resonance.

CONCEPT SUMMARY

Structural Isomers

- **Structural isomers** share only a molecular formula.
- They have different physical and chemical properties.

Stereoisomers

- **Conformational isomers** differ by rotation around a single (σ) bond.
  - **Staggered conformations** have groups 60° apart, as seen in a **Newman projection**. In ***anti* staggered** molecules, the two largest groups are 180° apart, and strain is minimized. In ***gauche* staggered** molecules, the two largest groups are 60° apart.
  - **Eclipsed conformations** have groups directly in front of each other as seen in a Newman projection. In **totally eclipsed conformations**, the two largest groups are directly in front of each other and strain is maximized.
  - The strain in cyclic molecules comes from **angle strain** (created by stretching or compressing angles from their normal size), **torsional strain** (from eclipsing conformations), and **nonbonded strain** (from interactions between substituents attached to nonadjacent carbons). Cyclic molecules will usually adopt nonplanar shapes to minimize this strain.
  - Substituents attached to cyclohexane can be classified as **axial** (sticking up or down from the plane of the molecule) or **equatorial** (in the plane of the molecule). Axial substituents create more nonbonded strain.
  - In cyclohexane molecules with multiple substituents, the largest substituent will usually take the equatorial position to minimize strain.
- **Configurational isomers** can only be interchanged by breaking and reforming bonds.
  - **Enantiomers** are nonsuperimposable mirror images and thus have opposite stereochemistry at every chiral carbon. They have the same chemical and physical properties except for rotation of plane-polarized light and reactions in a chiral environment.
  - **Optical activity** refers to the ability of a molecule to rotate plane-polarized light: d- or (+) molecules rotate light to the right; l- or (–) molecules rotate light to the left.
  - **Racemic mixtures**, with equal concentrations of two enantiomers, will not be optically active because the two enantiomers' rotations cancel each other out.
  - ***Meso* compounds**, with an internal plane of symmetry, will also be optically inactive because the two sides of the molecule cancel each other out.

- **Diastereomers** are non-mirror-image stereoisomers. They differ at some, but not all, chiral centers. They have different chemical and physical properties.
- ***Cis–trans*** isomers are a subtype of diastereomers in which groups differ in position about an immovable bond (such as a double bond or in a cycloalkane).

- **Chiral centers** have four different groups attached to the central carbon.

Relative and Absolute Configurations

- **Relative configuration** gives the stereochemistry of a compound in comparison to another molecule.
- **Absolute configuration** gives the stereochemistry of a compound without having to compare to other molecules.
  - Absolute configuration uses the **Cahn–Ingold–Prelog priority rules**, in which priority is given by looking at the atoms connected to the chiral carbon or double-bonded carbons; whichever has the highest atomic number gets highest priority. If there is a tie, one moves outward from the chiral carbon or double-bonded carbon until the tie is broken.
- An alkene is **(*Z*)** if the highest-priority substituents are on the same side of the double bond and **(*E*)** if on opposite sides.
- A stereocenter's configuration is determined by putting the lowest priority group in the back and drawing a circle from group 1 to 2 to 3 in descending priority. If this circle is clockwise, the stereocenter is **(*R*)**; if it is counterclockwise, the stereocenter is **(*S*)**.
- Vertical lines in **Fischer diagrams** go into the plane of the page (dashes); horizontal lines come out of the plane of the page (wedges).
  - Switching one pair of substituents in a Fischer diagram inverts the stereochemistry of the chiral center. Switching two pairs retains the stereochemistry.
  - Rotating a Fischer diagram 90° inverts the stereochemistry of the chiral center. Rotating 180° retains the stereochemistry.

ANSWERS TO CONCEPT CHECKS

2.1

1. Structural isomers share a molecular formula, and not necessarily anything else.
2. Cyclopropanol, acetone, and prop-2-ene-1-ol are all structural isomers of each other with the chemical formula C_3H_6O. 2-propanol has the chemical formula C_3H_8O.
3. Physical properties are aspects of a compound that do not play a role in changing chemical composition. Examples include melting point, boiling point, solubility, odor, color, and density.
4. Chemical properties are aspects of a compound that change chemical composition; in organic chemistry, chemical properties are usually dictated by the reactivity of various functional groups.

2.2

1. Conformational isomers are stereoisomers with the same molecular connectivity at different points of rotation around a single bond. Configurational isomers are stereoisomers with differing molecular connectivity.
2.

	Definition	Same Physical Properties?	Same Chemical Properties?
Enantiomers	Nonsuperimposable mirror images (differ at all chiral carbons, with no plane of symmetry)	Yes, except: rotation of plane-polarized light	Yes, except: reactions in chiral environments
Diastereomers	Non-mirror-image optical isomers (differ by at least one, but not all chiral carbons)	No	No (although may be similar)

3. A *meso* compound contains chiral centers but also has an internal plane of symmetry. This means that the molecule is overall achiral and will not rotate plane-polarized light.

2.3

1. (*E*) and (*Z*) configurations refer to arrangement of groups around a double bond. (*Z*) describes when the two highest-priority groups are on the same side; (*E*) describes when the two highest-priority groups are on opposite sides.
2. Priority is assigned by atomic number: the atom connected to the stereocenter or double-bonded carbon with the highest atomic number gets highest priority. If there is a tie, one works outward from the stereocenter or double-bonded carbon until the tie is broken.
3. Switching a pair of substituents inverts stereochemistry; switching two pairs retains it. Rotating the molecule 90° inverts stereochemistry; rotating 180° retains it.

EQUATIONS TO REMEMBER

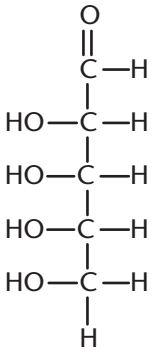
Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following does NOT show optical activity?

A. (*R*)-2-butanol
B. (*S*)-2-butanol
C. A solution containing 1 *M* (*R*)-2-butanol and 2 *M* (*S*)-2-butanol
D. A solution containing 2 *M* (*R*)-2-butanol and 2 *M* (*S*)-2-butanol

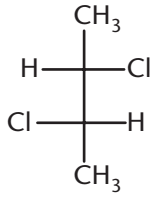
2. How many stereoisomers exist for the following aldehyde?



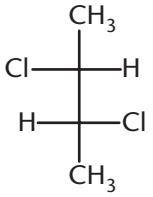
A. 2
B. 8
C. 9
D. 16

3. Which of the following compounds is optically inactive?

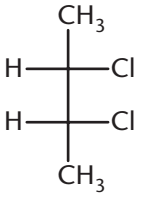
A.



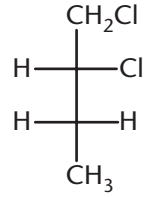
B.



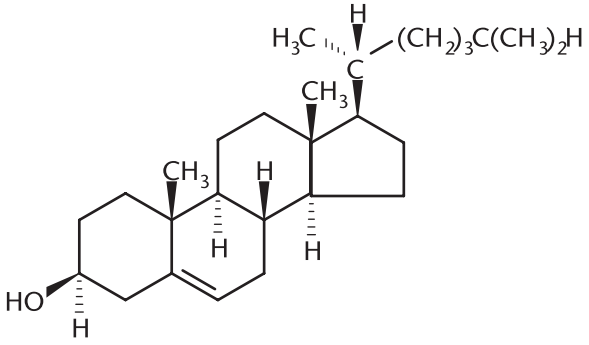
C.



D.



4. Cholesterol, shown below, contains how many chiral centers?



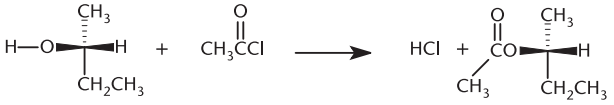
cholesterol

A. 5
B. 7
C. 8
D. 9

5. Which isomer of the following compound is the most stable?

A. 
B. 
C. 
D. They are all equally stable.

6. The following reaction results in:



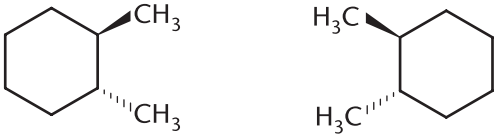
A. retention of relative configuration and a change in the absolute configuration.

B. a change in the relative and absolute configurations.

C. retention of the relative and absolute configurations.

D. retention of the absolute configuration and a change in the relative configuration.

7. The following molecules are considered to be:



A. enantiomers.

B. diastereomers.

C. *meso* compounds.

D. structural isomers.

8. (+)-glyceraldehyde and (–)-glyceraldehyde refer to the (*R*) and (*S*) forms of 2,3-dihydroxypropanal, respectively. These molecules are considered:

A. enantiomers.

B. diastereomers.

C. *meso* compounds.

D. structural isomers.

9. Consider (*E*)-2-butene and (*Z*)-2-butene. This is a pair of what type(s) of isomers?

I. *Cis–trans* isomers

II. Diastereomers

III. Enantiomers

A. I only

B. II only

C. I and II only

D. I and III only

10. 3-methylpentane and hexane are related in that they are:

A. enantiomers.

B. diastereomers.

C. constitutional isomers.

D. conformational isomers.

11. (*R*)-2-chloro-(*S*)-3-bromobutane and (*S*)-2-chloro-(*S*)-3-bromobutane are:

A. enantiomers.

B. diastereomers.

C. *meso* compounds.

D. the same molecule.

12. A scientist takes a 0.5 g/ml solution of an unknown pure dextrorotatory organic molecule and places it in a test tube with a diameter of 1 cm. He observes that a plane of polarized light is rotated 12° under these conditions. What is the specific rotation of this molecule?

A. –240°

B. –24°

C. +24°

D. +240°

13. Omeprazole is a proton pump inhibitor commonly used in gastroesophageal reflux disease. When omeprazole, a racemic mixture, went off-patent, pharmaceutical companies began to manufacture esomeprazole, the (*S*)-enantiomer of omeprazole, by itself. Given 1 *M* solutions of omeprazole and esomeprazole, which solution(s) would likely exhibit optical activity?

A. Omeprazole only
B. Esomeprazole only
C. Both omeprazole and esomeprazole
D. Neither omeprazole nor esomeprazole

14. (2*R*,3*S*)-2,3-dihydroxybutanedioic acid and (2*S*,3*R*)-2,3-dihydroxybutanedioic acid are:

I. *meso* compounds.
II. the same molecule.
III. enantiomers.

A. I only
B. III only
C. I and II only
D. I and III only

15. If the methyl groups of butane are 120° apart, as seen in a Newman projection, this molecule is in its:

A. highest-energy *gauche* form.
B. lowest-energy staggered form.
C. middle-energy eclipsed form.
D. highest-energy eclipsed form.

Explanations to Discrete Practice Questions

1. D

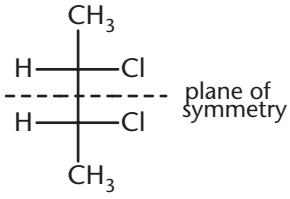
This is a racemic mixture of 2-butanol because it consists of equimolar amounts of (*R*)-2-butanol and (*S*)-2-butanol. The (*R*)-2-butanol molecule rotates the plane of polarized light in one direction, and the (*S*)-2-butanol rotates it by the same angle but in the opposite direction; as a result, no net rotation of polarized light is observed.

2. B

The maximum number of stereoisomers of a compound equals 2^n, where n is the number of chiral carbons in the compound. In this molecule, C-1 (the aldehydic carbon) is not chiral, nor is C-5 (because it is attached to two hydrogen atoms). Therefore, with three chiral centers, there are $2^3 = 8$ stereoisomers.

3. C

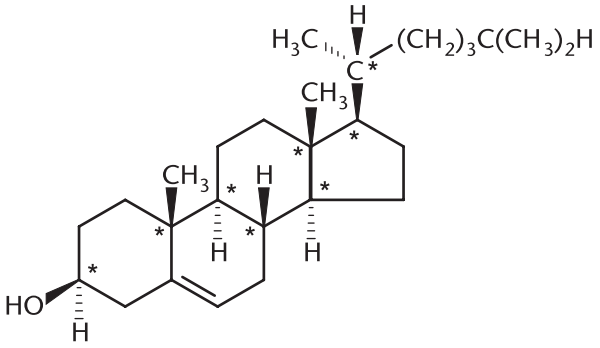
This answer choice is an example of a *meso* compound—a compound that contains chiral centers but has an internal plane of symmetry:



Owing to this internal plane of symmetry, the molecule is achiral and, hence, optically inactive. **Choices (A)** and **(B)** are enantiomers of each other and will certainly show optical activity on their own. **Choice (D)**, because it contains a chiral carbon and no internal plane of symmetry, is optically active as well.

4. C

To be considered a chiral center, a carbon must have four different substituents. There are eight stereocenters in this molecule, which are marked below with asterisks.



cholesterol

The other carbons are not chiral for various reasons. Many are bonded to two hydrogens; others participate in double bonds, which count as two bonds to the same atom.

5. B

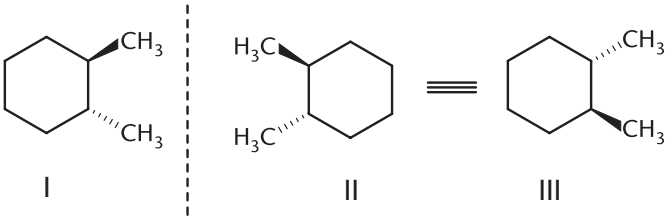
This molecule is a chair conformation in which the two equatorial methyl groups are *trans* to each other. Because the axial methyl hydrogens do not compete for the same space as the hydrogens attached to the ring, this conformation ensures the least amount of steric strain. **Choice (A)** would be less stable because the diaxial methyl group hydrogens are closer to the hydrogens on the ring, causing greater steric strain. **Choice (C)** is incorrect because it is in the more unstable boat conformation.

6. C

The relative configuration is retained because the bonds of the stereocenter are not broken; thus the positions of groups around the chiral carbon are maintained. The absolute configuration is also retained because both the reactant and product are (*R*).

7. A

These compounds are nonsuperimposable mirror images. To make analysis a bit easier, we can rotate structure II 180° to look like structure III. Structures I and III more clearly have opposite stereochemistry at every chiral center, meaning that they are enantiomers.



Choice (B) is incorrect because diastereomers are stereoisomers that are not mirror images of each other. **Choice (C)** is incorrect because *meso* compounds must contain a plane of symmetry, which neither of these molecules has. **Choice (D)** is incorrect because structural isomers are compounds with the same molecular formula but different atomic connections. The connectivity in these two molecules is the same, which means that they are stereoisomers, not structural isomers.

8. A

(+)-glyceraldehyde and (–)-glyceraldehyde, or (*R*)- and (*S*)-2,3-dihydroxypropanol, are enantiomers. Enantiomers are nonsuperimposable mirror images. Each has only one chiral center (C-2), which has opposite absolute configuration in these two molecules.

9. C

(*E*)-2-butene can also be called *trans*-2-butene; (*Z*)-2-butene can also be called *cis*-2-butene. As such, they are *cis–trans* isomers. Remember that *cis–trans* isomers are a subtype of diastereomers in which the position of substituents differs about an immovable bond. Diastereomers are molecules that are non-mirror-image stereoisomers (molecules with the same atomic connectivity). These are not enantiomers because they are not mirror images of each other.

10. C

Because they have the same molecular formula but different atomic connectivity, 3-methylpentane and hexane are constitutional isomers.

11. B

These two molecules are stereoisomers of one another, but are *not* nonsuperimposable mirror images. Therefore, they are diastereomers. Note that these molecules differ by at least one, but not all, chiral carbons.

12. D

Remember that the equation for specific rotation is $[\alpha] = \frac{\alpha_{obs}}{c \times l}$. In this example, α_{obs} is +12° (remember that dextrorotatory, or clockwise, rotation is considered positive), $c = 0.5$ g/ml, $l = 1$ cm $= 0.1$ dm. Remember that path length is always measured in decimeters when calculating specific rotation. Therefore, the specific rotation can be calculated as:

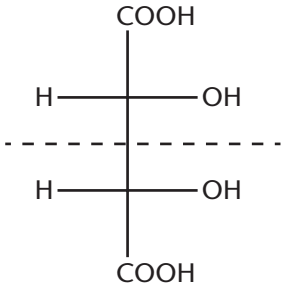
$$[\alpha] = \frac{\alpha_{obs}}{c \times l} = \frac{+12}{(0.5\ \text{g/ml}) \times (0.1\ \text{dm})} = +240°$$

13. B

Racemic mixtures like omeprazole contain equimolar amounts of two enantiomers and thus have no observed optical activity. Each of the two enantiomers causes rotation in opposite directions, so their effects cancel out. Esomeprazole only contains one of the two enantiomers and thus should cause rotation of plane-polarized light.

14. C

Draw out these structures. The two names describe the same molecule, which also happens to be a *meso* compound because it contains a plane of symmetry. These compounds are not enantiomers because they are superimposable mirror images of one another, *not* nonsuperimposable mirror images. These compounds are better termed *meso*-2,3-dihydroxybutanedioic acid:



15. C

In butane, the position at which the two methyl groups are 120° apart is an eclipsed conformation. This has a moderate amount of energy, although not as high as a totally eclipsed conformation in which the two methyl groups are 0° apart.

Concept Summary **73**

Introduction

Now that we have an understanding of nomenclature and how compounds are related, we are ready to start examining the real nature of chemical bonding. Bonding determines how atoms come together to form molecules. It also governs the ways those molecules interact with the other molecules in their environment.

Organic chemistry is the study of carbon and carbon-containing compounds. What makes carbon so special? The simple answer is that carbon has unique bonding properties. Carbon is tetravalent, which means that it can form bonds with up to four other atoms, allowing for the massive versatility required to form the foundation of biomolecules and life itself. This versatility is compounded by the fact that carbon, located near the center of the periodic table, can form bonds with many different elements because of its moderate electronegativity. In addition, because carbon atoms are fairly small, the bonds that they form are strong and stable.

Remember that there are two types of chemical bonds. The first is **ionic**, in which electrons are transferred from one atom to another and the resulting ions are held together by electrostatic interactions; the second is **covalent**, in which electrons are shared between atoms. Organic chemistry is deeply rooted in covalent bonding.

3.1 Atomic Orbitals and Quantum Numbers ★

Bonding occurs in the outermost electron shell of atoms, so an understanding of bonding is contingent on understanding the organization of electrons in an atom. Quantum numbers are discussed in detail in Chapter 1 of *MCAT General Chemistry Review*, and are briefly summarized here.

Bridge

Recall from Chapter 1 of *MCAT General Chemistry Review* that quantum numbers describe the location of an electron within an atom and that each electron has a unique combination of quantum numbers according to the Pauli exclusion principle.

The first three quantum numbers, n, l, and m_l, describe the size, shape, number, and orientation of atomic orbitals an element possesses. The **principal quantum number**, ***n***, corresponds to the energy level of a given electron in an atom and is essentially a measure of size. The smaller the number, the closer the shell is to the nucleus, and the lower its energy. The possible values of n range from 1 to ∞, although the MCAT only tests on n-values up to 7.

Within each electron shell, there can be several subshells. Subshells are described by the **azimuthal quantum number**, ***l***, which ranges from 0 to $n - 1$ for a given energy shell. The l-values 0, 1, 2, and 3 correspond to the s, p, d, and f subshells, respectively. Just as with the principal quantum number, energy increases as the azimuthal quantum number increases.

Within each subshell, there may be several orbitals. Orbitals are described by the **magnetic quantum number**, $\boldsymbol{m_l}$, which ranges from $-l$ to $+l$ for a given subshell. Each type of atomic orbital has a specific shape, which describes the probability of finding an electron in a given region of space. An ***s*-orbital** is spherical and symmetrical, centered around the nucleus. A ***p*-orbital** is composed of two lobes located symmetrically about the nucleus and contains a **node**—an area where the probability of finding an electron is zero—at the nucleus. Picture the p-orbital as a dumbbell that can be positioned in three different orientations, along the x-, y-, or z-axis. It should make sense that there are three p-orbitals; the p subshell has the l-value of 1, so there are three possible values for m_l: –1, 0, and 1. The shapes of the first five s- and p-orbitals are shown in Figure 3.1. A ***d*-orbital** is composed of four symmetrical lobes and contains two nodes. Four of the d-orbitals are clover-shaped, and the fifth looks like a donut wrapped around the center of a p-orbital. Thankfully, the multiple complex shapes of d- and f-orbitals are rarely encountered in organic chemistry. Each orbital can hold two electrons, which are distinguished by the **spin quantum number**, $\boldsymbol{m_s}$. The only values of m_s are $\pm\frac{1}{2}$.

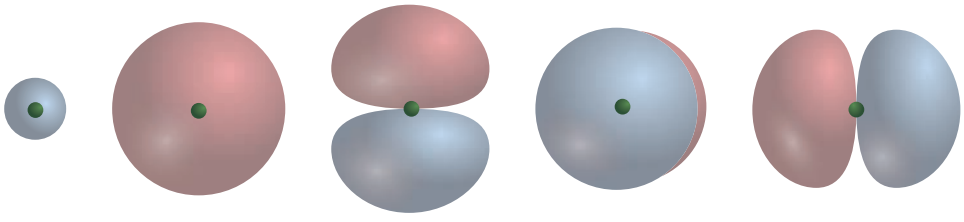

Figure 3.1. The First Five Atomic Orbitals

MCAT Concept Check 3.1:
Before you move on, assess your understanding of the material with this question.

1. Summarize the quantum numbers below. The first entry has been completed for clarification.

Symbol	Name	Describes...	Organizational Level	Possible Values
n	Principal QN	Size	Shell	1 to ∞
l				
m_l				
m_s				

3.2 Molecular Orbitals ★★★

When two atomic orbitals combine, they form **molecular orbitals**. Molecular orbitals are obtained mathematically by adding or subtracting the wave functions of the atomic orbitals. While the mathematics of combining wave functions is outside the scope of the MCAT, some questions may ask for the visualization of molecular orbitals, as shown in Figure 3.2. If the signs of the wave functions are the same, a lower-energy (more stable) **bonding orbital** is produced. If the signs are different, a higher-energy (less stable) **antibonding orbital** is produced.

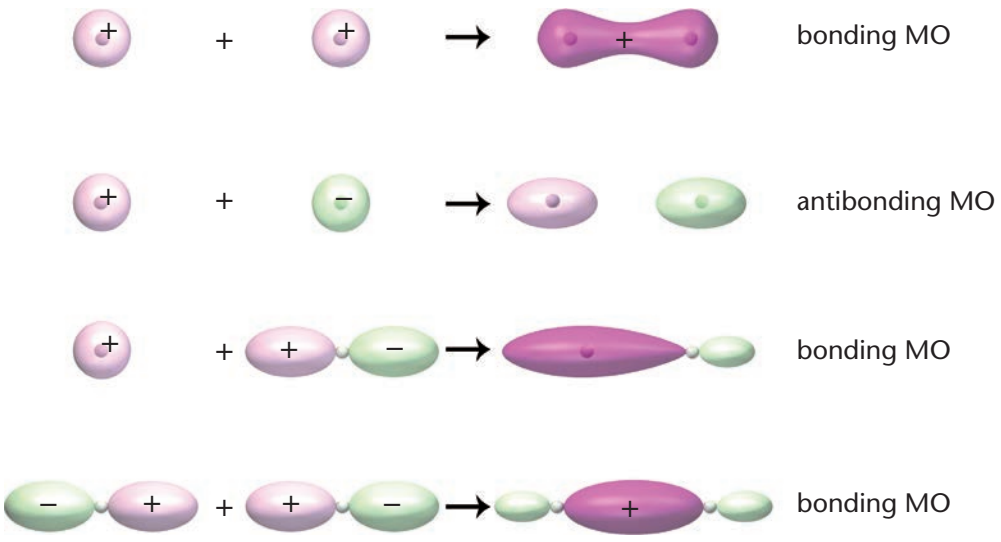

Figure 3.2. Molecular Orbitals
Molecular orbitals can be bonding or antibonding, depending on the signs of the atomic orbitals used to form them; head-to-head or tail-to-tail overlap of atomic orbitals results in a σ bond.

Key Concept

Sigma (σ) bonds are formed by head-to-head or tail-to-tail overlap of atomic orbitals. These bonds are by far the most common in organic compounds and on the MCAT.

σ AND π BONDS

When a molecular orbital is formed by head-to-head or tail-to-tail overlap, as in Figure 3.2, the resulting bond is called a **sigma** (σ) **bond**. All **single bonds** are σ bonds, accommodating two electrons.

When two *p*-orbitals line up in a parallel (side-by-side) fashion, their electron clouds overlap, and a bonding molecular orbital, called a **pi** (π) **bond**, is formed. This is demonstrated in Figure 3.3. One π bond on top of an existing σ bond is a **double bond**. A σ bond and two π bonds form a **triple bond**. Unlike single bonds, which allow free rotation of atoms around the bond axis, double and triple bonds hinder rotation and, in effect, lock the atoms into position.

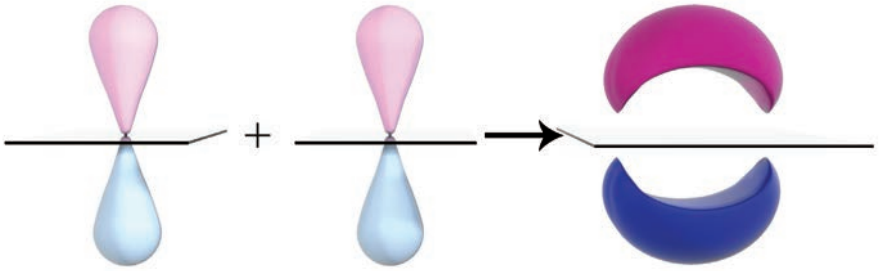

Figure 3.3. Pi (π) Bond
Electron density exists above and below the plane of the molecule, restricting rotation about a double bond.

It is important to remember that a π bond cannot exist independently of a σ bond. Only after the formation of a σ bond will the *p*-orbitals of adjacent carbons be parallel and in position to form the π bond. The more bonds that are formed between atoms, the shorter the overall bond length. Therefore, a double bond is shorter than a single bond, and a triple bond is shorter than a double bond. Shorter bonds hold atoms more closely together and are stronger than longer bonds; shorter bonds require more energy to break.

Key Concept

A double bond consists of both a σ bond and a π bond; a triple bond consists of a σ bond and two π bonds. π bonds are weaker than σ bonds, but the strength is additive, making double and triple bonds stronger overall than single bonds.

While double bonds are stronger than single bonds overall, individual π bonds are weaker than σ bonds. Therefore, it is possible to break only one of the bonds in a double bond, leaving a single bond intact. This happens often in organic chemistry, such as when *cis–trans* isomers are interconverted between conformations. Breaking a single bond requires far more energy.

As discussed previously, double and triple bonds do not freely rotate like single bonds. As such, double bonds in compounds make for stiffer molecules. Partial double-bond character in structures with resonance also restricts free rotation, resulting

in more rigid structures. Proteins exhibit this kind of limited rotation because there is resonance in the amide linkages between adjacent amino acids.

MCAT Concept Check 3.2:

Before you move on, assess your understanding of the material with these questions.

1. Which is more stable: a bonding orbital or an antibonding orbital? Which has higher energy?
   - More stable: _____
   - Higher energy: _____
2. What differences would be observed in a molecule containing a double bond compared to the same molecule containing only single bonds?

_____

_____

3. Rank the following orbitals in decreasing order of strength: σ bond, π bond, double bond, triple bond.

_____>_____>_____>_____.

3.3 Hybridization ★★

Carbon has the electron configuration $1s^2 2s^2 2p^2$ and therefore needs four electrons to complete its octet ($2s^2 2p^6$). A typical molecule formed by carbon is methane, CH_4. Experimentation shows that the four σ bonds in methane are equivalent. This may seem inconsistent with what we know about the asymmetrical distribution of carbon's valence electrons: two electrons in the 2*s*-orbital, one in the p_x-orbital, one in the p_y-orbital, and none in the p_z-orbital. This apparent discrepancy is accounted for by the theory of orbital **hybridization**.

sp^3

Hybrid orbitals are formed by mixing different types of orbitals. Just as with molecular orbitals, we can use advanced mathematics to merge three *p*-orbitals and one *s*-orbital. The result? As shown in Figure 3.4, this forms four identical sp^3 orbitals with new, hybridized shapes.

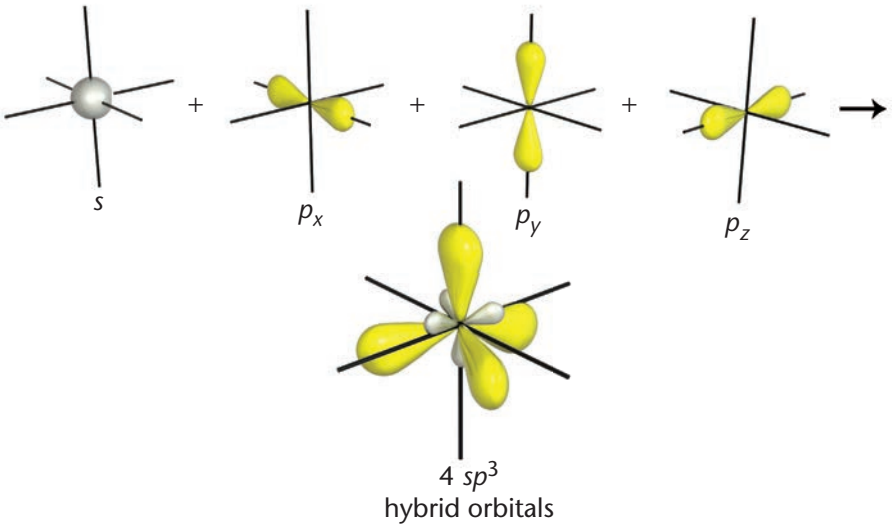

Figure 3.4. sp^3-Hybridized Orbitals
An atom with these orbitals has tetrahedral geometry, and there are no unhybridized *p*-orbitals to form π bonds.

Key Concept

Hybridization is a way of making all of the bonds to a central atom equivalent to each other. The sp^3 orbitals are the reason for the tetrahedral shape that is a hallmark of carbon-containing compounds.

All four of these orbitals point toward the vertices of a tetrahedron to minimize repulsion, which explains why carbon prefers tetrahedral geometry. The hybridization is accomplished by promoting one of the 2*s* electrons into the $2p_z$-orbital, as shown in Figure 3.5. This produces four valence orbitals, each with one electron, which can be mathematically mixed to model the hybrid orbitals.

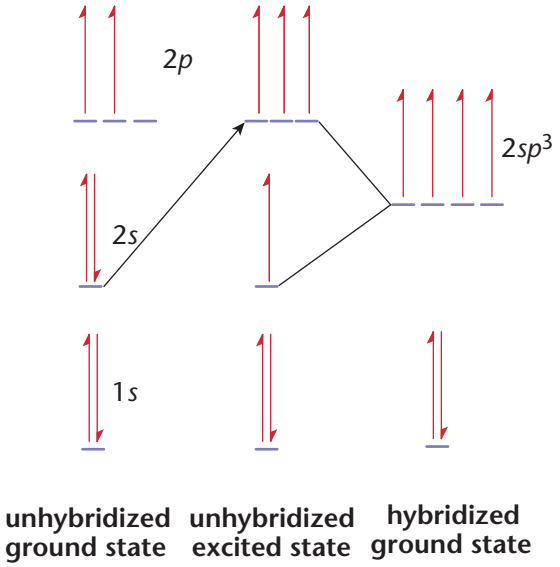

Figure 3.5. Hybridization of Carbon Orbitals

The MCAT sometimes tests how much "*s* character" a certain hybrid orbital has. To answer such questions, we simply need to determine what type of hybridization

exists and use the name to solve the problem. For example, in sp^3 orbitals, we have one *s*- and three *p*-orbitals, so the bond has 25% *s* character and 75% *p* character.

sp^2

Although carbon is most often bonded with sp^3 hybridization, there are two other possibilities. When one *s*-orbital is mixed with two *p*-orbitals, three sp^2-hybridized orbitals are formed, as shown in Figure 3.6. These orbitals have 33% *s* character and 67% *p* character.

This is the hybridization seen in alkenes. The third *p*-orbital of each carbon is left unhybridized. This is the orbital that participates in the π bond. The three sp^2 orbitals are oriented 120° apart, which allows for maximum separation. We know that the unhybridized *p*-orbital is involved in the π component of the double bond, but what about the hybrid orbitals? In ethene, two of the sp^2 hybridized orbitals will participate in C–H bonds, and the other hybrid orbital will line up with the π bond and form the σ component of the C=C double bond.

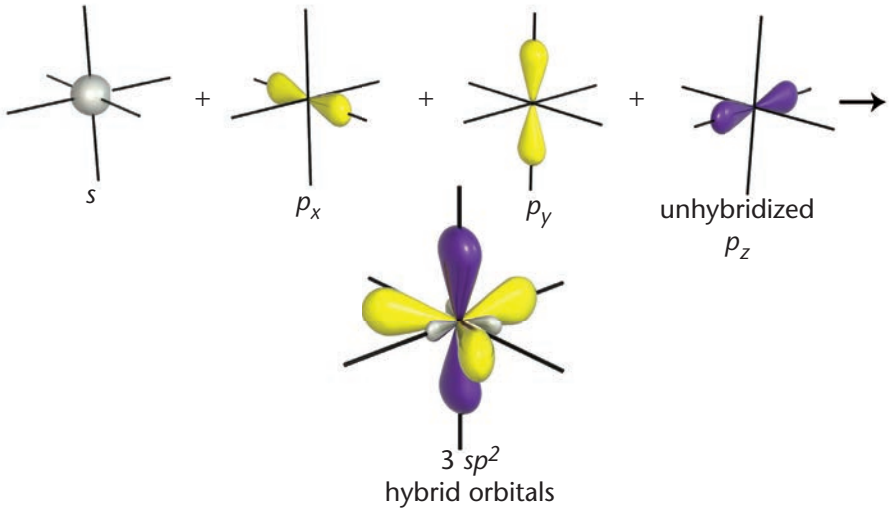

Figure 3.6. sp^2-Hybridized Orbitals
A molecule with these orbitals has trigonal planar geometry, and the one unhybridized *p*-orbital can be used to form a π bond.

sp

To form a triple bond, we need two of the *p*-orbitals to form π bonds, and the third *p*-orbital will combine with the *s*-orbital to form two *sp*-orbitals, as shown in Figure 3.7. These orbitals have 50% *s* character and 50% *p* character. These orbitals are oriented 180° apart, which explains the linear structure of molecules containing

sp-hybridized carbons. The two π bonds can be between the carbon and one other atom (forming a triple bond, like ethyne), or between the carbon and two different atoms (forming two double bonds in a row, like carbon dioxide). In both cases, the molecule is linear about the *sp*-hybridized carbon.

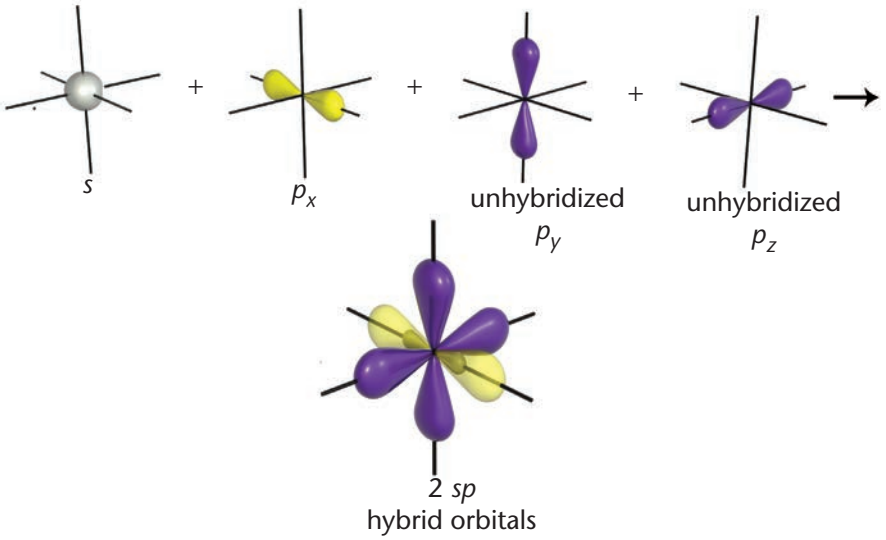

Figure 3.7. *sp*-Hybridized Orbitals
A molecule with these orbitals has linear geometry, and the two unhybridized *p*-oribtals can be used to form π bonds.

RESONANCE

Resonance delocalization of electrons occurs in molecules that have conjugated bonds. **Conjugation** requires alternating single and multiple bonds because this pattern aligns a number of unhybridized *p*-orbitals down the backbone of the molecule. π electrons can then delocalize through this *p*-orbital system, adding stability to the molecule. Resonance structures are drawn as the various transient forms the molecule takes, as shown in Figure 3.8.

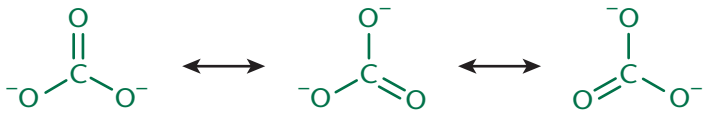

Figure 3.8. Resonance Forms of Carbonate
These forms have equal stability and therefore contribute equally to the true electron density of the molecule.

However, these forms aren't in any sort of equilibrium—the electron density is distributed throughout, making the true form a hybrid of the resonance structures, as shown with ozone in Figure 3.9.

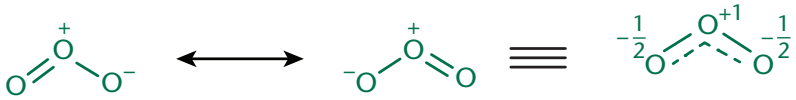

Figure 3.9. Structure of Ozone
The true electron density of ozone is somewhere between the two resonance forms, creating 1.5 bonds between each oxygen, and leaving each oxygen with a $-\frac{1}{2}$ charge.

If the stability of the various resonance forms differs, then the true electron density will favor the most stable form. Particular resonance structures can be favored because they lack formal charges or form full octets on highly electronegative atoms, like oxygen and nitrogen. Stabilization of positive and negative charges through induction and aromaticity can also favor certain resonance structures.

MCAT Concept Check 3.3:
Before you move on, assess your understanding of the material with these questions.

1. What is the *s* character of *sp*-, sp^2-, and sp^3-hybridized orbitals?
   - *sp*: _____
   - sp^2: _____
   - sp^3: _____
2. What are resonance structures? How does the true electron density of a compound relate to its resonance structures?

   _____

   _____

   _____

Conclusion

The ability of carbon to form single, double, and triple bonds (or to form σ and multiple π bonds) and to form hybrid orbitals gives rise to an entire branch of chemistry—as well as life on Earth. You may have thought this chapter was a bit brief; that's because the specifics of bonding fall mostly under the domain of general chemistry. However, without a solid grasp of orbitals and bonding, it would be difficult to explain the organic reactions that are tested on the MCAT, which will be the focus of the next seven chapters. Avoid compartmentalizing the information you learn throughout the course of your studies—bonding plays a role in general chemistry, organic chemistry, and biochemistry, and can therefore be tested in either the

Chemical and Physical Foundations of Biological Systems section or the *Biological and Biochemical Foundations of Living Systems* section. All of the subjects within science blend together into a seemingly complicated, yet beautifully simple, picture of the universe. The sooner you integrate the knowledge you're accumulating, the more manageable and rewarding your studying will become.

CONCEPT SUMMARY

Atomic Orbitals and Quantum Numbers

- **Quantum numbers** describe the size, shape, orientation, and number of **atomic orbitals** an element possesses.
- The **principal quantum number**, n, describes the energy level (shell) in which an electron resides and indicates the distance from the nucleus to the electron. Its possible values range from 1 to ∞.
- The **azimuthal quantum number**, l, determines the subshell in which an electron resides. Its possible values range from 0 to $n - 1$. The subshell is often indicated with a letter: $l = 0$ corresponds to *s*, 1 is *p*, 2 is *d*, and 3 is *f*.
- The **magnetic quantum number**, m_l, determines the orbital in which an electron resides. Its possible values range from $-l$ to $+l$. Different orbitals have different shapes: *s*-orbitals are spherical, while *p*-orbitals are dumbbell-shaped and located on the *x*-, *y*-, or *z*-axis.
- The **spin quantum number**, m_s, describes the spin of an electron. Its possible values are $\pm\frac{1}{2}$.

Molecular Orbitals

- **Bonding orbitals** are created by head-to-head or tail-to-tail overlap of atomic orbitals of the same sign and are energetically favorable.
- **Antibonding orbitals** are created by head-to-head or tail-to-tail overlap of atomic orbitals that have opposite signs and are energetically unfavorable.
- **Single bonds** are **sigma** (σ) **bonds**, which contain two electrons.
- **Double bonds** contain one σ bond and one **pi** (π) **bond**. π bonds are created by sharing of electrons between two unhybridized *p*-orbitals that align side-by-side.
- **Triple bonds** contain one σ bond and two π bonds.
- Multiple bonds are less flexible than single bonds because rotation is not permitted in the presence of a π bond. Multiple bonds are shorter and stronger than single bonds, although individual π bonds are weaker than σ bonds.

Hybridization

- sp^3-hybridized orbitals have 25% *s* character and 75% *p* character. They form tetrahedral geometry with 109.5° bond angles. Carbons with all single bonds are sp^3-hybridized.
- sp^2-hybridized orbitals have 33% *s* character and 67% *p* character. They form trigonal planar geometry with 120° bond angles. Carbons with one double bond are sp^2-hybridized.
- *sp*-hybridized orbitals have 50% *s* character and 50% *p* character. They form linear geometry with 180° bond angles. Carbons with a triple bond, or with two double bonds, are *sp*-hybridized.

- **Resonance** describes the delocalization of electrons in molecules that have conjugated bonds.
  - **Conjugation** occurs when single and multiple bonds alternate, creating a system of unhybridized *p*-orbitals down the backbone of the molecule through which π electrons can delocalize.
  - Resonance increases the stability of a molecule.
  - The various resonance forms all contribute to the true electron density of the molecule; the more stable the resonance form, the more it contributes. Resonance forms are favored if they lack formal charge, form full octets on electronegative atoms, or stabilize charges through induction and aromaticity.

ANSWERS TO CONCEPT CHECKS

3.1

1.

Symbol	Name	Describes . . .	Organizational Level	Possible Values
n	Principal QN	Size	Shell	1 to ∞
l	Azimuthal QN	Shape	Subshell	0 to $n - 1$
m_l	Magnetic QN	Orientation	Orbital	$-l$ to $+l$
m_s	Spin QN	Spin	—	$\pm\frac{1}{2}$

3.2

1. Bonding orbitals are more stable than antibonding orbitals. Therefore, antibonding orbitals have higher energy than bonding orbitals.
2. The differences would be in bond length (shorter in double bond than single), bond energy (higher in double bond than single), and molecular rigidity (higher in double bond than single).
3. Triple bond > double bond > σ bond > π bond. Remember that while an individual π bond is weaker than a σ bond, bond strength is additive. Therefore, double bonds are stronger than single, and triple bonds are stronger still.

3.3

1. *sp* orbitals have 50% *s* character and 50% *p* character, sp^2 have 33% *s* character and 67% *p* character, and sp^3 have 25% *s* character and 75% *p* character.
2. Resonance structures differ in their placement of electrons in hybridized *p*-orbitals and require bond conjugation to delocalize electrons in a molecule. The true electron density is a weighted average of the resonance structures of a given compound, favoring the most stable structures.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Within one principal energy level, which subshell has the least energy?

A. *s*
B. *p*
C. *d*
D. *f*

2. Which of the following compounds possesses at least one σ bond?

A. CH_4
B. C_2H_2
C. C_2H_4
D. All of the above contain at least one σ bond.

3. A carbon atom participates in one double bond. As such, this carbon contains orbitals with:

A. hybridization between the *s*-orbital and one *p*-orbital.
B. hybridization between the *s*-orbital and two *p*-orbitals.
C. hybridization between the *s*-orbital and three *p*-orbitals.
D. unhybridized *s* character.

4. The hybridizations of the carbon and nitrogen atoms in CN^- are:

A. sp^3 and sp^3, respectively.
B. sp^3 and sp, respectively.
C. sp and sp^3, respectively.
D. sp and sp, respectively.

5. Which of the following hybridizations does the Be atom in BeH_2 assume?

A. sp
B. sp^2
C. sp^3
D. sp^3d

6. Two atomic orbitals may combine to form:

I. a bonding molecular orbital.
II. an antibonding molecular orbital.
III. hybridized orbitals.

A. I only
B. III only
C. I and II only
D. I, II, and III

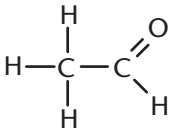
7. Molecular orbitals can contain a maximum of:

A. one electron.
B. two electrons.
C. four electrons.
D. $2n^2$ electrons, where n is the principal quantum number of the combining atomic orbitals.

8. π bonds are formed by which of the following orbitals?

A. Two *s*-orbitals
B. Two *p*-orbitals
C. One *s*- and one *p*-orbital
D. Two sp^2-hybridized orbitals

9. How many σ bonds and π bonds are present in the following compound?



A. Six σ bonds and one π bond
B. Six σ bonds and two π bonds
C. Five σ bonds and one π bond
D. Five σ bonds and two π bonds

10. The four C–H bonds of CH_4 point toward the vertices of a tetrahedron. This indicates that the hybridization of the carbon atom in methane is:

A. *sp*.
B. sp^2.
C. sp^3.
D. sp^3d.

11. Why is a single bond stronger than a π bond?

I. π bonds have greater orbital overlap.
II. *s*-orbitals have more overlap than *p*-orbitals.
III. sp^3 hybridization is always unstable.

A. I only
B. II only
C. I and III only
D. II and III only

12. The *p* character of the bonds formed by the carbon atom in HCN is:

A. 25%.
B. 50%.
C. 67%.
D. 75%.

13. A resonance structure describes:

I. the hybrid of all possible structures that contribute to electron distribution.
II. a potential arrangement of electrons in a molecule.
III. the single form that the molecule most often takes.

A. I only
B. II only
C. I and II only
D. I, II, and III

14. An electron is known to be in the $n = 4$ shell and the $l = 2$ subshell. How many possible combinations of quantum numbers could this electron have?

A. 1
B. 2
C. 5
D. 10

15. Compared to single bonds, triple bonds are:

A. weaker.
B. longer.
C. made up of fewer σ bonds.
D. more rigid.

Explanations to Discrete Practice Questions

1. A

The energies of the subshells within a principle quantum number are as follows: $s < p < d < f$

2. D

All single bonds are σ bonds; double and triple bonds each contain one σ bond and one or two π bonds, respectively. The compounds CH_4, C_2H_2, and C_2H_4 all contain at least one single bond and therefore contain at least one σ bond.

3. B

In a carbon with one double bond, sp^2 hybridization occurs—that is, one *s*-orbital hybridizes with two *p*-orbitals to form three sp^2-hybridized orbitals. The third *p*-orbital of the carbon atom remains unhybridized and takes part in the formation of the π bond of the double bond. Although there is an unhybridized *p*-orbital, there are no unhybridized *s*-orbitals, eliminating **choice (D)**.

4. D

The carbon and nitrogen atoms are connected by a triple bond in CN^- ($:C{\equiv}N:^-$). A triple-bonded atom is *sp* hybridized; one *s*-orbital hybridizes with one *p*-orbital to form two *sp*-hybridized orbitals. The two remaining unhybridized *p*-orbitals take part in the formation of two π bonds.

5. A

Beryllium has only two electrons in its valence shell. When it forms bonds to two hydrogens, it requires two hybridized orbitals, meaning that its hybridization must be *sp*. Note that the presence of only single bonds does not mean that the hybridization must be sp^3; this is a useful assumption for carbon, but does not apply to beryllium because of its smaller number of valence electrons. The two unhybridized *p*-orbitals around beryllium are empty in BeH_2, which takes on the linear geometry characteristic of *sp*-hybridized orbitals.

6. D

When atomic orbitals combine, they form molecular orbitals. When two atomic orbitals with the same sign are added head-to-head or tail-to-tail, they form bonding molecular orbitals. When two atomic orbitals with opposite signs are added head-to-head or tail-to-tail, they form antibonding molecular orbitals. Atomic orbitals can also hybridize, forming sp^3, sp^2 or *sp* orbitals.

7. B

Like atomic orbitals, molecular orbitals each can contain a maximum of two electrons with opposite spins. The $2n^2$ rule in **choice (D)** refers to the total number of electrons that can exist in a given energy shell, not in a molecular orbital.

8. B

π bonds are formed by the parallel overlap of unhybridized *p*-orbitals. The electron density is concentrated above and below the bonding axis. A σ bond, on the other hand, can be formed by the head-to-head overlap of two *s*-orbitals or hybridized orbitals. In a σ bond, the density of the electrons is concentrated between the two nuclei of the bonding atoms.

9. A

Each single bond has one σ bond, and each double bond has one σ and one π bond. In this question, there are five single bonds (five σ bonds) and one double bond (one σ bond and one π bond), which gives a total of six σ bonds and one π bond. Thus, the correct answer is **choice (A)**.

10. C

The four bonds point to the vertices of a tetrahedron, which means that the angle between two bonds is 109.5°, a characteristic of sp^3 orbitals. Hence, the carbon atom of CH_4 is sp^3-hybridized.

11. B

Bond strength is determined by the degree of orbital overlap; the greater the overlap, the greater the bond strength. A π bond is weaker than a single bond because there is significantly less overlap between the unhybridized *p*-orbitals of a π bond (due to their parallel orientation) than between the *s*-orbitals or hybrid orbitals of a σ bond. sp^3-hybridized orbitals can be quite stable, as evidenced by the number of carbon atoms with this hybridization forming stable compounds.

12. B

The carbon bond in hydrogen cyanide (H–C≡N:) is triple-bonded, and because triple bonds require two unhybridized *p*-orbitals, the carbon must be *sp*-hybridized; *sp*-hybridized orbitals have 50% *s* character and 50% *p* character.

13. B

A resonance structure describes an arrangement of electrons in a molecule. Different resonance structures can be derived by moving electrons in unhybridized *p*-orbitals throughout a molecule containing conjugated bonds. In molecules that contain multiple resonance structures, some are usually more stable than others; however, each resonance structure is not necessarily the most common form a molecule takes, eliminating statement III. Statement I has reversed the terminology for resonance structures: the electron density in a molecule is the weighted average of all possible resonance structures, not the other way around.

14. D

An electron in the $n = 4$ shell and the $l = 2$ subshell can have five different values for m_l: –2, –1, 0, 1, or 2. In each of these orbitals, electrons can have positive or negative spin. Thus, there are $5 \times 2 = 10$ possible combinations of quantum numbers for this electron.

15. D

π bonds do not permit free rotation, unlike σ bonds; this makes triple bonds more rigid than single bonds. Triple bonds are stronger and shorter bonds than single bonds, eliminating **choices (A)** and **(B)**. Both single and triple bonds contain one σ bond, eliminating **choice (C)**.

MCAT Expertise

This chapter is vital for understanding all the reactions you'll see in the next six chapters of this book (Chapters 5-10). On top of that, this material is directly tested on the MCAT as often as any other topic in organic chemistry. Make sure you know all of it!

Introduction

Sitting down to MCAT organic chemistry problems can be overwhelming at first, particularly if the reactants or reagents are new to you. The reactions on the page may seem like stage magic—fun to watch, but controlled by forces outside of our knowledge. The good news, however, is that organic chemistry isn't magic—and it is governed by sets of rules that make understanding what will happen much simpler. In this chapter, we will go over several of the aspects that determine how a complex reaction proceeds, and take a brief look at functional group reactivity. Then, armed with this knowledge, we lay out the simple, sequential steps that we can use to determine which reactions will take place. Chapters 5 through 10 of *MCAT Organic Chemistry Review* focus on applications of these principles with different functional groups, so look for patterns between these reactions as you continue preparing for Test Day. With these tools in hand, we can show the MCAT that we know how the trick is done—it isn't magic.

4.1 Acids and Bases ★★★★

In an acid–base reaction, an acid and a base react, resulting in the formation of the conjugate base of the acid and the conjugate acid of the base. This reaction proceeds so long as the reactants are more reactive, or stronger, than the products that they form. We will discuss acid and base definitions and strength in the following section. For the MCAT, we will concern ourselves with the broader Lewis and Brønsted–Lowry definitions of acids and bases. The Lewis definition concerns itself with the transfer of electrons in the formation of coordinate covalent bonds; the Brønsted–Lowry definition focuses on proton transfer.

Key Concept

An acid–base reaction will only proceed if the products that will be formed (the conjugate base of the acid and the conjugate acid of the base) are weaker than the original reactants.

Bridge

Acids and bases are critically important material in organic chemistry, biochemistry, and general chemistry. The most extensive coverage of acids and bases is in Chapter 10 of *MCAT General Chemistry Review*.

DEFINITIONS

A **Lewis acid** is defined as an **electron acceptor** in the formation of a covalent bond. Lewis acids also tend to be electrophiles, which we will touch on in the next section. Lewis acids have vacant *p*-orbitals into which they can accept an electron pair, or are positively polarized atoms.

A **Lewis base** is defined as an **electron donor** in the formation of a covalent bond. Lewis bases also tend to be nucleophiles, which we will touch on in the next section. Lewis bases have a lone pair of electrons that can be donated, and are often anions, carrying a negative charge.

When Lewis acids and bases interact, they form **coordinate covalent bonds**—covalent bonds in which both electrons in the bond came from the same starting atom (the Lewis base), as shown in Figure 4.1.

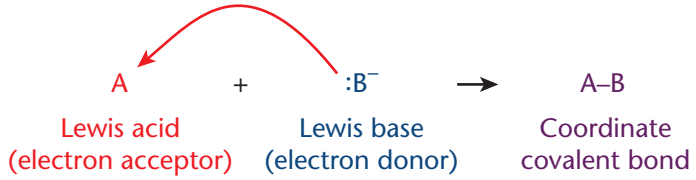

Figure 4.1. Lewis Acid–Base Reactions

In the **Brønsted–Lowry** definition, an acid is a species that can donate a proton (H^+); a base is a species that can accept a proton. Some molecules, like water, have the ability to act as either Brønsted–Lowry acids or bases, making them **amphoteric**. Water can act as an acid by donating its proton to a base, and thus becoming its conjugate base, OH^-. However, water can also act as a base by accepting a proton from an acid to become its conjugate acid, H_3O^+. The degree to which a molecule acts as an acid or a base is dependent upon the properties of the solution—water can only act as a base in an acidic solution, and only as an acid in a basic solution. Other examples of amphoteric molecules include $Al(OH)_3$, HCO_3^-, and HSO_4^-.

ACID AND BASE STRENGTH

The **acid dissociation constant**, or K_a, measures the strength of an acid in solution. In the dissociation of an acid HA ($HA \rightleftharpoons H^+ + A^-$), the equilibrium constant is given by:

$$K_a = \frac{[H^+][A^-]}{[HA]}$$

Equation 4.1

and the pK_a can be calculated as:

$$pK_a = -\log K_a$$

Equation 4.2

Thus, more acidic molecules will have a smaller (or even negative) pK_a; more basic molecules will have a larger pK_a. Acids with a pK_a below –2 are considered strong acids, which almost always dissociate completely in aqueous solution. Weak organic acids often have p*K*a values between –2 and 20. pK_a values for common functional groups are shown in Table 4.1.

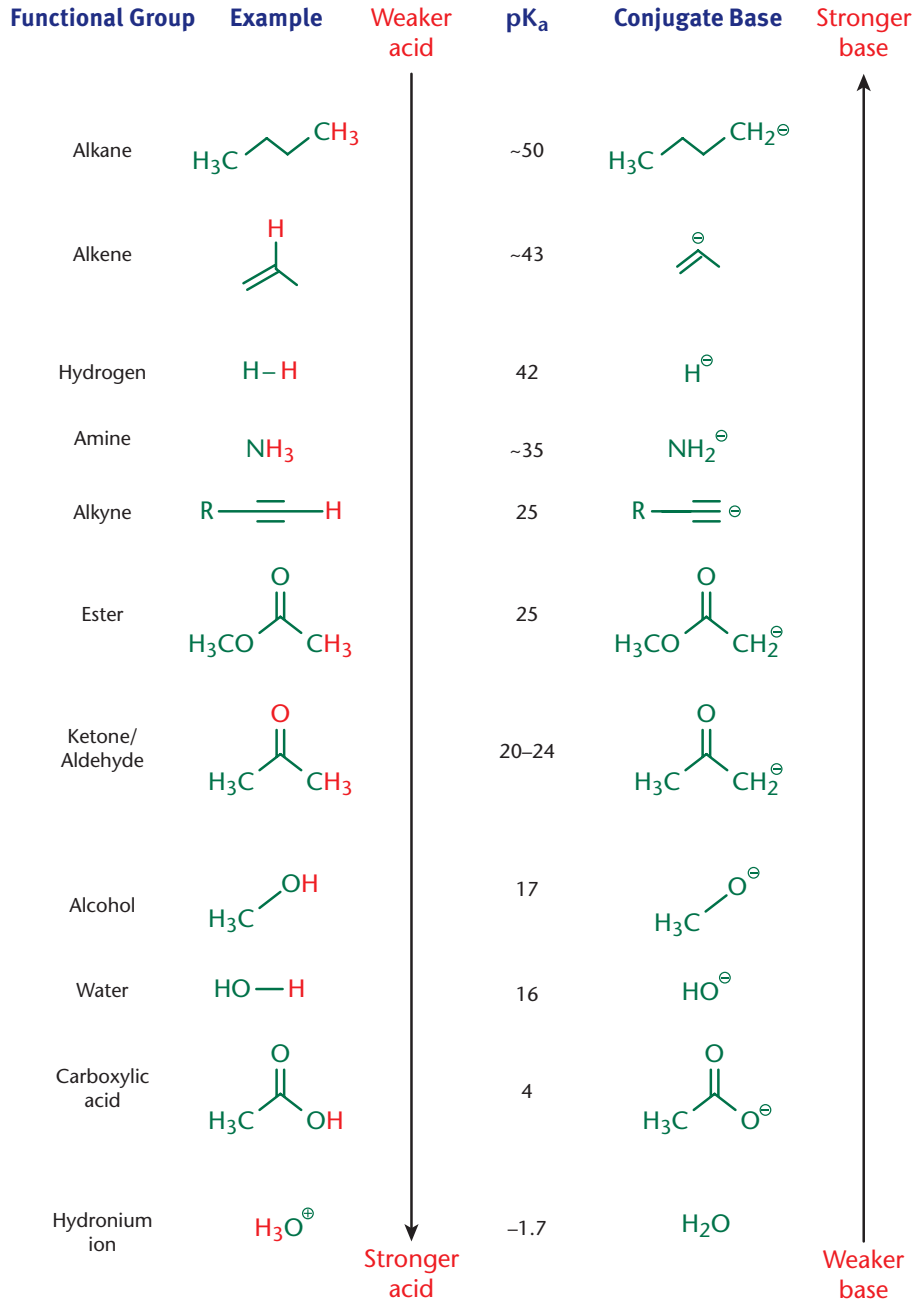

Table 4.1. pK_a Values for Common Functional Groups

Generally, bond strength decreases down the periodic table, and acidity therefore increases. Also, the more electronegative an atom, the higher the acidity. When these two trends oppose each other, low bond strength takes precedence.

For the common functional groups on the MCAT, the α-hydrogens of carbonyl compounds deserve special note. **α-hydrogens** are connected to the **α-carbon**, which is a carbon adjacent to the carbonyl. Because the *enol* form of carbonyl-containing carbanions is stabilized by resonance, these are acidic hydrogens that are easily lost. We will go into greater depth about enolate chemistry in Chapters 7 through 9 of *MCAT Organic Chemistry Review*.

COMMON FUNCTIONAL GROUPS

We can also apply these acid and base rules directly to the functional groups that appear on the MCAT. Functional groups that act as acids include alcohols, aldehydes and ketones (at the α-carbon), carboxylic acids, and most carboxylic acid derivatives. These compounds are therefore easier to target with basic (or nucleophilic) reactants because they readily accept a lone pair.

Amines and amides are the main functional groups that act as bases—keep an eye out for these compounds in the formation of peptide bonds. The nitrogen atom of an amine can form coordinate covalent bonds by donating a lone pair to a Lewis acid.

MCAT Concept Check 4.1:

Before you move on, assess your understanding of the material with these questions.

1. When will an acid–base reaction proceed, based on the strength of the reactants and products?

_____

_____

2. What does it mean for a molecule to be amphoteric? What biologically relevant molecules are also characteristically amphoteric?

_____

_____

_____

3. How is pK_a defined, and what does a low pK_a indicate?

_____

_____

_____

4. What are some functional groups that classically acts as acids? As bases?
   - Acids:

     _____
   - Bases:

     _____

4.2 Nucleophiles, Electrophiles, and Leaving Groups ★★★

Almost all reactions in organic chemistry can be divided into one of two groups: oxidation–reduction reactions or nucleophile–electrophile reactions. Nucleophiles, electrophiles, and leaving groups are particularly important to the reactions of alcohols and carbonyl-containing compounds, which we will look at in depth in later chapters. Let's take a look at how each of these terms is defined.

NUCLEOPHILES

Nucleophiles are defined as "nucleus-loving" species with either lone pairs or π bonds that can form new bonds to electrophiles. You may have noted that nucleophilicity and basicity appear to have similar definitions—and this is true! Good nucleophiles tend to be good bases. There is, however, a distinction between the two. Nucleophile strength is based on relative rates of reaction with a common electrophile—and is therefore a kinetic property. Base strength is related to the equilibrium position of a reaction—and is therefore a thermodynamic property. Some common examples of nucleophiles are shown in Figure 4.2.

Key Concept

Nucleophiles tend to have lone pairs or π bonds that can be used to form covalent bonds to electrophiles. On Test Day, look for carbon, hydrogen, oxygen, or nitrogen (CHON) with a minus sign or lone pair to identify most nucleophiles.

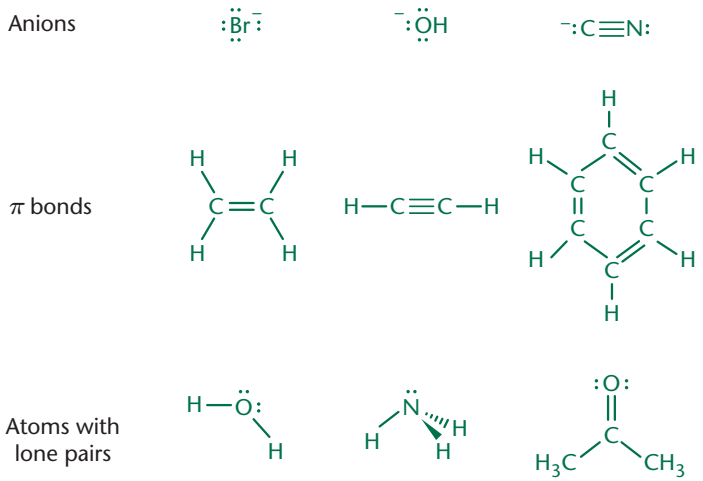

Figure 4.2. Examples of Nucleophiles

As long as the nucleophilic atom is the same, the more basic the nucleophile, the more reactive it is. This also holds when comparing atoms in the same row of the periodic table, but *not* when proceeding down a column in the periodic table. Nucleophilicity is determined by four major factors:

- **Charge**: Nucleophilicity increases with increasing electron density (more negative charge)
- **Electronegativity**: Nucleophilicity decreases as electronegativity increases because these atoms are less likely to share electron density
- **Steric hindrance**: Bulkier molecules are less nucleophilic
- **Solvent**: Protic solvents can hinder nucleophilicity by protonating the nucleophile or through hydrogen bonding

Solvent Effects

The solvent consideration is worth spending a bit more time on. In polar protic solvents, nucleophilicity increases *down* the periodic table. In polar aprotic solvents, nucleophilicity increases *up* the periodic table. Examples of both types of solvents are shown in Figure 4.3.

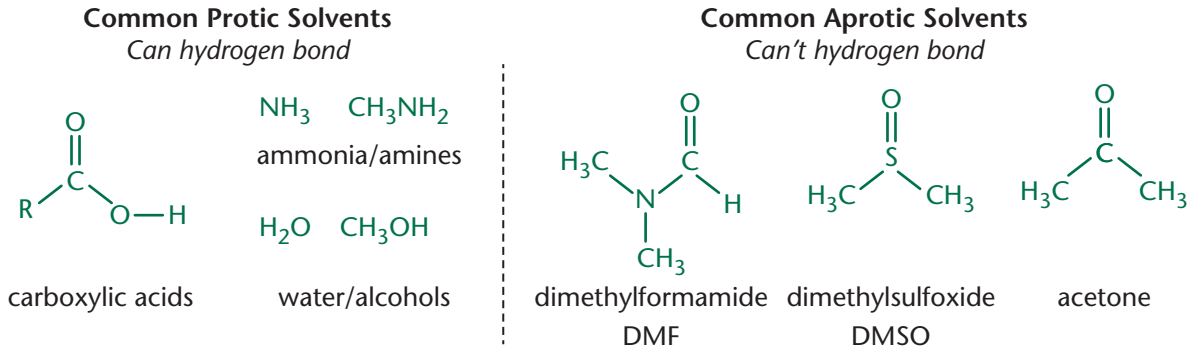

Figure 4.3. Examples of Polar Protic and Polar Aprotic Solvents

MCAT Expertise

If a solvent is not given on Test Day, assume that the reaction occurs in a polar solvent. Polar solvents—whether protic or aprotic—can dissolve nucleophiles and assist in any reaction in which electrons are moved. Organic chemistry is all about moving electrons, so it's less common for these reactions to be performed in nonpolar solvents.

The halogens are good examples of the effects of the solvent on nucleophilicity. In protic solvents, nucleophilicity decreases in the order:

$$I^- > Br^- > Cl^- > F^-$$

This is because the protons in solution will be attracted to the nucleophile. F^- is the conjugate base of HF, a weak acid. As such, it will form bonds with the protons in solution and be less able to access the electrophile to react. I^-, on the other hand, is the conjugate base of HI, a strong acid. As such, it is less affected by the protons in solution and can react with the electrophile.

In aprotic solvents, on the other hand, nucleophilicity decreases in the order:

$$F^- > Cl^- > Br^- > I^-$$

This is because there are no protons to get in the way of the attacking nucleophile. In aprotic solvents, nucleophilicity relates directly to basicity.

We won't use nonpolar solvents with this type of reaction because we need our nucleophile to dissolve. Because charged molecules are polar by nature, a polar solvent is required to dissolve the nucleophile as well because *like dissolves like*. Examples of strong nucleophiles include HO^-, RO^-, CN^-, and N_3^-. NH_3 and RCO_2^- are fair nucleophiles, and H_2O, ROH, and RCOOH are weak or very weak nucleophiles. As far as functional groups go, amine groups tend to make good nucleophiles.

Key Concept

We can't use nonpolar solvents in these nucleophile–electrophile reactions because our reactants are polar—they wouldn't dissolve!

ELECTROPHILES

Electrophiles are defined as "electron-loving" species with a positive charge or positively polarized atom that accepts an electron pair when forming new bonds with a nucleophile. Again, this definition brings to mind Lewis acids. The distinction, as with nucleophiles and bases above, is that electrophilicity is a kinetic property, whereas acidity is a thermodynamic property. Practically, however, electrophiles will almost always act as Lewis acids in reactions. A greater degree of positive charge increases electrophilicity, so a carbocation is more electrophilic than a carbonyl carbon. Some comparisons between electrophiles are drawn in Figure 4.4. Additionally, the nature of the leaving group influences electrophilicity in species without empty orbitals; better leaving groups make it more likely that a reaction will happen. If empty orbitals are present, an incoming nucleophile can make a bond with the electrophile without displacing the leaving group.

Electrophilicity and acidity are effectively identical properties when it comes to reactivity. Just as alcohols, aldehydes and ketones, carboxylic acids, and their derivatives act as acids, they also act as electrophiles, and can make good targets for nucleophilic attack.

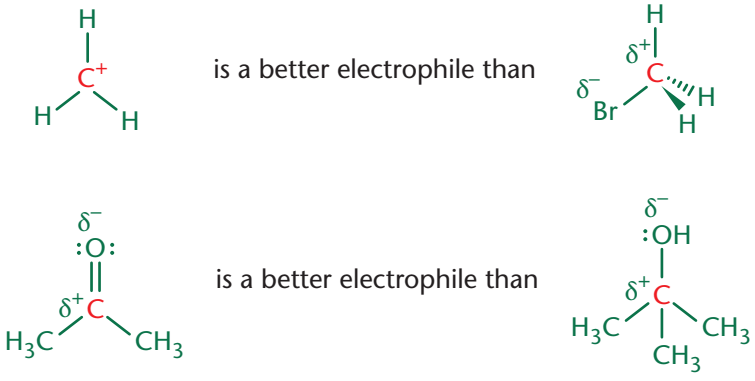

Figure 4.4. Comparisons of Electrophilicity

The carboxylic acid derivatives are often ranked by electrophilicity. Anhydrides are the most reactive, followed by carboxylic acids and esters, and then amides. In practical terms, this means that derivatives of higher reactivity can form derivatives of lower reactivity but not vice-versa, similar to the acid–base reactions described previously.

LEAVING GROUPS

Leaving groups are the molecular fragments that retain the electrons after heterolysis. **Heterolytic reactions** are essentially the opposite of coordinate covalent bond formation: a bond is broken and both electrons are given to one of the two products. The best leaving groups will be able to stabilize the extra electrons. Weak bases are more stable with an extra set of electrons and therefore make good leaving groups. By this logic, the conjugate bases of strong acids (like I^-, Br^-, and Cl^-) tend to make good leaving groups. Leaving group ability can be augmented by resonance and by inductive effects from electron-withdrawing groups: these help delocalize and stabilize negative charge.

Key Concept

Just like acid–base reactions, nucleophilic attack will only occur if the reactants are more reactive than the products. Thus, the nucleophile must be more reactive than the leaving group.

Alkanes and hydrogen ions will almost never serve as leaving groups because they form very reactive, strongly basic anions. We can think of leaving groups and nucleophiles as serving opposite functions. In substitution reactions, the weaker base (the leaving group) is replaced by the stronger base (the nucleophile).

NUCLEOPHILIC SUBSTITUTION REACTIONS

Nucleophilic substitution reactions are perfect examples for demonstrating nucleophile–electrophile reactions. In both S_N1 and S_N2 reactions, a nucleophile forms a bond with a substrate carbon and a leaving group leaves.

S_N1 Reactions

Unimolecular nucleophilic substitution (S_N1) reactions contain two steps. The first step is the rate-limiting step in which the leaving group leaves, generating a positively charged **carbocation**. The nucleophile then attacks the carbocation, resulting in the substitution product. This mechanism is shown in Figure 4.5 below.

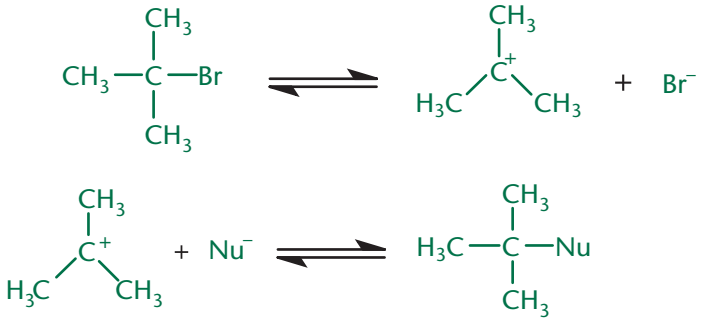

Figure 4.5. Mechanism of S_N1 Reaction
Step 1: Formation of the carbocation (rate-limiting);
Step 2: Nucleophilic attack.

The more substituted the carbocation, the more stable it is because the alkyl groups act as electron donors, stabilizing the positive charge. Because the formation of the carbocation is the rate-limiting step, the rate of the reaction depends only on the concentration of the substrate: rate = k[R–L], where R–L is an alkyl group containing a leaving group. This is a first-order reaction; anything that accelerates the formation of the carbocation will increase the rate of an S_N1 reaction.

Because S_N1 reactions pass through a planar intermediate before the nucleophile attacks, the product will usually be a racemic mixture. The incoming nucleophile can attack the carbocation from either side, resulting in varied stereochemistry.

S_N2 Reactions

Bimolecular nucleophilic substitution (S_N2) reactions contain only one step, in which the nucleophile attacks the compound at the same time as the leaving group leaves. Because this reaction has only one step, we call it a **concerted** reaction. The reaction is called bimolecular because this single rate-limiting step involves two molecules.

In S_N2 reactions, the nucleophile actively displaces the leaving group in a **backside attack**. For this to occur, the nucleophile must be strong, and the substrate cannot be sterically hindered. Therefore, the less substituted the carbon, the more reactive it is in S_N2 reactions. Note that this is the opposite of the trend for S_N1 reactions. The one-step mechanism is shown in Figure 4.6.

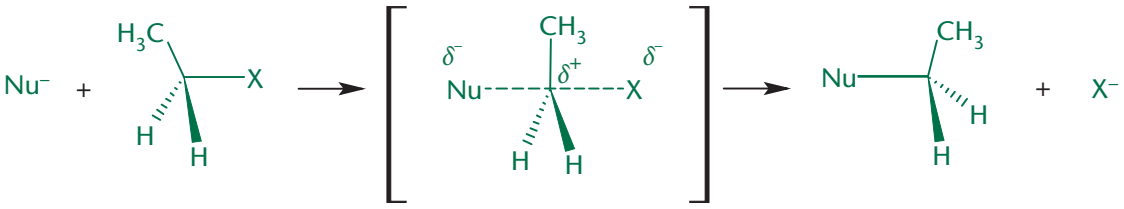

Figure 4.6. Mechanism of S_N2 Reaction

The single step of an S_N2 reaction involves two reacting species: the substrate (often an alkyl halide, tosylate, or mesylate) and the nucleophile. Therefore, the concentrations of both have a role in determining the rate: rate = k[Nu:][R–L]

S_N2 reactions are accompanied by an inversion of relative configuration. Much like an umbrella being turned inside out on a blustery day, the position of substituents around the substrate carbon will be inverted. If the nucleophile and leaving group have the same priority in their respective molecules, this inversion will also correspond to a change in absolute configuration from (*R*) to (*S*) or vice-versa.

MCAT Concept Check 4.2:
Before you move on, assess your understanding of the material with these questions.

1. How do the definitions of nucleophile and electrophile differ from those of Lewis base and acid?

_____

_____

_____

2. What are the four main trends that determine nucleophilicity?
   - _____
   - _____
   - _____
   - _____

3. How must the nucleophile and leaving group be related in order for a substitution reaction to proceed?

_____

_____

4. What trends increase electrophilicity?

_____

_____

5. What are some features of good leaving groups?

_____

_____

4.3 Oxidation–Reduction Reactions ★★★

Another important class of reactions are **oxidation–reduction (redox) reactions**, in which the oxidation states of the reactants change. **Oxidation state** is an indicator of the hypothetical charge that an atom would have if all bonds were completely ionic. Oxidation state can be calculated from the molecular formula for a molecule. For example, the carbon in methane (CH_4) has an oxidation state of –4 because the hydrogens each have an oxidation state of +1. This is the most reduced form of carbon. In carbon dioxide (CO_2), each of the oxygen atoms has an oxidation state of –2, and the carbon

has an oxidation state of +4. This is the most oxidized form of carbon. For an ion, the oxidation state is simply the charge—so Na^+ and S^{2-} would have oxidation states of +1 and –2, respectively. Carboxylic acids are more oxidized than aldehydes, ketones, and imines, which in turn are more oxidized than alcohols, alkyl halides, and amines.

We won't need to know too much about how to assign oxidation states in organic chemistry, but should know the definitions of oxidation and reduction. **Oxidation** refers to an increase in oxidation state, which means a loss of electrons. In organic chemistry, it is often easier to view oxidation as increasing the number of bonds to oxygen or other heteroatoms (atoms besides carbon and hydrogen). **Reduction** refers to a decrease in oxidation state, or a gain in electrons. In organic chemistry, it is often easier to view reduction as increasing the number of bonds to hydrogen.

OXIDIZING AGENTS AND REACTIONS

As we mentioned above, oxidation refers to an increase in oxidation state. Oxidation of a carbon atom occurs when a bond between a carbon atom and an atom that is less electronegative than carbon is replaced by a bond to an atom that is more electronegative than carbon. In practice, this usually means decreasing the number of bonds to hydrogen and increasing the number of bonds to other carbons, nitrogen, oxygen, or halides.

The **oxidizing agent** is the element or compound in an oxidation–reduction reaction that accepts an electron from another species. Because the oxidizing agent is gaining electrons, it is said to be reduced. Good oxidizing agents have a high affinity for electrons (such as O_2, O_3, and Cl_2) or unusually high oxidation states (like Mn^{7+} in permanganate, MnO_4^-; and Cr^{6+} in chromate, CrO_4^{2-}).

Primary alcohols can be oxidized by one level to become aldehydes, or can be further oxidized to form carboxylic acids. This reaction commonly proceeds all the way to the carboxylic acid when using strong oxidizing agents such as chromium trioxide (CrO_3) or sodium or potassium dichromate ($Na_2Cr_2O_7$ or $K_2Cr_2O_7$), but can be made to stop at the aldehyde level using specific reagents such as pyridinium chlorochromate (PCC). Secondary alcohols can be oxidized to ketones.

A number of oxidation reactions and the relevant oxidizing agents are shown in Figure 4.7. Note that the goal at this point should not be memorization of these reactions, but recognition of two themes: oxidation reactions tend to feature an increase in the number of bonds to oxygen, and oxidizing agents often contain metals bonded to a large number of oxygen atoms.

Key Concept

One can organize the different functional groups by "levels" of oxidation:

- Level 0 (no bonds to heteroatoms): alkanes
- Level 1: alcohols, alkyl halides, amines
- Level 2: aldehydes, ketones, imines
- Level 3: carboxylic acids, anhydrides, esters, amides
- Level 4 (four bonds to heteroatoms): carbon dioxide

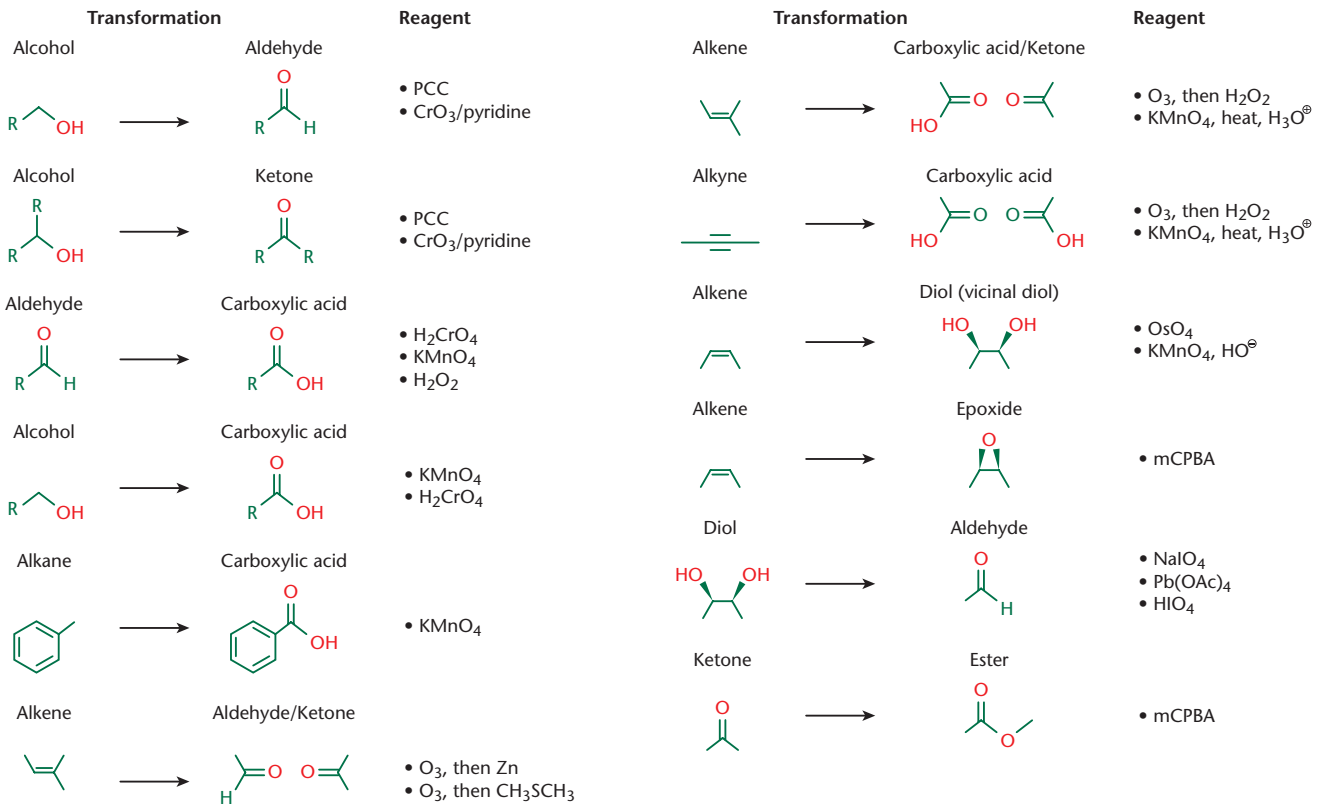

Figure 4.7. Oxidation Reactions and Common Oxidizing Agents

REDUCING AGENTS AND REACTIONS

Conversely, reduction refers to a decrease in oxidation state. Reduction of a carbon occurs when a bond between a carbon atom and an atom that is more electronegative than carbon is replaced by a bond to an atom that is less electronegative than carbon. In practice, this usually means increasing the number of bonds to hydrogen and decreasing the number of bonds to other carbons, nitrogen, oxygen, or halides.

Good reducing agents include sodium, magnesium, aluminum, and zinc, which have low electronegativities and ionization energies. Metal hydrides, such as NaH, CaH_2, $LiAlH_4$, and $NaBH_4$, are also good reducing agents because they contain the H^- ion.

Aldehydes and ketones will be reduced to primary and secondary alcohols, respectively. This reaction is exergonic, but exceedingly slow without a catalyst. Amides can be reduced to amines using $LiAlH_4$. This same reducing agent will reduce carboxylic acids to primary alcohols and esters to a pair of alcohols. Examples of reduction reactions are shown in Figure 4.8. Again, the focus is not on memorization,

but on recognizing that reduction reactions tend to feature an increase in the number of bonds to hydrogen, and reducing agents often contain metals bonded to a large number of hydrides.

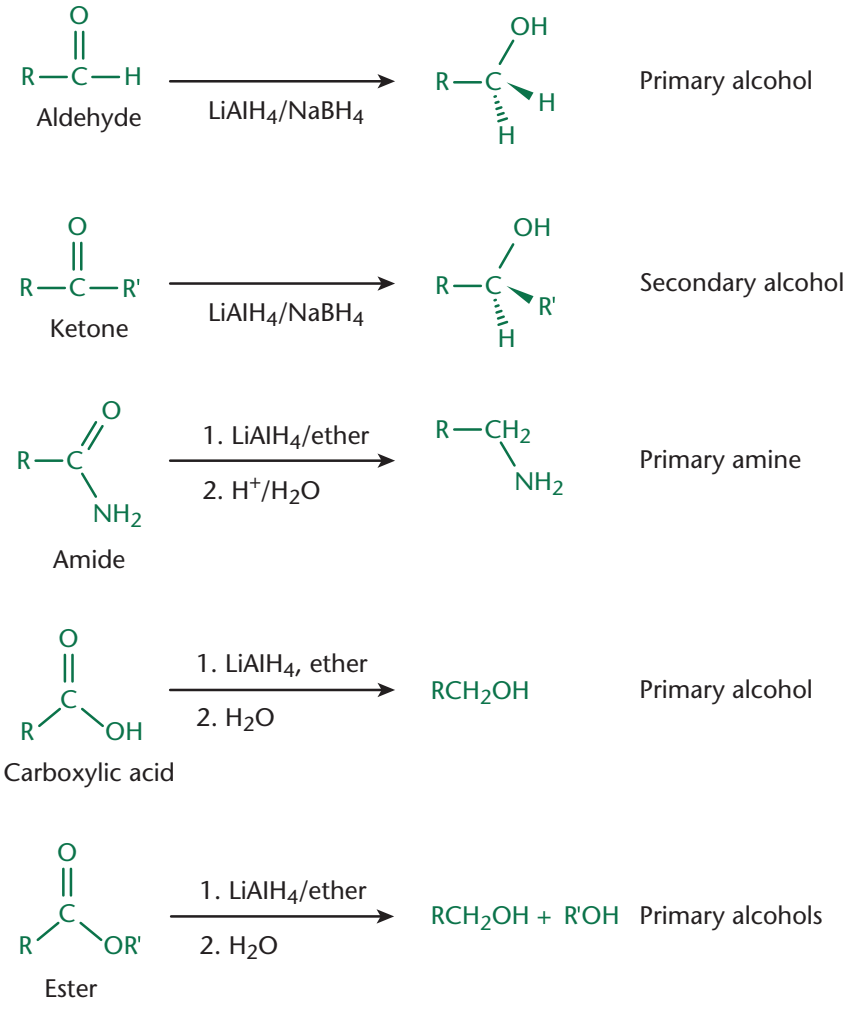

Figure 4.8. Reduction Reactions and Common Reducing Agents

Bridge

Note that many of the common oxidizing and reducing agents include transition metals. This is because transition metals can often take on many different oxidation states. Their low ionization energies and presence of *d*-orbitals allow them to give up and accept electrons easily. Transition metals and periodic trends are discussed in Chapter 2 of *MCAT General Chemistry Review*.

MCAT Concept Check 4.3:

Before you move on, assess your understanding of the material with these questions.

1. What are some characteristics of good oxidizing agents? List some examples of common oxidizing agents.
   - Characteristics:

     _____

   - Examples:

     _____

2. What are some characteristics of good reducing agents? List some examples of common reducing agents.
   - Characteristics:

     _____

   - Examples:

     _____

3. List the following carbon-containing compounds from most oxidized carbon to most reduced: methane, carbon dioxide, ketone, alcohol, carboxylic acid
   - Most oxidized: _____
   - _____
   - _____
   - _____
   - Most reduced: _____

4.4 Chemoselectivity

A key skill in recognizing which reactions will occur is recognizing the reactive regions within a molecule. The preferential reaction of one functional group in the presence of other functional groups is termed **chemoselectivity**.

REACTIVE LOCATIONS

Key Concept

The more oxidized the functional group, the more reactive it is in both nucleophile–electrophile and oxidation–reduction reactions.

Which site is the reactive site of a molecule depends on the type of chemistry that's occurring. A redox reagent, as described earlier, will tend to act on the highest-priority functional group. Thus, in a molecule with an alcohol and a carboxylic acid, a reducing agent is more likely to act on the carboxylic acid than on the alcohol. For a reaction involving nucleophiles and electrophiles, reactions also tend to occur at the highest-priority functional group because it contains the most oxidized carbon. A nucleophile is looking for a good electrophile; the more oxidized the carbon, the more electronegative groups around it, and the larger partial positive charge it will experience. Thus, carboxylic acids and their derivatives are the first to be targeted by a nucleophile, followed by an aldehyde or ketone, followed by an alcohol or amine. Aldehydes are generally more reactive toward nucleophiles than ketones because they have less steric hindrance.

One common reactive site on the MCAT is the carbon of a carbonyl, which can be found in carboxylic acids and their derivatives, aldehydes, and ketones. Within a carbonyl-containing compound, the carbon of the carbonyl acquires a positive polarity due to the electronegativity of the oxygen. Thus, the carbonyl carbon becomes electrophilic and can be a target for nucleophiles. Further, the α-hydrogens are much more acidic than in a regular C–H bond due to the resonance stabilization of the enol form. These can be deprotonated easily with a strong base, forming an enolate, as shown in Figure 4.9. The enolate then becomes a strong nucleophile, and alkylation can result if good electrophiles are available.

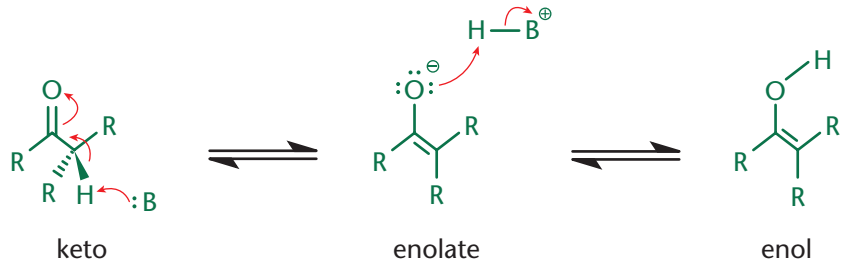

Figure 4.9. Enol and Enolate Forms of a Ketone

A second reactive site for consideration is the substrate carbon in substitution reactions. S_N1 reactions, which have to overcome the barrier of carbocation stability, prefer tertiary to secondary carbons as reactive sites, and secondary to primary. For S_N2 reactions, which have a bigger barrier in steric hindrance, methyl and primary carbons are preferred over secondary, and tertiary carbons won't react. This is all because of the mechanism of these two reactions.

STERIC PROTECTION

Steric hindrance describes the prevention of reactions at a particular location within a molecule due to the size of substituent groups. For example, S_N2 reactions won't occur with tertiary substrates. This characteristic of **steric protection** can be a useful tool in the synthesis of desired molecules and the prevention of the formation of alternative products. Effectively, bulky groups make it impossible for the nucleophile to reach the most reactive electrophile, making the nucleophile more likely to attack another region.

Another way that sterics come into play is in the protection of leaving groups. One can temporarily mask a reactive leaving group with a sterically bulky group during synthesis. For example, reduction of a molecule containing both carboxylic acids and aldehydes or ketones can result in reduction of all of the functional groups. To prevent this, the aldehyde or ketone is first converted to a nonreactive acetal or ketal, which serves as the **protecting group**, and the reaction can proceed. This reaction is shown in Figure 4.10. Another protective reaction is the reversible reduction of alcohols to *tert*-butyl ethers.

Bridge

When an aldehyde is mixed with a diol (or two equivalents of alcohol), it forms an acetal. When a ketone is mixed with a diol (or two equivalents of alcohol), it forms a ketal. Acetal and ketal chemistry is discussed in Chapter 6 of *MCAT Organic Chemistry Review*.

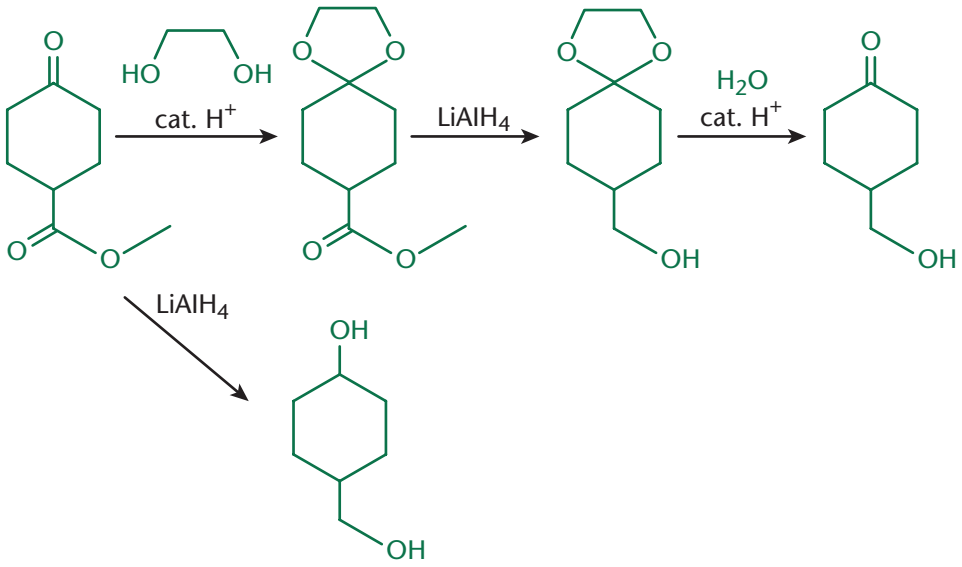

Figure 4.10. Protection of a Ketone by Conversion to an Acetal

Don't worry if this seems overwhelming—this is just a preview of what we will see in later chapters, along with a set of rules that will make it easier to understand how chemical reactions will proceed! Feel free to come back to this chapter later to remind yourself of the rules that apply across the board after reading further chapters.

MCAT Concept Check 4.4:

Before you move on, assess your understanding of the material with these questions.

1. What are the two reactive centers of carbonyl-containing compounds?
   - _____
   - _____

2. In which types of compounds are S_N1 reactions most likely to occur? Why?

_____

_____

_____

3. In which types of compounds are S_N2 reactions most likely to occur? Why?

_____

_____

_____

4.5 Steps to Problem-Solving ★★★★

With all of these rules in hand, we can now apply our knowledge in a systematic way to simplify organic chemistry reactions that appear on the MCAT. These steps are described below.

Step 1: Know Your Nomenclature

Before you can even start to understand what reactions will occur and what products will form, it is vital to know which compounds IUPAC and common names refer to! If you're still having trouble with nomenclature, be sure to review Chapter 1 of *MCAT Organic Chemistry Review*.

Step 2: Identify the Functional Groups

Look at the organic molecules in the reaction. What functional groups are in the molecules? Do these functional groups act as acids or bases? How oxidized is the carbon? Are there functional groups that act as good nucleophiles, electrophiles, or leaving groups? This step will help define a category of reactions that can occur with the given functional groups.

Step 3: Identify the Other Reagents

In this step, determine the properties of the other reagents in the reaction. Are they acidic or basic? Are they suggestive of a particular reaction? Are they good nucleophiles or a specific solvent? Are they good oxidizing or reducing agents?

Step 4: Identify the Most Reactive Functional Group(s)

Once you've identified the functional groups in the compound and the other reagents present, this step should be relatively quick. Remember that more oxidized carbons tend to be more reactive to both nucleophile–electrophile reactions and oxidation–reduction reactions. Note the presence of protecting groups that exist to prevent a particular functional group from reacting.

Step 5: Identify the First Step of the Reaction

If the reaction involves an acid or a base, the first step will usually be protonation or deprotonation. If the reaction involves a nucleophile, the first step is generally for the nucleophile to attack the electrophile, forming a bond with it. If the reaction involves an oxidizing or reducing agent, the most oxidized functional group will be oxidized or reduced, accordingly.

Once you know what will react, think through how the reaction will go. Did the protonation or deprotonation of a functional group increase its reactivity? When the nucleophile attacks, how does the carbon respond to avoid having five bonds? Does a leaving group leave, or does a double bond get reduced to a single bond (like the opening of a carbonyl)?

MCAT Expertise

While studying organic chemistry for the MCAT, don't permit yourself to simply nod along with the reaction mechanisms—get involved! During each step of a mechanism, ask yourself how the trends and problem-solving steps in this chapter play out.

Step 6: Consider Stereoselectivity

If there is more than one product, the major product will generally be determined by differences in strain or stability between the two molecules. More strained molecules (with significant angle, torsional, or nonbonded strain) are less likely to form than less strained molecules. Products with conjugation (alternating single and multiple bonds) are significantly more stable than those without.

EXAMPLE REACTIONS

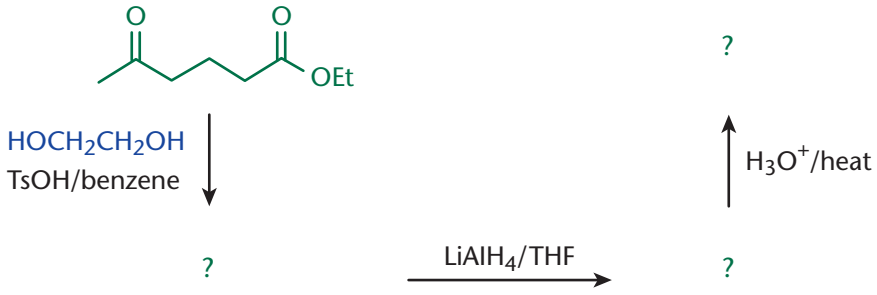
Now, we'll apply these rules to three novel reactions. Focus on the decision-making element of this process so that you will be able to apply the same logic to reactions that appear on Test Day.

Reaction 1

We'll start with a series of reactions involving ethyl 5-oxohexanoate. First, it is reacted with 1,2-ethanediol and *p*-toluenesulfonic acid in benzene; second, with lithium aluminum hydride in tetrahydrofuran, followed by a heated acidic workup. What are the intermediates and final product?

Let's go through the steps:

1. First, let's draw out the reactants and reaction conditions.



2. This molecule has an alkane backbone, a ketone, and an ester. Both of the carbonyl carbons are electrophilic targets for nucleophiles. The carbonyl oxygens can also be reduced. Acidic α-hydrogens are also present.

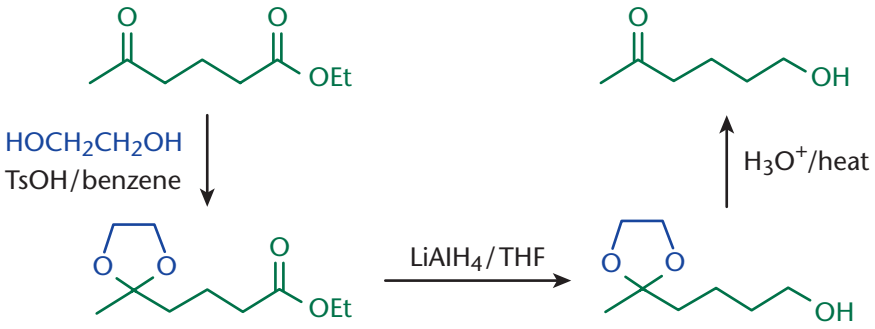
3. For the first part of the reaction, we have a diol, which is commonly used as a protecting group for aldehydes or ketones. Diols are nucleophiles because of lone pairs on the oxygens in the hydroxyl groups. For the second reaction, we have a reducing agent in an organic solvent. Finally, we have an acidic workup—which is often used to remove protecting groups. We're starting to get hints as to what is happening here.

4. In the first reaction, both the ketone and ester carbonyls are highly reactive. One or both of these functional groups will react in the first step.

5. The diol is a good nucleophile because it contains lone pairs on the oxygen atoms in the hydroxyl groups. Further, the presence of a diol hints at protecting the ketone carbonyl because diols are commonly used for this function. This gives our first intermediate—the ketone carbonyl will be replaced by a protected diether. The second reaction, then, will only be able to proceed on the ester. $LiAlH_4$ is a strong reducing agent, so the next reaction will be reduction of the carbonyl all the way to an alcohol. In the final reaction, the protecting group will be removed by acidic workup, leaving us with our original ketone group.

6. The product and intermediate have no stereoselectivity, so this won't be a consideration.

Let's see what we came up with. The first intermediate will have a protective diether at the ketone carbonyl. The second will show the reduction of the ester to an alcohol, with the protecting group still present. The third will be our final product.

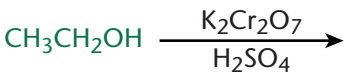


Reaction 2

If ethanol is reacted in acidic solution with potassium dichromate, what will the end product be?

Let's go through the steps again.

1. First, let's draw out our molecules.



2. This molecule has an alkane backbone and a primary alcohol. Alcohols make good nucleophiles and can also be oxidized. The hydroxyl group can also act as a leaving group, especially if it gets protonated.

3. Next, the reagents. Dichromate is a good oxidizing agent.

4. The alcohol carbon is most likely to react because it is the most oxidized.

5. The primary product of a primary alcohol with a strong oxidant like dichromate will be a carboxylic acid. One other possible product could have been an aldehyde, so this could trip us up! Remember, however, that primary alcohols can only be oxidized to aldehydes by reagents specifically designated for this purpose, like pyridinium chlorochromate (PCC). If we start with ethanol, we'll obtain ethanoic acid (acetic acid) after reaction with dichromate.

6. Stereospecificity again isn't a consideration and won't change the outcome in this reaction.

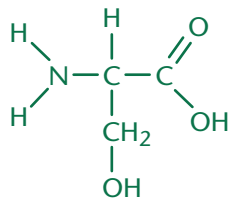
Therefore, the primary product of this reaction will be ethanoic acid.

Reaction 3

Determine the product of a reaction between 2-amino-3-hydroxypropanoic acid and 2,6-diaminohexanoic acid in aqueous solution.

Let's go through the steps one last time.

1. First, let's draw out both molecules.



2-amino-3-hydroxypropanoic acid

2,6-diaminohexanoic acid

2. Both of these molecules have a carboxylic acid (which has an acidic hydrogen and an electrophilic carbonyl carbon) and an amino group (which is nucleophilic). The first molecule also has a hydroxyl group; the second has an additional amino group and a long alkane chain.

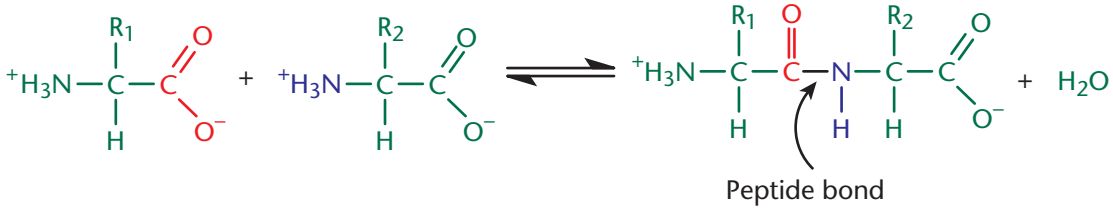
3. There are no additional reagents listed. Therefore, it will be the properties of the two reactants alone that determine how the reaction will proceed.

4. Either of the two molecules could act as the nucleophile in this reaction, and either could be the electrophile. The most reactive species are likely the nucleophilic amino groups attacking the electrophilic carbonyl carbon.

5. The first step of this reaction will be nucleophilic attack by the amino group on the electrophilic carbonyl carbon. Carbon cannot have five bonds, the so the carbonyl group will have to open up. The hydroxyl group on the carboxylic acid is a poor leaving group, but proton rearrangements in the molecule turn the hydroxyl group into water, improving its leaving group ability. Then, the carbonyl will reform, kicking off the water molecule as a leaving group.

6. We might ask why the hydroxyl group on 2-amino-3-hydroxypropanoic acid doesn't react. Remember that more oxidized groups tend to be more reactive, and the carboxylic acid is significantly more oxidized than the hydroxyl group. Another question to consider is which of the amino groups of 2,6-diaminohexanoic acid will react. This is a question that is perhaps best answered retrospectively; in this case, the amino group closer to the carbonyl will react because the resulting product will be stabilized by resonance.

Does this reaction look familiar? It should! 2-amino-3-hydroxypropanoic acid and 2,6-diaminohexanoic acid are serine and lysine, respectively—in this reaction, we are forming a peptide bond. If we treat them as generic amino acids, this is the reaction:



We've worked through a few problems here to get a handle on how to use this method. Once you have read further chapters and learned specific mechanisms that we did not touch on here, be sure to come back and see how these rules apply to novel reactions.

MCAT Concept Check 4.5:
Before you move on, assess your understanding of the material with these questions.

1. What are the six steps for solving organic chemistry reactions?

   1. _____
   2. _____
   3. _____
   4. _____
   5. _____
   6. _____

2. If there are no reaction conditions listed, what determines how the reaction will proceed?

_____

_____

Conclusion

In this chapter, we've outlined a framework for thinking through organic chemistry questions on the MCAT. We have discussed the various types of reactions that we may see, the properties that make them more or less likely to occur, and a few selective rules that can help us work through reactions, even if they are unfamiliar. Finally, we put this framework to the test on example problems in order to cement its application. With this framework in mind, there's nothing you can't tackle—revisit these rules and methods as you continue working through the different functional groups and their reactions in the next six chapters!

CONCEPT SUMMARY

Acids and Bases

- **Lewis acids** are electron acceptors; they have vacant orbitals or positively polarized atoms.
- **Lewis bases** are electron donors; they have a lone pair of electrons and are often anions.
- **Brønsted–Lowry acids** are proton donors; **Brønsted–Lowry bases** are proton acceptors.
- **Amphoteric molecules** can act as either acids or bases, depending on reaction conditions. Water is a common example of an amphoteric molecule.
- The **acid dissociation constant**, $\boldsymbol{K_a}$, is a measure of acidity. It is the equilibrium constant corresponding to the dissociation of an acid, HA, into a proton (H^+) and its conjugate base (A^-).
  - **p$\boldsymbol{K_a}$** is the negative logarithm of K_a. A lower (or even negative) pK_a indicates a stronger acid.
  - pK_a decreases down the periodic table and increases with electronegativity.
- Alcohols, aldehydes, ketones, carboxylic acids, and carboxylic acid derivatives are common acidic functional groups. **α-hydrogens** (hydrogens connected to an **α-carbon**, a carbon adjacent to a carbonyl) are acidic.
- Amines and amides are common basic functional groups.

Nucleophiles, Electrophiles, and Leaving Groups

- **Nucleophiles** are "nucleus-loving" and contain lone pairs or π bonds. They have increased electron density and often carry a negative charge.
  - Nucleophilicity is similar to basicity; however, nucleophilicity is a kinetic property, while basicity is thermodynamic.
  - Charge, electronegativity, steric hindrance, and the solvent can all affect nucleophilicity.
  - Amino groups are common organic nucleophiles.
- **Electrophiles** are "electron-loving" and contain a positive charge or are positively polarized.
  - More positive compounds are more electrophilic.
  - Alcohols, aldehydes, ketones, carboxylic acids, and their derivatives can act as electrophiles.

- **Leaving groups** are the molecular fragments that retain the electrons after **heterolysis**.
  - The best leaving groups can stabilize additional charge through resonance or induction.
  - Weak bases (the conjugate bases of strong acids) make good leaving groups.
  - Alkanes and hydrogen ions are almost never leaving groups because they form reactive anions.
- **Unimolecular nucleophilic substitution (S_N1) reactions** proceed in two steps.
  - In the first step, the leaving group leaves, forming a **carbocation**, an ion with a positively charged carbon atom.
  - In the second step, the nucleophile attacks the planar carbocation from either side, leading to a racemic mixture of products.
  - S_N1 reactions prefer more substituted carbons because the alkyl groups can donate electron density and stabilize the positive charge of the carbocation.
  - The rate of an S_N1 reaction is dependent only on the concentration of the substrate: rate = k[R–L]
- **Bimolecular nucleophilic substitution (S_N2) reactions** proceed in one **concerted** step.
  - The nucleophile attacks at the same time as the leaving group leaves.
  - The nucleophile must perform a **backside attack**, which leads to an inversion of stereochemistry.
  - The absolute configuration is changed—(*R*) to (*S*) and vice-versa—if the incoming nucleophile and the leaving group have the same priority in the molecule.
  - S_N2 reactions prefer less-substituted carbons because the alkyl groups create steric hindrance and inhibit the nucleophile from accessing the electrophilic substrate carbon.
  - The rate of an S_N2 reaction is dependent on the concentrations of both the substrate and the nucleophile: rate = k[Nu:][R–L]

Oxidation–Reduction Reactions

- The **oxidation state** of an atom is the charge it would have if all its bonds were completely ionic.
  - CH_4 is the lowest oxidation state of carbon (most reduced); CO_2 is the highest (most oxidized).
  - Carboxylic acids and carboxylic acid derivatives are the most oxidized functional groups; followed by aldehydes, ketones, and imines; followed by alcohols, alkyl halides, and amines.

- **Oxidation** is an increase in oxidation state and is assisted by oxidizing agents.
  - **Oxidizing agents** accept electrons and are reduced in the process. They have a high affinity for electrons or an unusually high oxidation state. They often contain a metal and a large number of oxygens.
  - Primary alcohols can be oxidized to aldehydes by pyridinium chlorochromate (PCC) or to carboxylic acids by stronger oxidizing agents, like chromium trioxide (CrO_3) or sodium or potassium dichromate ($Na_2Cr_2O_7$ or $K_2Cr_2O_7$).
  - Secondary alcohols can be oxidized to ketones by most oxidizing agents.
  - Aldehydes can be oxidized to carboxylic acids by most oxidizing agents.
- **Reduction** is a decrease in oxidation state and is assisted by reducing agents.
  - **Reducing agents** donate electrons and are oxidized in the process. They have low electronegativity and ionization energy. They often contain a metal and a large number of hydrides.
  - Aldehydes, ketones, and carboxylic acids can be reduced to alcohols by lithium aluminum hydride ($LiAlH_4$).
  - Amides can be reduced to amines by $LiAlH_4$.
  - Esters can be reduced to a pair of alcohols by $LiAlH_4$.

Chemoselectivity

- Both nucleophile–electrophile and oxidation–reduction reactions tend to act at the highest-priority (most oxidized) functional group.
- One can make use of steric hindrance properties to selectively target functional groups that might not primarily react, or to protect functional groups.
  - Diols are often used as protecting groups for aldehyde or ketone carbonyls.
  - Alcohols may be protected by conversion to *tert*-butyl ethers.

Steps for Problem-Solving

1. Know your nomenclature.
2. Identify the functional groups.
3. Identify the other reagents.
4. Identify the most reactive functional group(s).
5. Identify the first step of the reaction.
6. Consider stereoselectivity.

ANSWERS TO CONCEPT CHECKS

4.1

1. An acid–base reaction will proceed when the acid and base react to form conjugate products that are weaker than the reactants.
2. Amphoteric species can act as either an acid or a base. Water, bicarbonate, and dihydrogen phosphate are common amphoteric species in biological systems.
3. $pK_a = -\log K_a$, where K_a is the equilibrium constant for the dissociation of an acid. pK_a indicates acid strength: a stronger acid has a lower (or even negative) pK_a.
4. Alcohols, aldehydes and ketones, carboxylic acids, and most carboxylic acid derivatives act as acids. Amines and amides act as bases.

4.2

1. Nucleophilicity and electrophilicity are based on relative rates of reactions and are therefore kinetic properties. Acidity and basicity are measured by the position of equilibrium in a protonation or deprotonation reaction and are therefore thermodynamic properties.
2. The four main determinants of nucleophilicity are charge (more negative = better nucleophile), electronegativity (more electronegative = worse nucleophile), steric hindrance (larger = worse nucleophile), and the solvent (protic solvents can protonate or hydrogen bond with the nucleophile, decreasing its reactivity).
3. A substitution reaction will proceed when the nucleophile is a stronger base (more reactive) than the leaving group.
4. Greater positive charge increases electrophilicity, and better leaving groups increase electrophilicity by making the reaction more likely to proceed.
5. Good leaving groups can stabilize the extra electrons that result from heterolysis. Weak bases (the conjugate bases of strong acids) are good leaving groups. Resonance stabilization and inductive effects from electron-withdrawing groups also improve leaving group ability.

4.3

1. Good oxidizing agents have a high affinity for electrons or have very high oxidation states. Examples include O_2, O_3, Cl_2, permanganate (MnO_4^-), chromate (CrO_4^-), dichromate (CrO_7^{2-}), and pyridinium chlorochromate. These compounds often contain a metal and a large number of oxygen atoms.
2. Good reducing agents have low electronegativities and ionization energies or contain a hydride ion (H^-). Examples include sodium, magnesium, aluminum, zinc, sodium hydride (NaH), calcium dihydride (CaH_2), lithium aluminum hydride ($LiAlH_4$), and sodium borohydride ($NaBH_4$). These compounds often contain a metal and a large number of hydrides.
3. Carbon dioxide, carboxylic acid, ketone, alcohol, methane

4.4

1. The two reactive centers are the carbonyl carbon, which is electrophilic, and the α-hydrogens, which are acidic.
2. S_N1 reactions are most likely to occur on tertiary carbons where a carbocation can be most easily stabilized.
3. S_N2 reactions are most like to occur on methyl or primary carbons because these reactions are easily inhibited by steric hindrance.

4.5

1. 1. Know your nomenclature; 2. Identify the functional groups; 3. Identify the other reagents; 4. Identify the most reactive functional group(s); 5. Identify the first step of the reaction; 6. Consider stereoselectivity
2. If there are no reagents other than the reactants, then the properties of the functional groups on the reactants themselves (acid–base; nucleophile–electrophile) will determine the outcome.

EQUATIONS TO REMEMBER

(4.1) **Acid dissociation constant:** $K_a = \frac{[H^+][A^-]}{[HA]}$

(4.2) **Definition of pK_a:** $pK_a = -\log K_a$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following are Lewis bases?

I. Ag^+

II. H_2O

III. NH_3

A. I only
B. I and II only
C. II and III only
D. I, II, and III

2. Rank the following in order of decreasing nucleophilicity in an aprotic solvent: RO^-, RCOOH, ROH, HO^-

A. RCOOH > ROH > RO^- > HO^-
B. HO^- > ROH > RO^- > RCOOH
C. RO^- > HO^- > ROH > RCOOH
D. RCOOH > RO^- > HO^- > ROH

3. Rank the following in order of decreasing electrophilicity: CR_3^+, CH_3OH, CH_3OCH_3, CH_3Cl

A. CH_3OCH_3 > CR_3^+ > CH_3OH > CH_3Cl
B. CR_3^+ > CH_3OH > CH_3OCH_3 > CH_3Cl
C. CH_3OCH_3 > CH_3Cl > CR_3^+ > CH_3OH
D. CR_3^+ > CH_3Cl > CH_3OH > CH_3OCH_3

4. Rank the following in order of decreasing leaving group ability: H_2O, HO^-, Br^-, H^-

A. H_2O > Br^- > HO^- > H^-
B. H_2O > HO^- > Br^- > H^-
C. HO^- > Br^- > H_2O > H^-
D. HO^- > H^- > H_2O > Br^-

5. Rank the following in order of decreasing oxidation state: amine, carboxylic acid, aldehyde, alkane

A. Aldehyde, amine, alkane, carboxylic acid
B. Carboxylic acid, aldehyde, amine, alkane
C. Carboxylic acid, amine, aldehyde, alkane
D. Alkane, amine, aldehyde, carboxylic acid

6. If cinnamaldehyde was treated with $LiAlH_4$, what reaction would occur?

A. Reduction, resulting in a primary alcohol
B. Oxidation, resulting in a carboxylic acid
C. An acid–base reaction, resulting in a diol
D. No reaction would occur.

7. If 2-butanol was treated with dichromate, what reaction would occur?

A. Reduction, resulting in the formation of butene
B. Oxidation, resulting in the formation of butanoic acid
C. Oxidation, resulting in the formation of butanone
D. No reaction would occur.

8. If 1-hexanol was treated with pyridinium chlorochromate, what would the end product be?

A. 2-hexanol
B. 2-hexanone
C. Hexanal
D. Hexanoic acid

9. S_N1 reactions show first-order kinetics because:

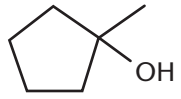
A. the rate-limiting step is the first step to occur in the reaction.
B. the rate-limiting step involves only one molecule.
C. there is only one rate-limiting step.
D. the reaction involves only one molecule.

10. In a protic solvent, which of the following halogens would be the best nucleophile?

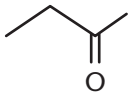
A. Br^-
B. Cl^-
C. F^-
D. I^-

11. Which of the compounds below can undergo oxidation?

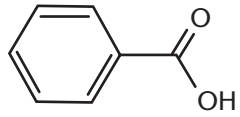
A.



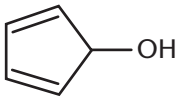
B.



C.



D.



12. Treatment of (*S*)-2-bromobutane with sodium hydroxide results in the production of a compound with an (*R*) configuration. This reaction has most likely taken place through:

A. an S_N1 mechanism.
B. an S_N2 mechanism.
C. an S_N1 and S_N2 mechanism in sequence.
D. an S_N1 and S_N2 mechanism simultaneously.

13. Which of the following solvents would be LEAST useful for a nucleophile–electrophile reaction?

A. H_2O
B. CH_3CH_2OH
C. CH_3SOCH_3
D. $CH_3CH_2CH_2CH_2CH_2CH_3$

14. Aldehydes are generally more reactive than equivalent ketones to nucleophiles. This is likely due to differences in:

A. steric hindrance.
B. leaving group ability.
C. resonance stabilization.
D. electron-withdrawing character.

15. Which conversion between carboxylic acid derivatives is NOT possible by a nucleophilic reaction?

A. Carboxylic acid to ester
B. Ester to carboxylic acid
C. Anhydride to amide
D. Ester to anhydride

Explanations to Discrete Practice Questions

1. C

NH_3 and H_2O are Lewis bases because nitrogen and oxygen can donate lone pairs. Ag^+ is a Lewis acid because it can accept a lone pair into an unoccupied orbital.

2. C

Remember, good nucleophiles tend to have lone pairs or π bonds and are negatively charged or polarized. Alkoxide (OR^-) and hydroxide (OH^-) anions are strong nucleophiles. Alcohols (ROH) and carboxylic acids (RCOOH) are weak nucleophiles. The alkyl group of an alkoxide anion donates additional electron density, making it more reactive than the hydroxide ion. The carboxylic acid contains more electron-withdrawing oxygen atoms than the alcohol, making it less nucleophilic.

3. D

Good electrophiles are positively charged or polarized. CR_3^+ is a tertiary carbocation; it has a positive charge, which makes it very electrophilic. CH_3Cl and CH_3OH are both polarized; however, the leaving groups differ between these two. Cl^- is a weaker base than OH^- (HCl is a stronger acid than H_2O). As such, Cl^- will be more stable in solution than OH^-, which increases the electrophilic reactivity of CH_3Cl above CH_3OH. CH_3OCH_3 has a much less stable leaving group, CH_3O^-, and is therefore significantly less electrophilic.

4. A

Good leaving groups are weak bases, which are the conjugates of strong acids. Leaving groups must also be stable once they leave the molecule. H_2O is, by far, the most stable leaving group and will be extremely unreactive once it leaves the molecule through heterolysis. Br^- is the conjugate base of HBr; HO^- is the conjugate base of water. HBr is a much stronger acid than water, so Br^- is a better leaving group than HO^-. Finally, hydride (H^-) is a very poor leaving group because it is extremely unstable in solution.

5. B

Carboxylic acids are the second most oxidized form of carbon (only carbon dioxide is more oxidized). In carboxylic acids, the carbon atom has three bonds to oxygen. In aldehydes, the carbon atom has two bonds to oxygen. In amines, the carbon atom has one bond to nitrogen. In an alkane, the carbon only has bonds to other carbons and hydrogens.

6. A

All that we need to know about cinnamaldehyde is that it is an aldehyde, and therefore will be reduced by a strong reducing agent like $LiAlH_4$ to a primary alcohol.

7. C

Because 2-butanol is a secondary alcohol, oxidation by a strong oxidizing agent like dichromate will result in a ketone, butanone.

8. C

Pyridinium chlorochromate is a weak oxidizing agent, and will oxidize an alcohol to an aldehyde. Stronger oxidizing agents are required to convert a primary alcohol to a carboxylic acid.

9. B

An S_N1 reaction is a first-order nucleophilic substitution reaction. It is called first-order because the rate-limiting step

involves only one molecule. **Choice (A)** is true, but does not explain why S_N1 reactions have first-order kinetics; the rate-limiting step of an S_N2 reaction is also the first (and only) step of that reaction, but S_N2 reactions have second-order kinetics, not first-order. **Choice (C)** is a true statement as well, but again does not explain why the reaction is first-order. Finally, **choice (D)** is incorrect because it is the rate-limiting step, not the reaction overall, that involves only one molecule.

10. D

In a protic solvent, the protons in solution can attach to the nucleophile, decreasing its nucleophilicity. The larger the nucleophile, and the stronger its conjugate acid, the stronger the nucleophile will be. Of the options given, I^- will therefore be the strongest nucleophile because it is least likely to associate with the protons in solution.

11. D

Primary and secondary alcohols can undergo oxidation because the carbon can form additional bonds with oxygen while losing bonds to hydrogen. **Choice (A)**, a tertiary alcohol; **choice (B)**, a ketone; and **choice (C)**, a carboxylic acid, cannot form additional bonds to oxygen because they have four bonds to other carbon or oxygen atoms already.

12. B

In this reaction, there has been an inversion of stereochemistry. The mostly likely explanation for this is that the reaction proceeded by an S_N2 reaction mechanism. Inversion of stereochemistry is a hallmark of S_N2 reactions, whereas racemization is a hallmark of S_N1 reactions.

13. D

To carry out a nucleophile–electrophile reaction, the nucleophile must be able to dissolve in the solvent. Nucleophiles are nearly always polar, and often carry a charge. Polar solvents are therefore preferred for these reactions. Hexane is a nonpolar solvent and will not be useful for a nucleophile–electrophile reaction.

14. A

Aldehydes have one alkyl group connected to the carbonyl carbon, whereas ketones have two. This creates more steric hindrance in ketones, which lowers their reactivity to nucleophiles. Ketones are also less reactive because their carbonyl carbon has less positive charge character; the additional alkyl group can donate electron density—the opposite of **choice (D)**—which decreases the electrophilicity of the compound.

15. D

Remember, there is a hierarchy to the reactivity of carboxylic acid derivatives that dictates how reactive they are toward nucleophilic attack. In order from highest to lowest, this is anhydrides $>$ carboxylic acids and esters $>$ amides. In practical terms, this means that derivatives of higher reactivity can form derivatives of lower reactivity but not vice-versa. Nucleophilic attack of an ester cannot result in the corresponding anhydride because anhydrides are more reactive than esters.

Concept Summary 128

Introduction

Alcohols are probably the most popular chemicals you'll encounter in organic chemistry. Ethanol has been popular with humans for more than 10,000 years. It's not just humans, either: many animals are known to seek out rotten fruits that have fermented enough to contain moderate levels of ethanol. Note that when we talk about consuming "alcohol," we are referring exclusively to ethanol (grain alcohol). In fact, consuming other alcohols can have drastically negative effects. Methanol (wood alcohol), for example, is oxidized by the body to formic acid, which is extremely toxic to the optic nerve and retina and can cause blindness when ingested. Isopropyl alcohol, commonly used as an antiseptic, can cause severe central nervous system depression. For organic chemistry purposes, of course, we do not restrict ourselves to only one type of alcohol—many are used synthetically and in analytic techniques.

5.1 Description and Properties ★★

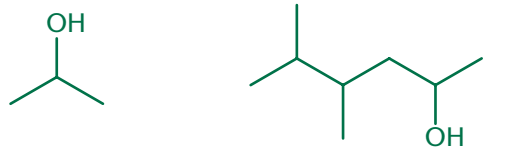
Alcohols have the general formula ROH, with the functional group –OH referred to as a **hydroxyl** group.

NOMENCLATURE

Alcohols are named in the IUPAC system by replacing the ***–e*** ending of the root alkane with the ending ***–ol***. If the alcohol is the highest-priority functional group, the carbon atom attached to it receives the lowest possible number. Some examples are shown in Figure 5.1.

MCAT Expertise

Alcohols are an important group of compounds. They will be seen on the MCAT as protic solvents, reactants, products, and prime examples of hydrogen bonding.



2-propanol 4,5-dimethyl-2-hexanol

Figure 5.1. IUPAC Names of Alcohols

Alternatively, the common naming practice is to name the alkyl group as a derivative, followed by ***alcohol***, as shown in Figure 5.2.

ethyl alcohol isobutyl alcohol

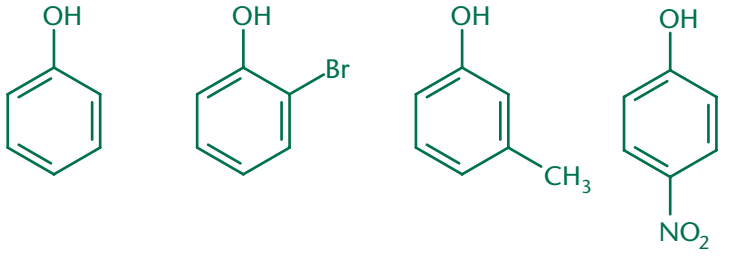
Figure 5.2. Common Names of Alcohols

When the alcohol is not the highest-priority group, it is named as a substituent, with the prefix ***hydroxy***–.

Key Concept

Aromatic alcohols are called phenols. The possible resonance between the ring and the lone pairs of the oxygen atom in the hydroxyl group make the hydrogen of the alcohol more acidic than other alcohols.

Finally, we will also see that hydroxyl groups can be attached to aromatic rings, as in Figure 5.3. These compounds are called **phenols**. The hydroxyl hydrogens of phenols are particularly acidic due to resonance within the phenol ring. When benzene rings contain two substituents, their relative positions must be indicated. Two groups on adjacent carbons are called ***ortho***–, or simply ***o***–. Two groups separated by a carbon are called ***meta***–, or ***m***–. Two groups on opposite sides of the ring are called ***para***–, or ***p***–.



phenol *o*-bromophenol *m*-cresol (*m*-methylphenol) *p*-nitrophenol

Figure 5.3. Phenols: Aromatic Alcohols

PHYSICAL PROPERTIES

One of the prominent properties of alcohols is that they are capable of intermolecular hydrogen bonding, which results in significantly higher melting and boiling points than those of analogous hydrocarbons, as shown in Figure 5.4.

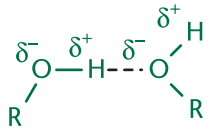


Figure 5.4. Intermolecular Hydrogen Bonding in Alcohols

Molecules with more than one hydroxyl group show greater degrees of hydrogen bonding. This is evident from the boiling points shown in Figure 5.5.

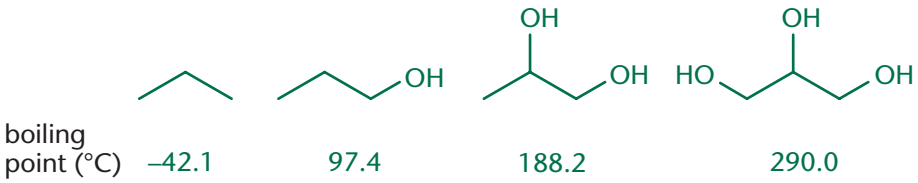

Figure 5.5. Boiling Points for Various Alcohols
Boiling point increases significantly with additional hydroxyl groups, which permit more hydrogen bonding.

Hydrogen bonding occurs when hydrogen atoms are attached to highly electronegative atoms like nitrogen, oxygen, or fluorine. Hydrogen bonding is the result of the extreme polarity of these bonds. In the case of a hydroxyl group, the electronegative oxygen atom pulls electron density away from the less electronegative hydrogen atom. This generates a slightly positive charge on the hydrogen and slightly negative charge on the oxygen. Then, the partially positive hydrogen of one molecule electrostatically attracts the partially negative oxygen of another molecule, generating a noncovalent bonding force known as a **hydrogen bond**.

The hydroxyl hydrogen is weakly acidic, and alcohols can dissociate into protons and alkoxide ions in the same way that water dissociates into protons and hydroxide ions. Table 5.1 gives pK_a values of several hydroxyl-containing compounds.

Dissociation			pK_a
H_2O	⇌	$HO^- + H^+$	14.0
CH_3OH	⇌	$CH_3O^- + H^+$	15.5
C_2H_5OH	⇌	$C_2H_5O^- + H^+$	15.9
i-PrOH	⇌	*i*-PrO^- + H^+	16.5
t-BuOH	⇌	*t*-BuO^- + H^+	17.0
CF_3CH_2OH	⇌	$CF_3CH_2O^- + H^+$	12.5
PhOH	⇌	$PhO^- + H^+$	~10.0

Table 5.1. pK_a Values of Hydroxyl-Containing Compounds

MCAT Expertise

Hydrogen bonding causes increased melting points, boiling points, and solubility in water.

Bridge

Remember from Chapter 10 of *MCAT General Chemistry Review* that pK_a = –log K_a. Strong acids have high K_a values and low pK_a values. Thus, phenol, which has the smallest pK_a, is the most acidic of the alcohols listed in Table 5.1.

Looking at Table 5.1, we can see that the hydroxyl hydrogens of phenols are more acidic than those of other alcohols. This is due to the aromatic nature of the ring, which allows for the resonance stabilization of the negative charge on oxygen, stabilizing the anion. Like other alcohols, phenols form intermolecular hydrogen bonds and have relatively high melting and boiling points. Phenol is slightly soluble in water, owing to hydrogen bonding, as are some of its derivatives. Because phenols are much more acidic than nonaromatic alcohols, they can form salts with inorganic bases such as NaOH.

The presence of other substituents on the ring has significant effects on the acidity, boiling points, and melting points of phenols. As with other compounds, electron-withdrawing substituents increase acidity, and electron-donating groups decrease acidity.

Key Concept

Charges like to be spread out as much as possible. Acidity decreases as more alkyl groups are attached because they are electron-donating, which destabilizes the alkoxide anion. Resonance or electron-withdrawing groups stabilize the alkoxide anion, making the alcohol more acidic.

Another trend seen in Table 5.1 is that the presence of more alkyl groups in nonaromatic alcohols produces less acidic molecules. Because alkyl groups donate electron density, they destabilize a negative charge. Additionally, alkyl groups help stabilize positive charges, explaining why more substituted carbocations have higher stability than less substituted carbocations.

MCAT Concept Check 5.1:

Before you move on, assess your understanding of the material with these questions.

1. Which has a lower pK_a: ethanol or *p*-ethylphenol? Why?

_____

_____

_____

2. Rank the following by decreasing boiling point: 1-pentanol, 1-hexanol, 1,6-hexanediol

   1. _____
   2. _____
   3. _____

5.2 Reactions of Alcohols ★★★

The main reactions that we will see on the MCAT for alcohols include oxidation, preparation of mesylates and tosylates, and protection of carbonyls by alcohols.

OXIDATION REACTIONS

Oxidation of alcohols can produce several products. Primary alcohols can be oxidized to aldehydes, but only by **pyridinium chlorochromate** (**PCC**), a mild anhydrous oxidant, as shown in Figure 5.6. This reactant stops after the primary alcohol has been converted to an aldehyde because PCC lacks the water necessary to hydrate the otherwise easily hydrated aldehyde. With other oxidizing agents, aldehydes are rapidly hydrated to form **geminal diols** (1,1-diols), which can be easily oxidized to carboxylic acids.

Figure 5.6. Oxidation of a Primary Alcohol to an Aldehyde by Pyridinium Chlorochromate (PCC)

Secondary alcohols can be oxidized to ketones by PCC or any stronger oxidizing agent. Tertiary alcohols cannot be oxidized because they are already as oxidized as they can be without breaking a carbon–carbon bond.

The oxidation of primary alcohols with a strong oxidizing agent like chromium(VI) will produce a carboxylic acid. In the process, chromium(VI) is reduced to chromium(III). Common examples of chromium-containing oxidizing agents include sodium and potassium dichromate salts ($Na_2Cr_2O_7$ and $K_2Cr_2O_7$). As with other strong oxidizing agents, these will fully oxidize primary alcohols to carboxylic acids, and secondary alcohols to ketones. An example is shown in Figure 5.7.

Key Concept

Alcohols are readily oxidized to carboxylic acids by any oxidizing agent other than PCC (which will only oxidize primary alcohols to aldehydes).

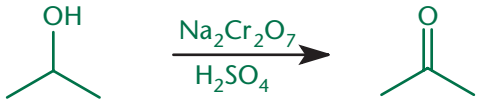

Figure 5.7. Oxidation of a Secondary Alcohol to a Ketone by a Dichromate Salt

Finally, an even stronger chromium-containing oxidizing agent is chromium trioxide, CrO_3. When dissolved with dilute sulfuric acid in acetone, this is called the **Jones oxidation**, as shown in Figure 5.8. As expected, this reaction oxidizes primary alcohols to carboxylic acids and secondary alcohols to ketones.

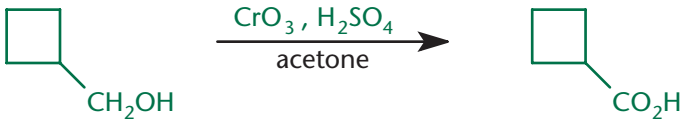

Figure 5.8. Jones Oxidation
A primary alcohol is oxidized to a carboxylic acid by CrO_3.

MESYLATES AND TOSYLATES

The hydroxyl groups of alcohols are fairly poor leaving groups for nucleophilic substitution reactions. However, they can be protonated, or reacted to form much better leaving groups called mesylates and tosylates. A **mesylate** is a compound containing the functional group $–SO_3CH_3$, derived from **methanesulfonic acid**; its anionic form is shown in Figure 5.9.

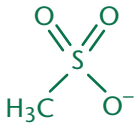

Figure 5.9. Structure of the Mesylate Anion

Mesylates are prepared using methylsulfonyl chloride and an alcohol in the presence of a base.

Tosylates contain the functional group $–SO_3C_6H_4CH_3$, derived from **toluenesulfonic acid**. These compounds are produced by reaction of alcohols with *p*-toluenesulfonyl chloride, forming esters of toluenesulfonic acid. A tosylate is shown in Figure 5.10.

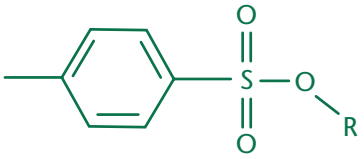

Figure 5.10. Structure of a Tosylate

In addition to making hydroxyl groups of alcohols into better leaving groups for nucleophilic substitution reactions, mesyl and tosyl groups can also serve as protecting groups when we do not want alcohols to react. These groups are protective in that they will not react with many of the other reagents that would attack alcohols, especially oxidizing agents. Thus, reacting an alcohol to form a mesylate or tosylate is sometimes performed before multistep reactions in which the desired products do not derive from the alcohol.

PROTECTING GROUPS

Alcohols can also be used as protecting groups for other functional groups themselves. For example, aldehydes and ketones can be reacted with two equivalents of an alcohol or a diol (dialcohol), forming **acetals** (primary carbons with two –OR groups and a hydrogen atom) or **ketals** (secondary carbons with two –OR groups). Carbonyls are very reactive with strong reducing agents like lithium aluminum hydride ($LiAlH_4$). Acetals and ketals, on the other hand, do not react with $LiAlH_4$. The acetal or ketal functionality thereby protects the aldehyde or ketone from reaction. After reducing other functionalities in the molecule, the acetal or ketal can be reverted back to a carbonyl with aqueous acid, a step called **deprotection**. These reactions are shown in Figure 5.11.

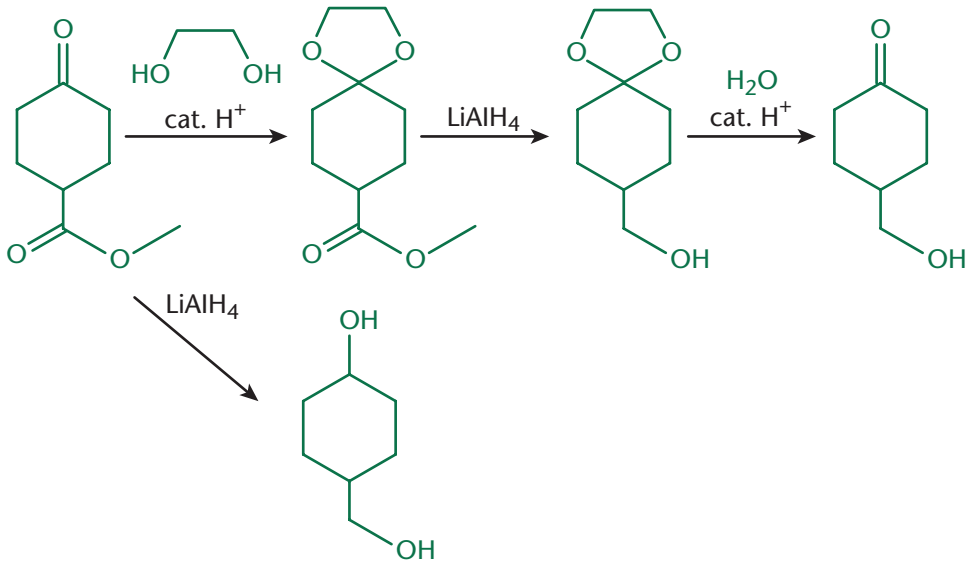

Figure 5.11. Protection of a Ketone by Ketal Formation Using a Dialcohol

MCAT Concept Check 5.2:

Before you move on, assess your understanding of the material with these questions.

1. What will happen to primary and secondary alcohols, respectively, in the presence of strong oxidizing agents?
   - Primary alcohols:

     _____
   - Secondary alcohols:

     _____
2. How can primary alcohols be oxidized to aldehydes?

   _____

   _____
3. What is the purpose of a mesylate or tosylate?

   _____

   _____
4. How can aldehydes or ketones be protected using alcohols?

   _____

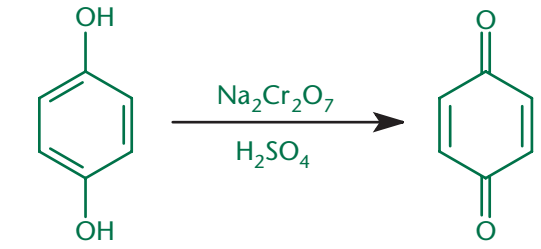
   _____

5.3 Reactions of Phenols ★★

Reactions of phenols proceed in similar fashion to reactions of alcohols. However, as discussed previously, the hydrogen in the hydroxyl group of phenols is particularly acidic because the oxygen-containing anion is resonance-stabilized by the ring.

QUINONES AND HYDROXYQUINONES

Treatment of phenols with oxidizing agents produces compounds called **quinones** (2,5-cyclohexadiene-1,4-diones), as shown in Figure 5.12.



p-benzenediol 1,4-benzoquinone

Figure 5.12. Oxidation of *p*-Benzenediol (a Hydroquinone) to a Quinone

Quinones are named by indicating the position of the carbonyls numerically and adding ***quinone*** to the name of the parent phenol. Due to the conjugated ring system, these molecules are resonance-stabilized electrophiles. Remember, however, that these are not necessarily aromatic because they lack the classic aromatic conjugated ring structure. Some quinones do have an aromatic ring, but this is not always the case. Quinones serve as electron acceptors biochemically, specifically in the electron transport chain in both photosynthesis and aerobic respiration. Vitamin K_1 is the common name of the quinone 2-methyl-3-[(2*E*)-3,7,11,15-tetramethylhexadec-2-en-1-yl]naphthoquinone, shown in Figure 5.13. This molecule is also called **phylloquinone** and is important for photosynthesis and the carboxylation of some of the clotting factors in blood. Vitamin K_2, similarly, corresponds to a class of molecules called **menaquinones**.

Bridge

Phylloquinone and menaquinone are the common names of Vitamin K_1 and Vitamin K_2, respectively. These molecules are fat-soluble vitamins that play a role in carboxylation of clotting factors II, VII, IX, and X, and proteins C and S in blood. The functions of fat-soluble vitamins are explored in Chapter 5 of *MCAT Biochemistry Review*.

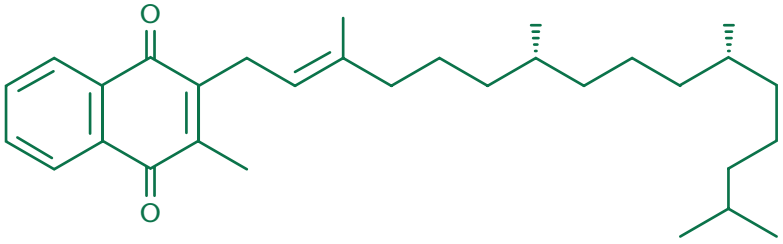


Figure 5.13. Phylloquinone (Vitamin K_1)

These molecules can be further oxidized to form a class of molecules called hydroxyquinones. **Hydroxyquinones** share the same ring and carbonyl backbone as quinones, but differ by the addition of one or more hydroxyl groups. Many hydroxyquinones have biological activity, and some are used in the synthesis of medications. One classic example is shown in Figure 5.14.

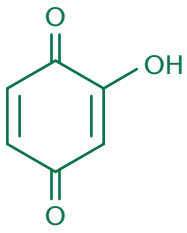

Figure 5.14. 2-Hydroxy-1,4-benzoquinone, a Hydroxyquinone

Because of resonance, hydroxyquinones behave like quinones with electron-donating groups, making these slightly less electrophilic (although still quite reactive). When naming these compounds, the position of the hydroxyl groups is indicated by a number, and the total number of hydroxyl groups (if there is more than one) is indicated by a prefix (such as *di–*, or *tri–*) with the substituent name ***hydroxy–***. Several examples are shown in Figure 5.15.

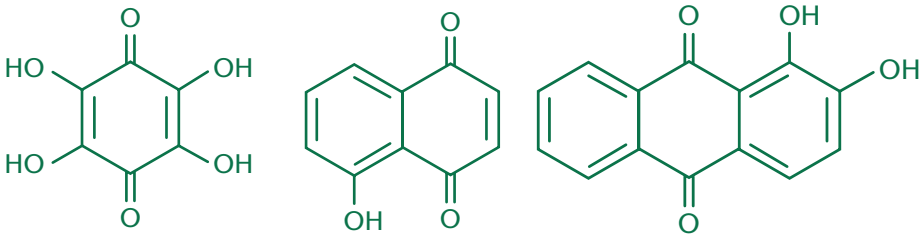

Figure 5.15. Three Examples of Hydroxyquinones
(a) Tetrahydroxybenzoquinone; (b) 5-hydroxynaphthoquinone;
(c) 1,2-dihydroxyanthraquinone.

UBIQUINONE

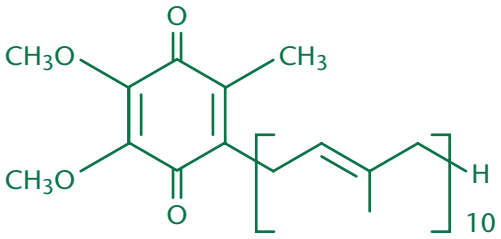
Ubiquinone is one example of a biologically active quinone. Ubiquinone is also called **coenzyme Q** and is a vital electron carrier associated with Complexes I, II, and III of the electron transport chain. Ubiquinone is the most oxidized form that this molecule takes physiologically: it can also be reduced to **ubiquinol** upon the acceptance of electrons, as shown in Figure 5.16. This oxidation–reduction capacity allows the molecule to perform its physiological function of electron transport.

MCAT Expertise

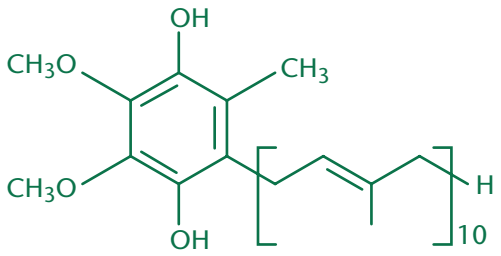
Note the subtle difference in terminology between Figure 5.12 and Figure 5.14. A *hydroquinone* is a benzene ring with two hydroxyl groups. A *hydroxyquinone* contains two carbonyls and a variable number of hydroxyl groups.

Bridge

Coenzyme Q plays a role in Complexes I, II, and III of the electron transport chain. In Complex III, it is the main player in the Q cycle, which contributes to the formation of the proton-motive force across the inner mitochondrial membrane. The respiratory complexes are discussed in Chapter 10 of *MCAT Biochemistry Review.*



ubiquinone



ubiquinol

Figure 5.16. Ubiquinone (Coenzyme Q) and Ubiquinol
Ubiquinone is the oxidized form; when it picks up electrons, it is converted to its reduced form (ubiquinol).

The long alkyl chain of this molecule allows it to be lipid soluble, which allows it to act as an electron carrier within the phospholipid bilayer.

Other biological molecules that undergo oxidation–reduction reactions as part of their normal function include NADH, $FADH_2$, and NADPH. These molecules accept and donate electrons readily, similar to ubiquinone, and are discussed more thoroughly in Chapters 9 and 10 of *MCAT Biochemistry Review*.

MCAT Concept Check 5.3:
Before you move on, assess your understanding of the material with these questions.

1. How are quinones generally produced?

_____

_____

2. How are hydroxyquinones produced?

_____

_____

3. What chemical properties of ubiquinone allow it to carry out its biological functions?

_____

_____

_____

Conclusion

Alcohols are a particular favorite of the MCAT testmakers. We got our first look at the unique properties that stem from hydrogen bonding, an important ability of alcohols. Alcohols can be oxidized to aldehydes, ketones, or carboxylic acids depending on the substitution of the alcohol and the strength of the oxidizing agent. From this point forward, oxidation and reduction will be important reactions with all functional groups. Alcohols can also participate in nucleophilic substitution reactions, which may be facilitated by converting the alcohol into a mesylate or tosylate. Finally, phenols (and their oxidized counterparts, quinones and hydroxyquinones) are involved in a number of biochemical pathways. In particular, their utility is seen in processes that require rapid oxidation and reduction, such as photosynthesis and the electron transport chain.

Over the next four chapters, we'll explore other oxygen-containing compounds. Recognize that these chapters are put in a specific order: as you move further along in *MCAT Organic Chemistry Review*, the functional groups will become more oxidized and more reactive. First, we'll look at aldehydes and ketones (and their deprotonated forms, *enols* and *enolates*). Then, we'll explore carboxylic acids and their derivatives: amides, esters, and anhydrides.

CONCEPT SUMMARY

Description and Properties

- **Alcohols** have the general form ROH and are named with the suffix ***–ol***. If they are not the highest priority, they are given the prefix ***hydroxy–***.
- **Phenols** are benzene rings with hydroxyl groups. They are named for the relative positions of the hydroxyl groups: ***ortho–*** (adjacent carbons), ***meta–*** (separated by one carbon), or ***para–*** (on opposite sides of the ring).
- Alcohols can hydrogen bond, raising their boiling and melting points relative to corresponding alkanes. Hydrogen bonding also increases the solubility of alcohols.
- Phenols are more acidic than other alcohols because the aromatic ring can delocalize the charge of the conjugate base.
- Electron-donating groups like alkyl groups decrease acidity because they destabilize negative charges. Electron-withdrawing groups, such as electronegative atoms and aromatic rings, increase acidity because they stabilize negative charges.

Reactions of Alcohols

- Primary alcohols can be oxidized to aldehydes only by **pyridinium chlorochromate** (**PCC**); they will be oxidized all the way to carboxylic acids by any stronger oxidizing agents.
- Secondary alcohols can be oxidized to ketones by any common oxidizing agent.
- Alcohols can be converted to mesylates or tosylates to make them better leaving groups for nucleophilic substitution reactions.
  - **Mesylates** contain the functional group $–SO_3CH_3$, which is derived from methanesulfonic acid.
  - **Tosylates** contain the functional group $–SO_3C_6H_4CH_3$, which is derived from toluenesulfonic acid.
- Aldehydes or ketones can be protected by converting them into acetals or ketals.
  - Two equivalents of alcohol or a dialcohol are reacted with the carbonyl to form an **acetal** (a primary carbon with two –OR groups and a hydrogen atom) or **ketal** (a secondary carbon with two –OR groups).
  - Other functional groups in the compound can be reacted (especially by reduction) without effects on the newly formed acetal or ketal.
  - The acetal or ketal can then be converted back to a carbonyl by catalytic acid, which is called **deprotection**.

Reactions of Phenols

- **Quinones** are synthesized through oxidation of phenols.
  - Quinones are resonance-stabilized electrophiles.
  - Vitamin K_1 (**phylloquinone**) and Vitamin K_2 (the **menaquinones**) are examples of biochemically relevant quinones.
- **Hydroxyquinones** are produced by oxidation of quinones, adding a variable number of hydroxyl groups.
- **Ubiquinone** (**coenzyme Q**) is another biologically active quinone that acts as an electron acceptor in Complexes I, II, and III of the electron transport chain. It is reduced to **ubiquinol**.

ANSWERS TO CONCEPT CHECKS

5.1

1. Phenols like *p*-ethylphenol have increased acidity due to resonance and the electron-withdrawing character of the phenol aromatic ring. Because *p*-ethylphenol is a stronger acid than ethanol, it will have a lower pK_a.
2. 1,6-Hexanediol will have the highest boiling point; a molecule with two hydroxyl moieties can have more hydrogen bonding. The 1-hexanol boiling point will be next, with 1-pentanol having the lowest boiling point. 1-Hexanol has a higher boiling point than 1-pentanol because the longer hydrocarbon chain has increased van der Waals forces.

5.2

1. In the presence of strong oxidizing agents, primary alcohols are completely oxidized to carboxylic acids. Secondary alcohols can only be oxidized to ketones.
2. Primary alcohols can only be oxidized to aldehydes using pyridinium chlorochromate (PCC).
3. Mesylates and tosylates are used to convert an alcohol into a better leaving group. This is particularly useful for nucleophilic substitution reactions because it increases the stability of the product. They can also be used as protecting groups because many reagents (especially oxidizing agents) that would react with an alcohol cannot react with these compounds.
4. Aldehydes or ketones can be reacted with two equivalents of alcohol or a diol to form an acetal or ketal. Acetals and ketals are less reactive than aldehydes and ketones (especially to reducing agents), and can thus protect the functional group from reacting. The acetal or ketal can then be reverted back to the carbonyl by catalytic acid.

5.3

1. Quinones are produced by oxidation of phenols.
2. Hydroxyquinones are produced by the oxidation of quinones, adding a variable number of additional hydroxyl groups.
3. Ubiquinone has conjugated rings, which stabilize the molecule when accepting electrons. Additionally, the long alkyl chain in the molecule allows for lipid solubility, which allows the molecule to function in the phospholipid bilayer.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

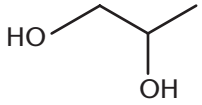
1. Alcohols have higher boiling points than their analogous hydrocarbons because:

A. the oxygen atoms in alcohols have shorter bond lengths.
B. hydrogen bonding is present in alcohols.
C. alcohols are more acidic than their analogous hydrocarbons.
D. alcohols can be oxidized to ketones.

2. Tertiary alcohols are oxidized with difficulty because:

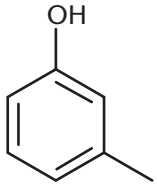
A. there is no hydrogen attached to the carbon with the hydroxyl group.
B. there is no hydrogen attached to the α-carbon of the carbonyl.
C. tertiary alcohols contain hydroxyl groups with no polarization.
D. they are relatively inert.

3. The IUPAC name of this molecule is:



A. ethane-1,2-diol.
B. propane-1,2-diol.
C. dimethanol.
D. dipropanol.

4. The IUPAC name of this molecule is:



A. 2-methylcyclohexanol.
B. *m*-methylphenol.
C. *p*-methylphenol.
D. 3-methylcyclohexanol.

5. Which of the following correctly lists methanol, isobutyl alcohol, and propanol by decreasing boiling point?

A. Methanol > isobutyl alcohol > propanol
B. Isobutyl alcohol > methanol > propanol
C. Isobutyl alcohol > propanol > methanol
D. Methanol > propanol > isobutyl alcohol

6. Which of the following correctly lists hexanol, phenol, and cyclohexanol by increasing acidity of the hydroxyl hydrogen?

A. Phenol < hexanol < cyclohexanol
B. Cyclohexanol < hexanol < phenol
C. Cyclohexanol < phenol < hexanol
D. Phenol < cyclohexanol < hexanol

7. Which of the following will convert $CH_3CH_2CH_2OH$ to CH_3CH_2CHO?

I. CrO_3

II. PCC

III. $K_2Cr_2O_7$

A. I only
B. II only
C. I and III only
D. I, II, and III

8. Which of the following will convert cyclohexanol to cyclohexanone?

I. Chromium trioxide

II. Pyridinium chlorochromate

III. Sodium dichromate

A. I only
B. II only
C. I and III only
D. I, II, and III

9. Successfully converting 3-phenylpropanol to 3-phenylpropanoic acid by the Jones oxidation requires the oxidizing agent, the solvent, and:

A. dilute sulfuric acid.
B. dilute sodium hydroxide.
C. anhydrous conditions.
D. high temperature.

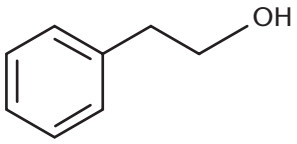
10. Treating 2-methyl-1-propanol with methylsulfonyl chloride in base, followed by reaction with pyridinium chlorochromate, and a final step in strong acid, will give an end product of:

A. 2-methyl-1-propanol.
B. 2-methylpropanal.
C. 2-methylpropanoic acid.
D. 2-methyl-1-propane.

11. Reaction of 1-phenylethanone with ethylene glycol, also known as ethane-1,2-diol, in aqueous H_2SO_4 will result in the formation of:

A. a ketal.
B. a carboxylic acid.
C. an aldehyde.
D. a hemiacetal.

12. Treatment of this molecule with CrO_3 under appropriate reaction conditions will yield which of the following molecules?



A. 2-Phenylethanol
B. Phenylacetaldehyde
C. Phenylacetone
D. 2-Phenylethanoic acid

13. In order to convert phenols into hydroxyquinones, how many steps of oxidation or reduction are required?

A. 1 oxidation step
B. 2 oxidation steps
C. 1 reduction step
D. 2 reduction steps

14. The conversion of ubiquinone to ubiquinol requires what type of reaction?

A. Condensation
B. Oxidation
C. Reduction
D. Hydrolysis

15. Which of the following will convert a cyclic acetal to a carbonyl and a dialcohol?

A. Aqueous acid
B. $LiAlH_4$
C. CrO_3
D. Acetone

Explanations to Discrete Practice Questions

1. B

Alcohols have higher boiling points than their analogous hydrocarbons as a result of their polarized O–H bonds, in which oxygen is partially negative and hydrogen is partially positive. This enables the oxygen atoms of other alcohol molecules to be attracted to the hydrogen, forming a hydrogen bond. Heat is required to overcome these hydrogen bonds, thereby increasing the boiling point. The analogous hydrocarbons do not form hydrogen bonds and, therefore, vaporize at lower temperatures. **Choice (A)** is irrelevant; oxygen's bond length is not a factor in determining a substance's boiling point. **Choices (C)** and **(D)** are true statements, but are also irrelevant to boiling point determination.

2. A

Tertiary alcohols can be oxidized but only under extreme conditions because their substrate carbons do not have spare hydrogens to give up. Alcohol oxidation involves the removal of such a hydrogen so that carbon can instead make another bond to oxygen. If no hydrogen is present, a carbon–carbon bond must be cleaved, which requires a great deal of energy and will, therefore, occur only under extreme conditions. **Choice (B)** is incorrect because alcohols are not carbonyl-containing compounds and would more properly describe a carbonyl-containing compound that is unable to form an enolate. **Choice (C)** is incorrect because the hydroxyl group of the tertiary carbon is still polarized. **Choice (D)** is a false statement; tertiary alcohols are still involved in other reactions, such as S_N1 reactions.

3. B

Remember, diols are named after the parent alkane, with the position of the alcohols indicated, and ending in the suffix *–diol*. Here the carbon chain is three carbons, with a hydroxyl group on carbons 1 and 2. Thus, the name is propane-1,2-diol.

4. B

This molecule is a phenol, not a hexanol, because the cyclic group has aromatic double bonds rather than single bonds. The methyl group is separated from the hydroxyl carbon by one carbon in between, making this molecule *m*-methylphenol.

5. C

All else being equal, boiling points increase with increasing size of the alkyl chain because of increased van der Waals attractions. Isobutyl alcohol has the largest alkyl chain and will thus have the highest boiling point; methanol has the smallest chain and will thus have the lowest boiling point.

6. B

Phenols have significantly more acidic hydroxyl hydrogens than other alcohols because of resonance stabilization of the conjugate base, so this will be the most acidic hydroxyl hydrogen. The acidity of hexanol and cyclohexanol are close, but the hydroxyl hydrogen of hexanol is slightly more acidic because the ring structure of cyclohexanol is slightly electron-donating, which makes its hydroxyl hydrogen slightly less acidic.

7. B

$CH_3CH_2CH_2OH$ is 1-propanol, a primary alcohol. The desired end product, CH_3CH_2CHO, is propanal, an aldehyde. Of the available options, the only reactant capable of oxidizing primary alcohols to aldehydes is pyridinium chlorochromate (PCC). Chromic trioxide and dichromate salts will both oxidize primary alcohols to carboxylic acids.

8. D

Cyclohexanol is a secondary alcohol, so any of the oxidizing agents listed will convert it to a ketone.

9. A

Acidic conditions, provided by dilute sulfuric acid, are required to complete the Jones oxidation. This reaction is carried out in aqueous conditions, eliminating **choice (C)**. While heat may speed up the reaction, high temperatures are not required for this reaction, eliminating **choice (D)**.

10. A

Methylsulfonyl chloride serves as a protecting group for alcohols, which are converted into mesylates. Reacting with this reagent before continuing with what would normally be an oxidation reaction keeps the alcohol from reacting; when the protecting group is then removed using strong acid, the resultant product is the same as the initial reactant. Neither of the oxidation products in **choices (B)** or **(C)**, nor the reduction product in **choice (D)**, will be formed.

11. A

This reaction will create a ketal. This is the first step of the protection of aldehydes or ketones using dialcohols.

12. D

This is the Jones oxidation, which will convert a primary alcohol into a carboxylic acid. **Choice (A)** is the original reacting molecule, and because the reaction will proceed, this is not correct. Because the reaction uses strong oxidizing agents, it won't stop at the aldehyde, **choice (B)**. This reaction also cannot make the ketone in **choice (C)** because it starts with a primary alcohol.

13. B

In order to convert phenols into hydroxyquinones, they must first be converted to quinones through an oxidation step; a second oxidation step is required in order to further oxidize quinones to hydroxyquinones.

14. C

The reaction that converts ubiquinone into ubiquinol is a reduction reaction in which two ketones are reduced to two hydroxyl groups.

15. A

An acetal can be converted to a carbonyl and a dialcohol by treatment with aqueous acid. This is the final step when using alcohols as protecting groups, called deprotection.

Concept Summary 149

Introduction

This chapter focuses on an important functional group for the MCAT: the carbonyl. Aldehydes and ketones, the two functional groups highlighted here, have a lot in common because they both contain a **carbonyl**—a double bond between a carbon and an oxygen. The only difference between the two is what is attached to the carbonyl carbon.

The carbonyl group is one of the most common functional groups in organic chemistry for two reasons. First, the carbonyl is a component of many different functional groups. In addition to aldehydes and ketones, the carbonyl is found in carboxylic acids, esters, amides, anhydrides, and several other compounds. More importantly, the carbonyl has the unique ability to behave as either a nucleophile (as in condensation reactions) or an electrophile (as in nucleophilic addition reactions). In this chapter, we will investigate the overall properties of aldehydes and ketones, as well as their oxidation–reduction reactions and electrophilic properties. In the following chapter, we will investigate their nucleophilic properties through *enolate* chemistry.

6.1 Description and Properties ★★★

A **ketone** has two alkyl groups bonded to the carbonyl, whereas an **aldehyde** has one alkyl group and one hydrogen. This means that the carbonyl in a ketone is never a terminal group, whereas it always is in an aldehyde. Like many organic compounds, aldehydes and ketones are often strong-smelling compounds. Volatile carbonyls are found in many spices, including cinnamon (*cinnamaldehyde*), vanilla (*vanillin*), cumin (*cuminaldehyde*), dill (*carvenone*), and ginger (*zingerone*).

Key Concept

An aldehyde is a terminal functional group. A ketone, on the other hand, will always be internal and can never be a terminal functional group.

MCAT Expertise

Notice that these common names have a pattern that can help us: *form–* will also be seen in *formic acid* (a one-carbon carboxylic acid), and *acet–* is seen in many two-carbon compounds (*acetylene*, *acetic acid*, and *acetyl-CoA*).

NOMENCLATURE

Aldehydes are named by replacing the ***–e*** at the end of the alkane name with the suffix ***–al***. Common names for the first five aldehydes, shown in Figure 6.1, are *formaldehyde*, *acetaldehyde*, *propionaldehyde*, *butyraldehyde*, and *valeraldehyde*. When aldehydes are named as substituents, use the prefix ***oxo–***.

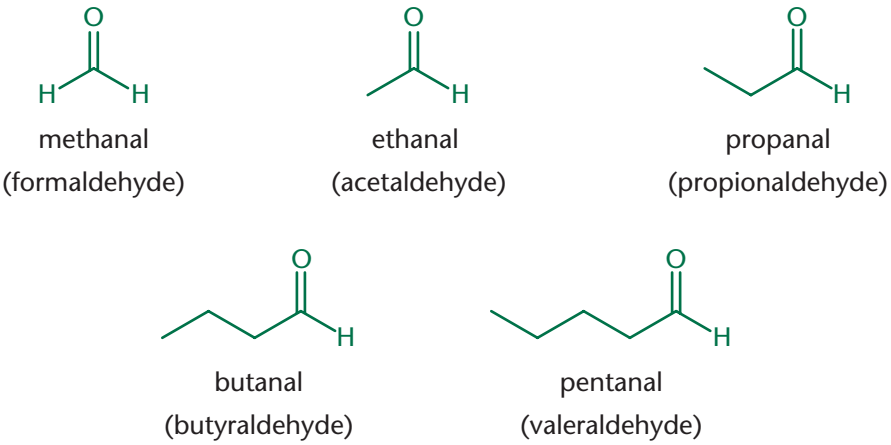

Figure 6.1. Naming Aldehydes

If the aldehyde is attached to a ring, the suffix ***–carbaldehyde*** is used instead. This is shown in Figure 6.2.

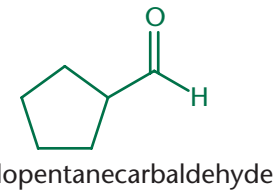

Figure 6.2. Naming Cyclic Aldehydes

Ketones are named by replacing the ***–e*** with the suffix ***–one***. When naming ketones by their common names, the two alkyl groups are named alphabetically, followed by ***–ketone***. When ketones are named as substituents, use either the prefix ***oxo–*** or ***keto–***. Figure 6.3 shows some examples of ketones.

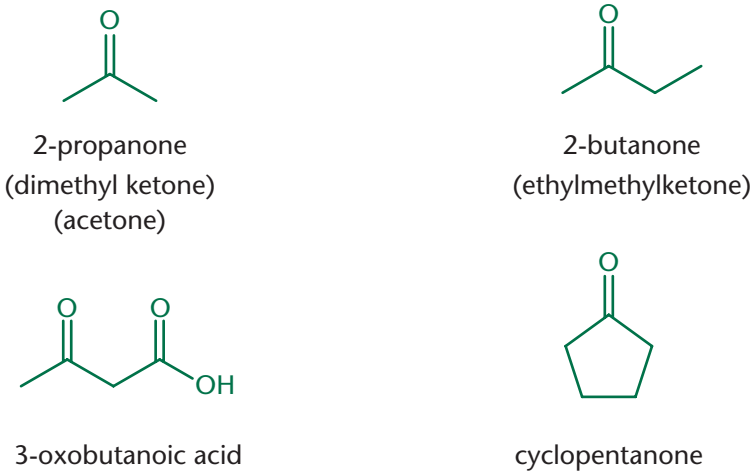

Figure 6.3. Naming Ketones

PHYSICAL PROPERTIES

The physical properties of aldehydes and ketones are governed by the presence of the carbonyl group. The dipole of the carbonyl is stronger than the dipole of an alcohol because the double-bonded oxygen is more electron-withdrawing than the single bond to oxygen in the hydroxyl group. In solution, the dipole moments associated with these polar carbonyl groups increase intermolecular attractions, causing an elevation in boiling point relative to their parent alkanes. However, even though aldehydes and ketones have dipoles more polar than those of alcohols, the elevation in boiling point is less than that in alcohols because no hydrogen bonding is present. In reactions, aldehydes and ketones both act as electrophiles, making good targets for nucleophiles. This is due to the electron-withdrawing properties of the carbonyl oxygen, which leaves a partial positive charge on the carbon, as shown in Figure 6.4. Generally, aldehydes are more reactive toward nucleophiles than ketones because they have less steric hindrance and fewer electron-donating alkyl groups.

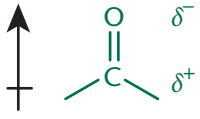

Figure 6.4. Polarity of the Carbonyl Group

Key Concept

While the dipole moment in the carbonyl group increases the intermolecular forces (and therefore boiling points) of aldehydes and ketones relative to alkanes, this is not as significant as the impact of hydrogen bonding seen in alcohols.

MCAT Expertise

The carbonyl carbon is the most common electrophile you'll see on Test Day. Remember why this group has a dipole moment: oxygen is more electronegative and pulls electrons away from the carbon, making the carbon electrophilic and a good target for nucleophiles.

FORMATION

Aldehydes and ketones can be produced by several mechanisms. An aldehyde can be obtained from the partial oxidation of a primary alcohol, although only by **pyridinium chlorochromate** (**PCC**; $C_5H_5NH[CrO_3Cl]$). With any stronger oxidants, aldehydes will continue to be oxidized to carboxylic acids. A ketone can be obtained from the oxidation

of a secondary alcohol. This can be performed using reagents ranging from sodium or potassium dichromate salts ($Na_2Cr_2O_7$ or $K_2Cr_2O_7$) to chromium trioxide (CrO_3) to PCC. When oxidizing a secondary alcohol,there is no concern for oxidizing too far because the reaction will stop at the ketone stage.

MCAT Concept Check 6.1:

Before you move on, assess your understanding of the material with these questions.

1. What is the suffix for an aldehyde? For a ketone?
   - Aldehyde: _____
   - Ketone: _____
2. Given an alkane, an aldehyde, and an alcohol with equal-length carbon chains, which will have the highest boiling point? Why?

   _____

   _____
3. Is the carbon of a carbonyl electrophilic or nucleophilic? Why?

   _____

   _____
4. What is one method for forming an aldehyde? A ketone?
   - Aldehyde:

     _____
   - Ketone:

     _____

6.2 Nucleophilic Addition Reactions

MCAT Expertise

Memorizing one reaction may help you to get one question right on the MCAT, but understanding trends and overarching concepts will allow you to answer many more questions correctly. You will see that the carbonyl carbon is a great target for nucleophilic attack in many of the reactions in this chapter.

In each of the following reactions, the general reaction mechanism is the same: nucleophilic addition to a carbonyl. This is one of the most important reaction mechanisms on the MCAT, and many of the reactions of aldehydes, ketones, and more complex molecules share this general reaction mechanism. Rather than memorizing each reaction individually, focus on the overall pattern—then learn how a particular reaction exemplifies it.

As we have seen, the C=O bond is polarized, with a partial positive charge on the carbonyl carbon and a partial negative charge on the oxygen. This makes the carbonyl carbon an electrophile, ripe for nucleophilic attack.

When the nucleophile attacks, it forms a covalent bond to the carbon, breaking the π bond in the carbonyl. The electrons from the π bond are pushed onto the oxygen atom. Oxygen happily accepts extra electrons due to its electronegativity. Breaking the π bond forms a tetrahedral intermediate. Any time a carbonyl is opened, one should ask: *Can I reform the carbonyl?* If no good leaving group is present (as is the case with aldehydes and ketones), the carbonyl will not reform. Generally, O^- will accept a proton from the solvent to form a hydroxyl group, resulting in an alcohol. However, if a good leaving group is present (as is the case with carboxylic acids and their derivatives), the carbonyl double bond can reform, pushing off the leaving group. Figure 6.5 shows the reaction mechanism of nucleophilic addition for an aldehyde.

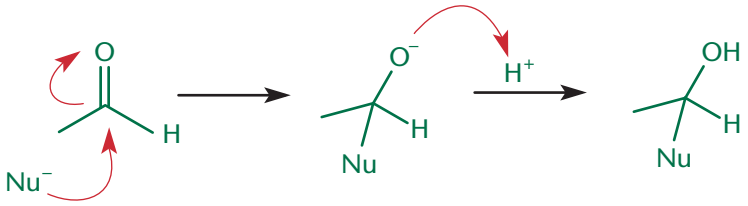

Figure 6.5. Nucleophilic Addition Reaction Mechanism
The nucleophile attacks the carbonyl carbon, opening the carbonyl. The carbonyl cannot reform because there is no good leaving group; thus, the O^- is protonated to generate an alcohol.

HYDRATION

In the presence of water, aldehydes and ketones react to form **geminal diols** (1,1-diols), as shown in Figure 6.6. In this case, the nucleophilic oxygen in water attacks the electrophilic carbonyl carbon. This hydration reaction normally proceeds slowly, but we can increase the rate by adding a small amount of catalytic acid or base.

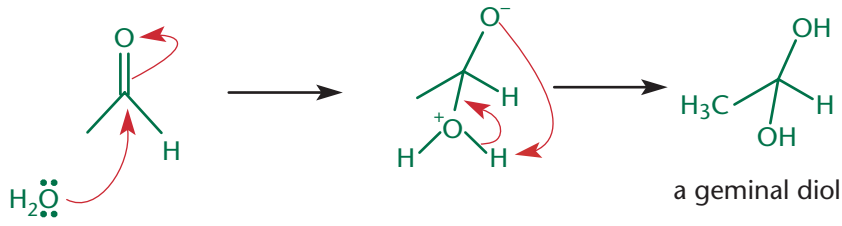

Figure 6.6. Hydration Reaction
The carbonyl is hydrated by water, then protonated, resulting in a geminal diol.

ACETALS AND HEMIACETALS

A similar reaction occurs when aldehydes and ketones are treated with alcohols. When one equivalent of alcohol (the nucleophile in this reaction) is added to an aldehyde or ketone, the product is a **hemiacetal** or **hemiketal**, respectively, as shown in Figure 6.7. Hemiacetals and hemiketals can be recognized by the retention of the hydroxyl group. This "halfway" step (hence the *hemi–* prefix) is the endpoint in basic conditions.

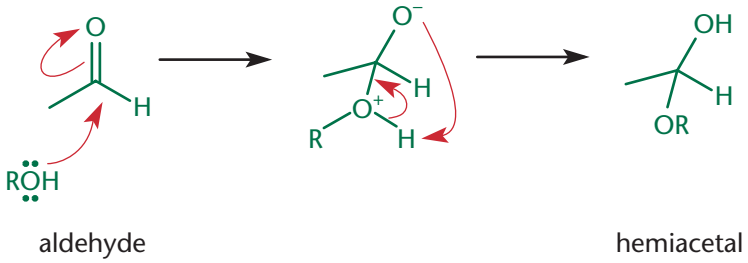

Figure 6.7. Hemiacetal Formation
The oxygen in the alcohol functions as the nucleophile, attacking the carbonyl carbon, and generating a hemiacetal.

When two equivalents of alcohol are added, the reaction proceeds to completion, resulting in the formation of an **acetal** or **ketal**, as shown in Figure 6.8. This reaction proceeds by a nucleophilic substitution reaction (S_N1) and is catalyzed by anhydrous acid. The hydroxyl group of a hemiacetal or hemiketal is protonated under acidic conditions and lost as a molecule of water. A carbocation is thus formed, and another equivalent of alcohol attacks this carbocation, resulting in the formation of an acetal or ketal. Acetals and ketals, which are comparatively inert, are frequently used as protecting groups for carbonyl functionalities. Molecules with protecting groups can easily be converted back to carbonyls with aqueous acid and heat.

Key Concept

In the formation of hemiacetals and hemiketals, alcohol is the nucleophile and the carbonyl carbon is the electrophile. In the formation of acetals and ketals, alcohol is the nucleophile, and the carbocation carbon (formerly the carbonyl carbon) is the electrophile.

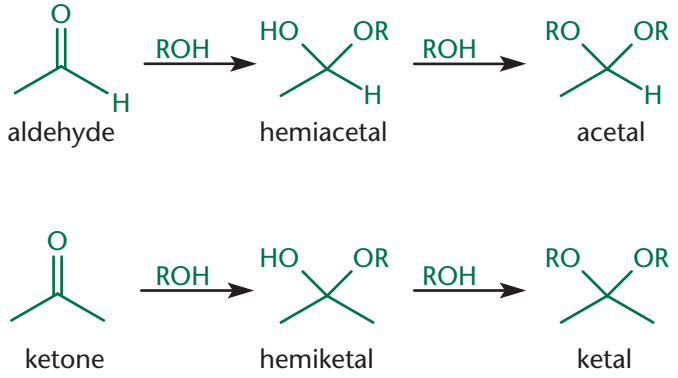

Figure 6.8. Acetal and Ketal Formation
Once a hemiacetal or hemiketal is formed, the hydroxyl group is protonated and released as a molecule of water; alcohol then attacks, forming an acetal or ketal.

IMINES AND ENAMINES

Nitrogen and nitrogen-based functional groups act as good nucleophiles due to the lone pair of electrons on nitrogen, and react readily with the electrophilic carbonyls of aldehydes and ketones. In the simplest case, ammonia adds to the carbon atom and water is lost, producing an **imine**, a compound with a nitrogen atom double-bonded to a carbon atom. This reaction is shown in Figure 6.9. Because a small molecule is lost during the formation of a bond between two molecules, this is an example of a **condensation reaction**. Because nitrogen replaces the carbonyl oxygen, this is also an example of a **nucleophilic substitution**. Some common ammonia derivatives that react with aldehydes and ketones are **hydroxylamine** ($H_2N–OH$), **hydrazine** ($H_2N–NH_2$), and **semicarbazide** ($H_2N–NH–C(O)NH_2$); these form **oximes**, **hydrazones**, and **semicarbazones**, respectively.

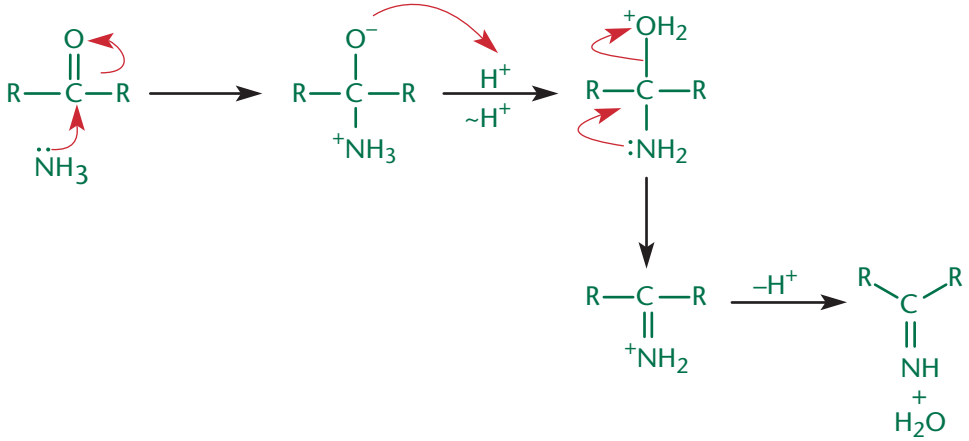

Figure 6.9. Imine Formation
Ammonia is added to the carbonyl, resulting in the elimination of water, and generating an imine.

Imines and related compounds can undergo tautomerization to form **enamines**, which contain both a double bond and a nitrogen-containing group. This is analogous to the *keto–enol* tautomerization of carbonyl compounds and will be explored in Chapter 7 of *MCAT Organic Chemistry Review*.

CYANOHYDRINS

Hydrogen cyanide (HCN) is a classic nucleophile on the MCAT. HCN has both triple bonds and an electronegative nitrogen atom, rendering it relatively acidic with a pK_a of 9.2. After the hydrogen dissociates, the nucleophilic cyanide anion can attack the carbonyl carbon atom, as shown in Figure 6.10. Reactions with aldehydes and ketones produce stable compounds called **cyanohydrins** once the oxygen has been reprotonated. The cyanohydrin gains its stability from the newly formed C–C bond.

Key Concept

In a reaction with HCN, $^-$:CN: is the nucleophile; the carbonyl carbon is the electrophile.

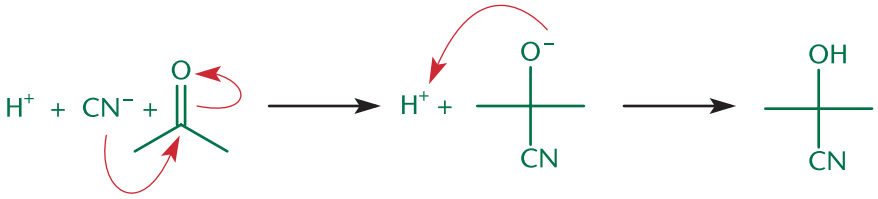

Figure 6.10. Cyanohydrin Formation
Cyanide functions as a nucleophile, attacking the carbonyl carbon and generating a cyanohydrin.

MCAT Concept Check 6.2:

Before you move on, assess your understanding of the material with these questions.

1. When an aldehyde or ketone is reacted with one equivalent of an alcohol, what occurs? What would be different if it were reacted with two equivalents in acidic conditions?
   - Aldehyde or ketone + 1 equivalent of alcohol:

     _____
   - Aldehyde or ketone + 2 equivalents of alcohol:

     _____
2. When nitrogen or nitrogen-containing derivatives react with aldehydes and ketones, what type of reaction happens, and what functional group is formed?

   _____

   _____

   _____
3. When HCN reacts with an aldehyde or ketone, what functional group is produced? Is the product stable?

   _____

   _____

   _____

6.3 Oxidation–Reduction Reactions ★★

Aldehydes occupy the middle of the oxidation–reduction spectrum; they are more oxidized than alcohols but less oxidized than carboxylic acids. Ketones, on the other hand, are as oxidized as secondary carbons can get.

OXIDATION OF ALDEHYDES

When aldehydes are further oxidized, they form carboxylic acids. Any oxidizing agent stronger than PCC can perform this reaction. Some examples include potassium permanganate ($KMnO_4$), chromium trioxide (CrO_3), silver(I) oxide (Ag_2O), and hydrogen peroxide (H_2O_2). This is shown in Figure 6.11.

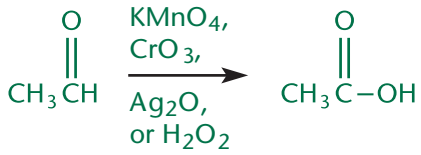

Figure 6.11. Aldehyde Oxidation
Most oxidizing agents will turn aldehydes into carboxylic acids; PCC, however, is anhydrous and is not strong enough to oxidize past the point of an aldehyde.

REDUCTION BY HYDRIDE REAGENTS

Aldehydes and ketones can also undergo reduction to form alcohols. This is often performed with **hydride reagents**. The most common of these seen on the MCAT are **lithium aluminum hydride** ($LiAlH_4$) and **sodium borohydride** ($NaBH_4$), which is often used when milder conditions are needed. This reaction is shown in Figure 6.12.

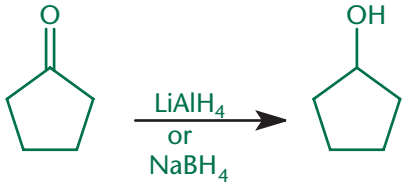

Figure 6.12. Ketone Reduction
Ketones are easily reduced to their respective alcohols using hydride reagents.

MCAT Concept Check 6.3:
Before you move on, assess your understanding of the material with these questions.

1. What functional group is formed when an aldehyde is oxidized? What are some common oxidizing agents that assist this reaction?
   - Functional group:

     _____

   - Oxidizing agents:

     _____

2. What functional group is formed when aldehydes and ketones are reduced? What are some common reducing agents that assist this reaction?
   - Functional group:

     _____

   - Reducing agents:

     _____

Conclusion

In this chapter, we have examined the properties of aldehydes and ketones. Specifically, we have taken a look at the reactivity of the carbonyl carbon in nucleophilic addition reactions and examined how aldehydes and ketones can be oxidized and reduced. Carbonyls are common reaction sites in many biosynthetic processes, which helps explain their importance on the MCAT.

In the following chapter, we will continue our exploration of aldehydes and ketones by looking the chemistry of enolates, which are nucleophilic carbonyl-containing compounds.

CONCEPT SUMMARY

Description and Properties

- **Aldehydes** are terminal functional groups containing a carbonyl bonded to at least one hydrogen. In nomenclature, they use the suffix ***–al*** and the prefix ***oxo***–. In rings, they are indicated by the suffix ***–carbaldehyde***.
- **Ketones** are internal functional groups containing a carbonyl bonded to two alkyl chains. In nomenclature, they use the suffix ***–one*** and the prefix ***oxo***– or ***keto***–.
- The reactivity of a **carbonyl** (C=O) is dictated by the polarity of the double bond. The carbon has a partial positive charge and is therefore electrophilic.
- Carbonyl-containing compounds have higher boiling points than equivalent alkanes because of dipole interactions. Alcohols have higher boiling points than carbonyls because of hydrogen bonding.
- Aldehydes and ketones are commonly produced by oxidation of primary and secondary alcohols, respectively.
  - Weaker, anhydrous oxidizing agents like **pyridinium chlorochromate** (**PCC**) must be used for synthesizing aldehydes, or the reaction will continue oxidizing to the level of the carboxylic acid.
  - Various oxidizing agents can be used for ketones, such as dichromate, chromium trioxide, or PCC because ketones are the most oxidized functional group for secondary carbons.

Nucleophilic Addition Reactions

- When a nucleophile attacks and forms a bond with a carbonyl carbon, electrons in the π bond are pushed to the oxygen atom.
  - If there is no good leaving group (aldehydes and ketones), the carbonyl will remain open and is protonated to form an alcohol.
  - If there is a good leaving group (carboxylic acids and derivatives), the carbonyl will reform and kick off the leaving group.
- In **hydration** reactions, water adds to a carbonyl, forming a **geminal diol**.
- When one equivalent of alcohol reacts with an aldehyde (via nucleophilic addition), a **hemiacetal** is formed. When the same reaction occurs with a ketone, a **hemiketal** is formed.
- When another equivalent of alcohol reacts with a hemiacetal (via nucleophilic substitution), an **acetal** is formed. When the same reaction occurs with a **hemiketal**, a ketal is formed.

- Nitrogen and nitrogen derivatives react with carbonyls to form **imines**, oximes, hydrazones, and semicarbazones. Imines can tautomerize to form **enamines**.
- Hydrogen cyanide reacts with carbonyls to form **cyanohydrins**.

Oxidation–Reduction Reactions

- Aldehydes can be oxidized to carboxylic acids using an oxidizing agent like $KMnO_4$, CrO_3, Ag_2O, or H_2O_2. They can be reduced to primary alcohols via **hydride reagents** ($LiAlH_4$, $NaBH_4$).
- Ketones cannot be further oxidized, but can be reduced to secondary alcohols using the same hydride reagents.

ANSWERS TO CONCEPT CHECKS

6.1

1. The suffix for an aldehyde is *–al*. The suffix for a ketone is *–one*.
2. The alkane will have the lowest boiling point, followed by the aldehyde and then the alcohol. The boiling point of the aldehyde is elevated by its dipole, but the boiling point of an alcohol is further elevated by hydrogen bonding.
3. The carbon in a carbonyl is electrophilic; it is partially positively charged because oxygen is highly electron-withdrawing.
4. Aldehydes can be formed by the oxidation of primary alcohols, but can only be produced using weaker (and anhydrous) oxidizing agents like PCC—otherwise, they will oxidize fully to carboxylic acids. Ketones can be formed by the oxidation of secondary alcohols. Other methods can be used as well (ozonolysis, Friedel–Crafts acylation), but these are outside the scope of the MCAT.

6.2

1. With one equivalent of alcohol, aldehydes and ketones will form hemiacetals and hemiketals, respectively. With two equivalents of alcohol, the reaction will run to completion, forming acetals and ketals, respectively.
2. The reaction that occurs is a condensation reaction because a small molecule is lost, and also a nucleophilic substitution reaction. This reaction results in the formation of an imine (or, for nitrogen-containing derivatives: oximes, hydrazones, or semicarbazones).
3. When HCN reacts with an aldehyde or ketone, a cyanohydrin is produced, which is a stable product.

6.3

1. Oxidizing an aldehyde yields a carboxylic acid. Common oxidizing agents include $KMnO_4$, CrO_3, Ag_2O, and H_2O_2.
2. Reducing an aldehyde or ketone yields an alcohol. Under certain conditions not tested on the MCAT, aldehydes and ketones can be reduced all the way to alkanes. Common reducing agents include $LiAlH_4$ and $NaBH_4$.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

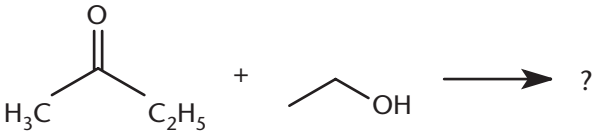
1. All of the following are true with respect to carbonyls EXCEPT:

A. the carbonyl carbon is electrophilic.
B. the carbonyl oxygen is electron-withdrawing.
C. a resonance structure of the functional group places a positive charge on the carbonyl carbon.
D. the π electrons are mobile and are pulled toward the carbonyl carbon.

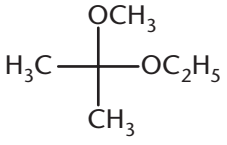
2. Order the following compounds by increasing boiling point: butane, butanol, butanone

A. Butanol < butane < butanone
B. Butane < butanone < butanol
C. Butanone < butane < butanol
D. Butane < butanol < butanone

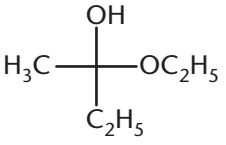
3. What is the product of the reaction below?



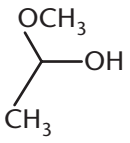
A.



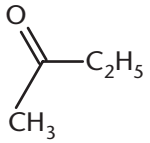
C.



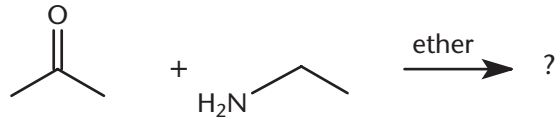
B.



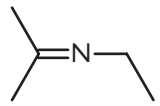
D.



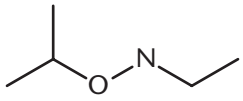
4. What is the product of the reaction below?



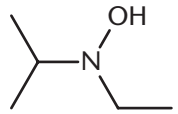
A.



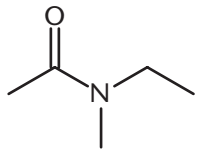
C.



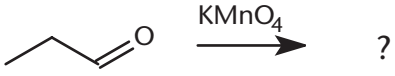
B.



D.

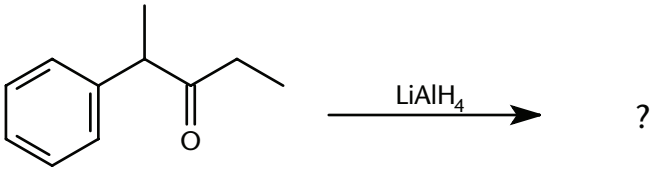


5. What is the product of the reaction below?



A. C_3H_7OH
B. C_2H_5COOH
C. C_2H_5CHO
D. CH_3COOH

6. What is the product of the reaction below?



A. 
C. 
B. 
D. 
7. What is the product of the reaction between benzaldehyde and an excess of ethanol (CH_3CH_2OH) in the presence of anhydrous HCl?

A. 
B. 
C. 
D. 
8. Hemiacetals and hemiketals usually keep reacting to form acetals and ketals. Why is it difficult to isolate hemiacetals and hemiketals?

I. These molecules are unstable.

II. The hydroxyl group is rapidly protonated and lost as water under acidic conditions, leaving behind a reactive carbocation.

III. The molecules are extremely basic and react rapidly with one another.

A. I only
B. I and II only
C. II and III only
D. I, II, and III

9. In a hemiacetal, the central carbon is bonded to:

A. –OH, –OR, –H and –R.
B. –H, –OR, –OR, and –R.
C. –OH, –OR, –R, and –R.
D. –OR, –OR, –R, and –R.

10. In a reaction between hydrogen cyanide, butyraldehyde, and ethylmethylketone, which compounds will come together to form the major product?

A. Butyraldehyde and hydrogen cyanide
B. Ethylmethylketone and butyraldehyde
C. Hydrogen cyanide and ethylmethylketone
D. No reaction will occur.

11. Which of the following describe(s) pyridinium chlorochromate (PCC)?

I. An oxidant that can form aldehydes from primary alcohols

II. An oxidant that can completely oxidize primary alcohols

III. An oxidant that can completely oxidize secondary alcohols

A. I only
B. I and II only
C. I and III only
D. I, II, and III

12. To form a geminal diol, which of the following could attack a carbonyl carbon?

A. Hydrogen peroxide
B. Water
C. Potassium dichromate
D. Ethanol

13. In a reaction between ammonia and glutaraldehyde, what is the major product?

A. An imine
B. A cyanohydrin
C. A semicarbazone
D. A hydrazone

14. Which of the following can be used to reduce a ketone to a secondary alcohol?

A. CrO_3
B. $KMnO_4$
C. $LiAlH_4$
D. Ag_2O

15. Imines naturally tautomerize to form:

A. oximes.
B. hydrazones.
C. semicarbazones.
D. enamines.

Explanations to Discrete Practice Questions

1. D

The reactivity of the carbonyl can be attributed to the difference in electronegativity between the carbon and oxygen atoms. The more electronegative oxygen atom attracts the bonding electrons and is therefore electron-withdrawing. Thus, the carbonyl carbon is electrophilic. One resonance structure of the carbonyl pushes the π electrons onto the oxygen, resulting in a positively charged carbonyl carbon.

2. B

Assuming the length of the carbon chain remains the same, the alkane consistently has the lowest boiling point. The boiling point of the ketone is elevated by the dipole in the carbonyl. The boiling point of the alcohol is elevated further by hydrogen bonding.

3. C

The reaction between a ketone and one equivalent of alcohol produces a hemiketal. This has an –OR group, an –OH group, and two alkyl groups attached at the same carbon. **Choice (A)** is a ketal, with two –OR groups and two –R groups. **Choice (B)** is a hemiacetal, with an –OH group, an –OR group, one R group, and a hydrogen atom (not drawn). **Choice (D)** is a ketone. Note that a hemiketal is a very unstable compound, and will react rapidly with a second equivalent of alcohol to form a ketal in acidic conditions.

4. A

Aldehydes and ketones react with ammonia and nitrogen-based derivatives to form imines—compounds with a double bond between carbon and nitrogen.

5. B

Aldehydes are easily oxidized to the corresponding carboxylic acids by $KMnO_4$. In **choice (A)**, the aldehyde has been reduced to an alcohol. In **choice (C)**, the molecule has not reacted. In **choice (D)**, the aldehyde has been oxidized, but a $–CH_2–$ group has been removed.

6. B

$LiAlH_4$ reduces aldehydes to primary alcohols and ketones to secondary alcohols. In this reaction, a ketone is converted to a secondary alcohol.

7. D

Because an excess of ethanol is present, the product of the reaction between this aldehyde and ethanol will be an acetal. The benzaldehyde will first be converted to a hemiacetal, shown in **choice (C)**, but will then proceed to completion as an acetal. **Choices (A)** and **(B)** are incorrect because they show the presence of two benzene rings in the final product.

8. B

Hemiacetals and hemiketals are usually short-lived because the –OH group will rapidly become protonated in acidic conditions and is lost as water, leaving behind a carbocation that is very susceptible to attack by an alcohol. Once the alcohol has been added, the acetal or ketal becomes more stable because the newly added group is less likely to become protonated and leave as compared to –OH.

9. A

A hemiacetal is a molecule in which one equivalent of alcohol has been added to a carbonyl (–OR) and the carbonyl oxygen has been protonated (–OH). Otherwise, there is the same alkyl group (–R) and hydrogen atom (–H) as the parent aldehyde. **Choice (B)** describes an acetal, **choice (C)** a hemiketal, and **choice (D)** a ketal.

10. A

Although both the aldehyde and ketone listed will be reactive with the strongly nucleophilic hydrogen cyanide, aldehydes are slightly more reactive toward nucleophiles than ketones for steric reasons, so the aldehyde and HCN will form the major product (which will be a cyanohydrin).

11. C

PCC is a mild anhydrous oxidant that can oxidize primary alcohols to aldehydes, and secondary alcohols to ketones. It is not strong enough to oxidize alcohols or aldehydes to carboxylic acids.

12. B

In a hydration reaction, water adds to a carbonyl, forming a geminal diol—a compound with two hydroxyl groups on the same carbon. Hydrogen peroxide and potassium dichromate are oxidizing agents that can convert an aldehyde to a carboxylic acid. Ethanol will react with a carbonyl compound to form an acetal or a ketal, if excess ethanol is available.

13. A

Ammonia, or NH_3, will react with an aldehyde like glutaraldehyde to form an imine. This is a condensation and a substitution reaction, as the C=O of the carbonyl will be replaced with a C=N bond.

14. C

Hydrides like $LiAlH_4$ and $NaBH_4$ are reducing agents; as such, they will reduce aldehydes and ketones to alcohols. The other reagents listed are oxidizing agents, which will not act on a ketone.

15. D

During tautomerization, the double bond between the carbon and nitrogen in an imine is moved to lie between two carbons. This results in an enamine—a compound with a double bond and an amine.

Introduction

In the previous chapter, we took a look at a few key properties and reactions of aldehydes and ketones. These molecules have highly predictable chemistry centered on their electrophilic, positively charged carbonyl carbon and will be sure to show up on Test Day. In this chapter, we take a look at several more properties of aldehydes and ketones, and focus on the reactivity of the α-hydrogen of carbonyl-containing compounds. The acidity of this α-hydrogen allows many aldehydes and ketones to act as both electrophiles and nucleophiles. Sometimes, they can even serve both functions in the same reaction. But don't worry—we'll also review some tips about how to understand when and how aldehydes and ketones will react.

7.1 General Principles ★★

In the previous chapter, we focused on how the electronegativity of the oxygen atom in a carbonyl pulls electrons away from the carbonyl carbon, making it partially positively charged. In this chapter, we take the electron-withdrawing characteristics of oxygen one bond further, focusing on the α-carbon in an aldehyde or ketone.

ACIDITY OF α-HYDROGENS

An **α-carbon** is adjacent to the carbonyl carbon, and the hydrogens connected to the α-carbon are termed **α-hydrogens**. Through induction, oxygen pulls some of the electron density out of these C–H bonds, weakening them. This makes it relatively easy to deprotonate the α-carbon of an aldehyde or ketone, as shown in Figure 7.1. The acidity of α-hydrogens is augmented by resonance stabilization of the conjugate base. Specifically, when the α-hydrogen is removed, the extra electrons that remain

can resonate between the α-carbon, the carbonyl carbon, and the carbonyl oxygen. This increases the stability of this enolate intermediate, described in the next section. Through this resonance, the negative charge can be distributed to the more electronegative oxygen atom. The electron-withdrawing oxygen atom thereby helps stabilize the **carbanion** (a molecule with a negatively charged carbon atom). When in basic solutions, α-hydrogens will easily deprotonate.

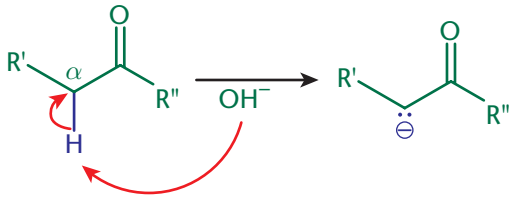

Figure 7.1. Deprotonation of an α-Carbon, Forming a Carbanion

Key Concept

Electron-withdrawing groups like oxygen stabilize organic anions. Electron-donating groups like alkyl groups destabilize organic anions.

The α-hydrogens of ketones tend to be slightly less acidic than those of aldehydes due to the electron-donating properties of the additional alkyl group in a ketone. This property is the same reason that alkyl groups help to stabilize carbocations—but in this case, they destabilize the carbanion.

STERIC HINDRANCE

Key Concept

Ketones are slightly less likely to react with nucleophiles than aldehydes because the extra alkyl group destabilizes the carbanion and increases steric hindrance.

In reactions, aldehydes are slightly more reactive to nucleophiles than ketones. This is due in part to steric hindrance in the ketone, which arises from the additional alkyl group that ketones contain. When the nucleophile approaches the ketone or aldehyde in order to react, the additional alkyl groups on the ketone are in the way, more so than the single hydrogen of the aldehyde. This makes for a higher-energy, more crowded intermediate step. Remember, higher-energy intermediates mean that the reaction is less likely to proceed.

MCAT Concept Check 7.1:

Before you move on, assess your understanding of the material with these questions.

1. Why are the α-hydrogens of aldehydes and ketones acidic?

_____

_____

_____

2. Are the α-hydrogens of aldehydes or ketones more acidic? Why?

_____

_____

3. How does steric hindrance affect the relative reactivity of aldehydes and ketones?

_____

_____

7.2 Enolate Chemistry ★★

Due to the acidity of the α-hydrogen, aldehydes and ketones exist in solution as a mixture of two isomers: the familiar *keto* form, and the *enol* form.

KETO–ENOL TAUTOMERIZATION

The **enol** form gets its name from the presence of a carbon–carbon double bond (the *en–* component) and an alcohol (the *–ol* component). The two isomers, which differ in the placement of a proton and the double bond, are called **tautomers**. The equilibrium between the tautomers lies far to the keto side, so there will be many more keto isomers in solution. The process of interconverting from the keto to the enol tautomer, shown in Figure 7.2, is called **enolization**, or, more generally, **tautomerization**. By extension, any aldehyde or ketone with a chiral α-carbon will rapidly become a racemic mixture as the keto and enol forms interconvert, a phenomenon known as **α-racemization**.

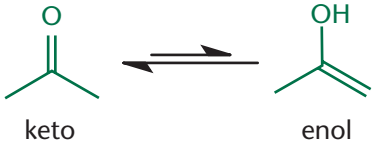

Figure 7.2. Enolization (Tautomerization)
On the left is the keto form, which is thermodynamically favored over the enol form on the right.

Enols are important intermediates in many reactions of aldehydes and ketones. The enolate carbanion results from the deprotonation of the α-carbon by a strong base, as described earlier. Common strong bases include the hydroxide ion, lithium diisopropyl amide (LDA), and potassium hydride (KH). A 1,3-dicarbonyl is particularly acidic because there are two carbonyls to delocalize negative charge and, as such, is often used to form enolate carbanions. Once formed, the nucleophilic carbanion reacts readily with electrophiles. We will see one example of this shortly in the aldol condensation. Another example of this type of reaction is a **Michael addition**, shown in Figure 7.3, in which the carbanion attacks an α,β-unsaturated carbonyl compound—a molecule with a multiple bond between the α- and β-carbons next to a carbonyl.

Key Concept

Aldehydes and ketones exist in the traditional keto form (C=O) and as the less common enol tautomer (enol = *ene* + *ol*). The deprotonated enolate form can act as a nucleophile. Note that tautomers are *not* resonance structures because they have different connectivity of atoms.

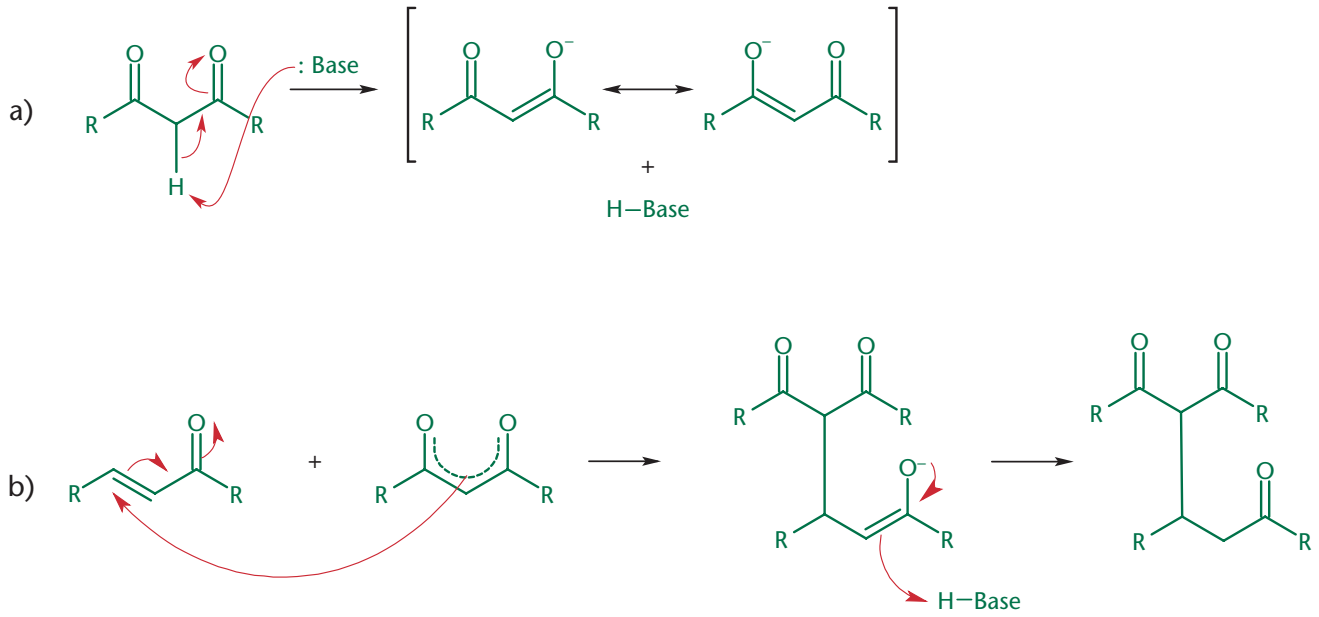

Figure 7.3. Michael Addition
(a) The base deprotonates the α-carbon, making it a good nucleophile;
(b) The carbanion attacks the double bond, resulting in a Michael addition.

This reaction proceeds as shown due to the resonance stabilization of the intermediates. The better you understand the resonance forms of molecules, the more you will be able to predict the specific location on a molecule where a reaction will occur.

KINETIC AND THERMODYNAMIC ENOLATES

Given a ketone that has two different alkyl groups, each of which may have α-hydrogens, two forms of the enolate can form, with the carbon–carbon double bond between the carbonyl carbon and either the more or less substituted carbon, as shown in Figure 7.4. The equilibrium between these forms is dictated by the kinetic and thermodynamic control of the reaction. The kinetically controlled product is formed more rapidly but is less stable. This form has the double bond to the less substituted α-carbon. As expected, this product is formed by the removal of the α-hydrogen from the less substituted α-carbon because it offers less steric hindrance. The thermodynamically controlled product is formed more slowly, but is more stable and features the double bond being formed with the more substituted α-carbon. Accordingly, this is formed by the removal of the α-hydrogen from the more substituted α-carbon.

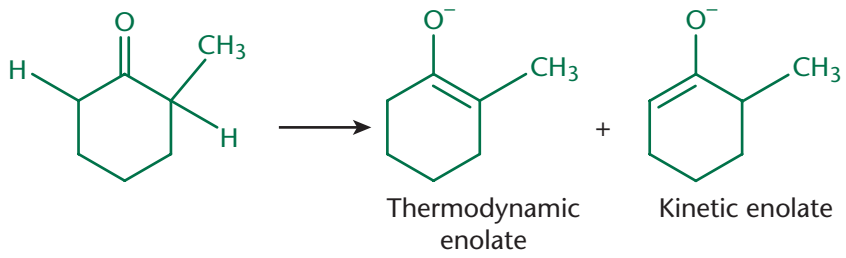

Figure 7.4. Kinetic and Thermodynamic Enolates
The kinetic enolate forms more quickly, but is less stable than the thermodynamic enolate.

Each of these two products is favored by different conditions. The kinetic product is favored in reactions that are rapid, irreversible, at lower temperatures, and with a strong, sterically hindered base. If the reaction is reversible, the kinetic product can revert to the original reactant and react again to form the thermodynamic product. The thermodynamic product is favored with higher temperatures; slow, reversible reactions; and weaker, smaller bases.

ENAMINES

Just as enols are tautomers of carbonyls, enamines are tautomers of imines. An imine is a compound that contains a C=N bond. The nitrogen in the imine may or may not be bonded to an alkyl group or other substituent. Through tautomerization (movement of a hydrogen and a double bond), imines can be converted into enamines, as shown in Figure 7.5.

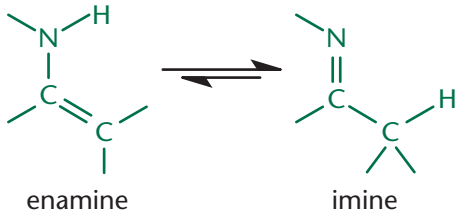

Figure 7.5. Enamination (Tautomerization)
On the right is the imine form, which is thermodynamically favored over the enamine form on the left.

MCAT Concept Check 7.2:
Before you move on, assess your understanding of the material with these questions.

1. What are tautomers?

_____

_____

2. Which tautomer of aldehydes and ketones is thermodynamically favored: keto or enol?

_____

3. Which role does the enolate carbanion play in organic reactions: nucleophile, electrophile, oxidizing agent, or reducing agent?

_____

4. What conditions favor the kinetic enolate form? The thermodynamic enolate form?
   - Kinetic enolate:

     _____

     _____
   - Thermodynamic enolate:

     _____

     _____

7.3 Aldol Condensation

The **aldol condensation** is another vital reaction for the MCAT. This reaction follows the same general mechanism of nucleophilic addition to a carbonyl as previously described. In this case, however, an aldehyde or ketone acts both as an electrophile (in its keto form) and a nucleophile (in its enolate form), and the end result is the formation of a carbon–carbon bond.

As shown in Figure 7.6, when acetaldehyde (ethanal) is treated with a catalytic amount of base, an enolate ion is produced. The enolate is more nucleophilic than the enol because it is negatively charged. This nucleophilic enolate ion can react with the electrophilic carbonyl group of another acetaldehyde molecule. The key to this

reaction is that both species are in the same flask. The product is 3-hydroxybutanol, which is an example of an **aldol** (a molecule that contains both **ald**ehyde and alcoh**ol** functional groups). Note that mechanism is still called an aldol reaction even when the reactants are ketones.

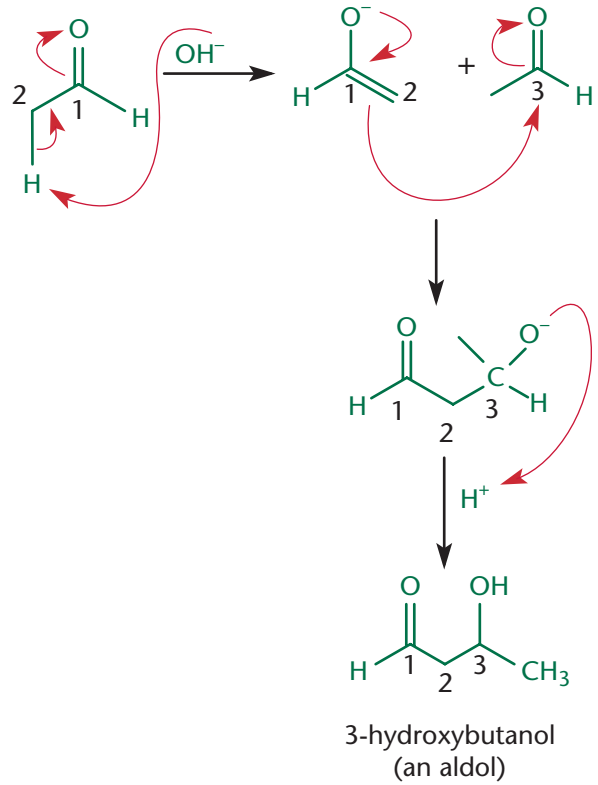

Figure 7.6. Aldol Condensation, Step 1: Forming the Aldol
An enolate ion is formed, which then attacks the carbonyl carbon, forming an aldol.

With a strong base and high temperatures, dehydration occurs by an E1 or E2 mechanism: we kick off a water molecule and form a double bond, producing an α,β-unsaturated carbonyl, as shown in Figure 7.7.

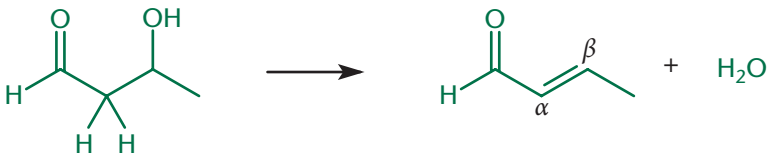

Figure 7.7. Aldol Condensation, Step 2: Dehydration of the Aldol
The –OH is removed as water (dehydration), forming a double bond.

Aldol condensations are most useful if we only use one type of aldehyde or ketone. If there are multiple aldehydes or ketones, we cannot easily control which will act as the nucleophile and which will act as the electrophile, and a mixture of products will

Key Concept

In aldol condensations, it's the same nucleophilic addition reaction that we have seen before with carbonyl compounds—just with the carbonyl-containing compound acting as both a nucleophile and an electrophile.

result. This can be prevented if one of the molecules has no α-hydrogens because the α-carbons are quaternary (like benzaldehyde).

This reaction is referred to as a **condensation reaction** because two molecules are joined with the loss of a small molecule. This type of reaction is also a **dehydration reaction** because the small molecule that is lost is water.

Key Concept

In a retro-aldol reaction, a bond is broken between the α-and β-carbons of a carbonyl, forming two aldehydes, two ketones, or one aldehyde and one ketone.

THE RETRO-ALDOL REACTION

The reverse of this reaction is called a **retro-aldol reaction**. To push the reaction in a retro-aldol direction, aqueous base is added and heat is applied. The retro-aldol reaction is useful for breaking bonds between the α-and β-carbons of a carbonyl, as shown in Figure 7.8. This reaction is facilitated if the intermediate can be stabilized in the enolate form, just as in the forward reaction.

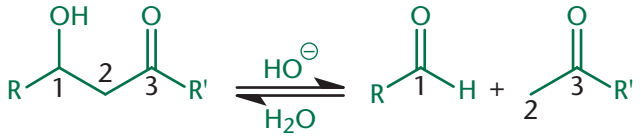

Figure 7.8. Retro-Aldol Reaction
The bond between the α- and β-carbons of a carbonyl is broken.

MCAT Concept Check 7.3:
Before you move on, assess your understanding of the material with these questions.

1. What species acts as the nucleophile in an aldol condensation?

_____

2. What species acts as the electrophile in an aldol condensation?

_____

3. What is a retro-aldol reaction? What conditions favor retro-aldol reactions?

_____

_____

4. The aldol condensation can be classified under many categories of reactions. List some of these reaction types, and provide a short description of each.

_____

_____

_____

Conclusion

In this second chapter on aldehydes and ketones, we've taken a look at the important resonance structures that the carbonyl of aldehydes and ketones allows. The high electronegativity of the oxygen atom in a carbonyl not only makes the carbonyl carbon electrophilic, but also weakens the C–H bonds on α-carbons. Deprotonation of this α-carbon results in an enolate, a nucleophilic version of carbonyl-containing compounds. Thus, while the carbonyl carbon dictates the electrophilic chemistry of carbonyls, it is the α-carbon, along with its acidic hydrogens, that dictates the nucleophilic chemistry of carbonyls.

Aldehydes and ketones are not the only carbonyl-containing compounds, of course. Carboxylic acids and their derivatives, including esters, anhydrides, and amides, also have chemistry controlled by a carbonyl. But there is one critical difference between aldehydes and ketones, and carboxylic acids and their derivatives: the absence or presence of a leaving group. While aldehydes and ketones lack leaving groups, carboxylic acids and carboxylic acid derivatives have leaving groups with varying degrees of stability. Over the next two chapters, we'll explore the chemistry of these interesting groups of compounds.

CONCEPT SUMMARY

General Principles

- The carbon adjacent to the carbonyl carbon is termed an **α-carbon**; the hydrogens attached to the α-carbon are called **α-hydrogens**.
- α-Hydrogens are relatively acidic and can be removed by a strong base.
  - The electron-withdrawing oxygen of the carbonyl weakens the C–H bonds on α-carbons.
  - The **enolate** resulting from deprotonation can be stabilized by resonance with the carbonyl.
- Ketones are less reactive toward nucleophiles because of steric hindrance and α-carbanion destabilization.
  - The presence of an additional alkyl group crowds the transition step and increases its energy.
  - The alkyl group also donates electron density to the carbanion, making it less stable.

Enolate Chemistry

- Aldehydes and ketones exist in the traditional **keto form** (C=O) and in the less common **enol form** (*ene* + *ol* = double bond + hydroxyl group).
  - **Tautomers** are isomers that can be interconverted by moving a hydrogen and a double bond. The keto and enol forms are tautomers of each other.
  - The enol form can be deprotonated to form an **enolate**. Enolates are good nucleophiles.
- In the **Michael addition**, an enolate attacks an α,β-unsaturated carbonyl, creating a bond.
- The **kinetic enolate** is favored by fast, irreversible reactions at lower temperatures with strong, sterically hindered bases. The **thermodynamic enolate** is favored by slower, reversible reactions at higher temperatures with weaker, smaller bases.
- **Enamines** are tautomers of imines. Like enols, enamines are the less common tautomer.

Aldol Condensation

- In the **aldol condensation**, the aldehyde or ketone acts as both nucleophile and electrophile, resulting in the formation of a carbon–carbon bond in a new molecule called an aldol.
  - An **aldol** contains both aldehyde and alcohol functional groups.
  - The nucleophile is the enolate formed from the deprotonation of the α-carbon.

- The electrophile is the aldehyde or ketone in the form of the keto tautomer.
- First, a **condensation reaction** occurs in which the two molecules come together.
- After the aldol is formed, a **dehydration reaction** (loss of a water molecule) occurs. This results in an α,β-unsaturated carbonyl.

- **Retro-aldol reactions** are the reverse of aldol condensations.
  - Retro-aldol reactions are catalyzed by heat and base.
  - In these reactions, the bond between an α- and β-carbon is cleaved.

ANSWERS TO CONCEPT CHECKS

7.1

1. The α-hydrogens of aldehydes and ketones are acidic, or deprotonate easily, due to both inductive effects and resonance effects. The electronegative oxygen atom pulls electron density from the C–H bond, weakening it. Once deprotonated, the resonance stabilization of the negative charge between the α-carbon, carbonyl carbon, and electron-withdrawing carbonyl oxygen increases the stability of this form.
2. The α-hydrogens of aldehydes are slightly more acidic due to the electron-donating characteristics of the second alkyl group in ketones. This extra alkyl group destabilizes the carbanion, which slightly disfavors the loss of the α-hydrogens in ketones as compared to aldehydes.
3. Steric hindrance is one of the two reasons that aldehydes are slightly more reactive than ketones. The additional alkyl group gets in the way and makes for a higher-energy, crowded intermediate.

7.2

1. Tautomers are isomers that can be interconverted by the movement of a hydrogen and a double bond.
2. The keto form is thermodynamically favored.
3. Enolate carbanions act as nucleophiles.
4. Because the kinetic enolate forms rapidly and can interconvert with the thermodynamic form if given time, the kinetic form is favored by fast, irreversible reactions, such as with a strong, sterically hindered base, and lower temperatures. The thermodynamic form, on the other hand, is favored by slower, reversible reactions, with weaker or smaller bases, and higher temperatures.

7.3

1. The enolate carbanion acts as the nucleophile (the deprotonated aldehyde or ketone).
2. The keto form of the aldehyde or ketone acts as the electrophile.
3. A retro-aldol reaction is the reverse of an aldol reaction and can be favored by the addition of base and heat. In this reaction, a bond between the α-and β-carbons of a carbonyl is broken.
4. An aldol condensation is a condensation reaction, in which two molecules are joined to form a single molecule with the loss of a small molecule; a dehydration reaction, in which a molecule of water is lost; and a nucleophile–electrophile reaction, in which a nucleophile pushes an electron pair to form a bond with an electrophile.

Discrete Practice Questions

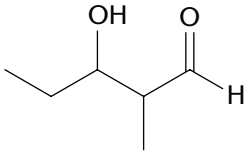
Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. What is the product of the reaction below?

A. 
B. 
C. 
D. 
2. The reaction below is an example of:

A. esterification.
B. tautomerization.
C. elimination.
D. dehydration.

3. Which of the following reactions would produce the compound below?



A. $CH_3CHO + CH_3CH_2CH_2CHO \rightarrow$
B. $CH_3COCH_3 + CH_3CH_2CH_2CHO \rightarrow$
C. $CH_3CH_2COCH_3 + CH_3CHO \rightarrow$
D. $CH_3CH_2CHO + CH_3CH_2CHO \rightarrow$

4. Why does the equilibrium between keto and enol tautomers lie far to the keto side?

I. The keto form is more thermodynamically stable.
II. The enol form is lower energy.
III. The enol form is more thermodynamically stable.

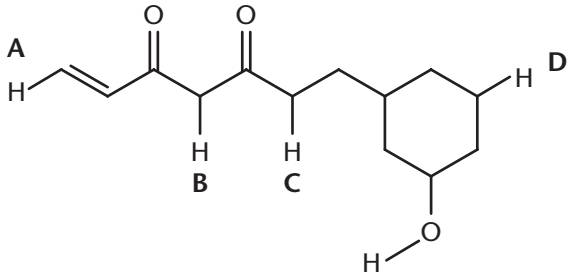
A. I only
B. III only
C. I and II only
D. II and III only

5. The aldol condensation is an example of which reaction type(s)?

I. Dehydration
II. Cleavage
III. Nucleophilic addition

A. I only
B. I and III only
C. II and III only
D. I, II, and III

6. Which of the hydrogens in the following molecule is the most acidic?



A. A
B. B
C. C
D. D

7. When reacted with ammonia (NH_3) at 200°C, which enolate of a carbonyl-containing compound would predominate?

A. Kinetic enolate
B. Thermodynamic enolate
C. Neither enolate; they would be present in roughly equal proportions.
D. Neither enolate; these reaction conditions would not form either enolate.

8. Which of the following compounds would be most reactive toward a nucleophile?

A. Pentanal
B. 3-pentanone
C. Pentane
D. 2-nonanone

9. α-hydrogens of a ketone are acidic due to:

I. resonance stabilization.
II. the electron-withdrawing properties of the alkyl groups.
III. the electronegative carbonyl oxygen.

A. I only
B. I and III only
C. II and III only
D. I, II, and III

10. Which of the following is considered a tautomer of the imine functional group?

A. Cyanohydrin
B. Hydrazone
C. Enamine
D. Semicarbazone

11. When succinaldehyde is treated with lithium diisopropylamide (LDA), it:

I. becomes more nucleophilic.
II. becomes less nucleophilic.
III. generates a carbanion.

A. I only
B. II only
C. I and III only
D. II and III only

12. Which of the following best describes the final product of an aldol condensation?

A. 1,3-dicarbonyl
B. 1,2-dicarbonyl
C. α,β-unsaturated carbonyl
D. β,γ-unsaturated carbonyl

13. When benzaldehyde is reacted with acetone, which will act as the nucleophile?

A. Benzaldehyde, after addition of strong acid
B. Benzaldehyde, after reaction with strong base
C. Acetone, after addition of strong acid
D. Acetone, after reaction with strong base

14. 3-hydroxybutanal can be formed by the reaction of:

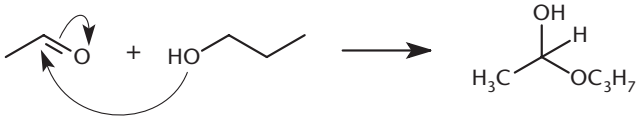
A. methanol in diethyl ether.
B. ethanal in base, then in acid.
C. butanal in strong acid.
D. methanal and ethanal in catalytic base.

15. The catalytic production of dihydroxyacetone and glyceraldehyde 3-phosphate (2-hydroxy-3-oxopropyl dihydrogen phosphate) from fructose-1,6-bisphosphate ({[(2*S*,3*S*,4*S*,5*R*)-3,4-dihydroxy-5-[(phosphonooxy) methyl]oxolan-2-yl]methoxy}phosphonic acid) is what type of reaction?

A. Aldol condensation
B. Retro-aldol reaction
C. Dehydration
D. Nucleophilic attack

Explanations to Discrete Practice Questions

1. D



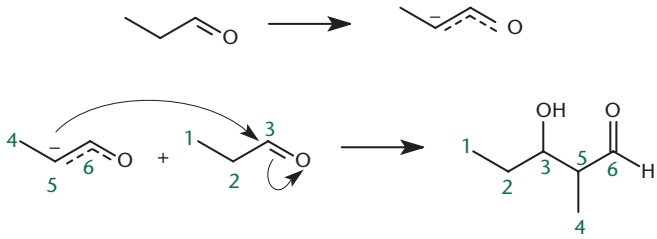
One mole of aldehyde reacts with one mole of alcohol via a nucleophilic addition reaction to form a product called a hemiacetal. In a hemiacetal, an –OH group, an –OR group, a hydrogen atom, and an –R group are attached to the same carbon atom.

2. B

Tautomerization is the interconversion of two isomers in which a hydrogen and a double bond are moved. The keto and enol tautomers of aldehydes and ketones are common examples of tautomers seen on Test Day. Note that the equilibrium lies to the left because the keto form is more stable. Esterification, **choice (A)**, is the formation of esters from carboxylic acids and alcohols. Elimination, **choice (C)**, is a reaction in which a part of a reactant is removed and a new multiple bond is introduced. Dehydration, **choice (D)**, is a reaction in which a molecule of water is eliminated.

3. D

The reactions listed in the answer choices are examples of aldol condensations. In the presence of a base, the α-hydrogen is abstracted from an aldehyde, forming an enolate ion, $[CH_3CHCHO]^-$. This enolate ion then attacks the carbonyl group of the other aldehyde molecule, CH_3CH_2CHO, forming the pictured aldol.



4. A

The keto–enol equilibrium lies far to the keto side because the keto form is significantly more thermodynamically stable than the enol form. This thermodynamic stability stems from the fact that the oxygen is more electronegative than the carbon, and the keto tautomer puts more electron density around the oxygen than the enol tautomer. If the enol tautomer is less thermodynamically stable, it is also higher energy than the keto tautomer.

5. B

The aldol condensation is both a dehydration reaction because a molecule of water is lost, and a nucleophilic addition reaction because the nucleophilic enolate attacks and bonds to the carbonyl carbon.

6. B

This hydrogen is on the carbon between two carbonyls, which means that it is particularly acidic. This is due to both the inductive effects of the two oxygen atoms in the carbonyls and the resonance stabilization of the anion between the carbonyl groups.

7. B

At high temperatures and with a weak base like NH_3, the thermodynamic enolate will be favored. The reaction proceeds

slowly with the weak base, giving the kinetic enolate time to interconvert to the more stable thermodynamic enolate.

8. A

Aldehydes are generally more reactive than ketones because the additional alkyl group of a ketone is sterically hindering; this alkyl group is also electron-donating, destabilizing the carbanion intermediate. This eliminates **choices (B)** and **(D)**. The carbonyl carbon is highly electrophilic; alkanes lack any significant electrophilicity, eliminating **choice (C)**.

9. B

When α-carbons are deprotonated, the negative charge is resonance stabilized in part by the electronegative carbonyl oxygen, which is electron-withdrawing. Alkyl groups are actually electron-donating, which destabilizes carbanion intermediates; this invalidates statement II.

10. C

All of the answer choices are nitrogen-containing functional groups, but only enamines are tautomers of imines. Imines contain a double bond between a carbon and a nitrogen; enamines contain a double bond between two carbons as well as an amine.

11. C

When succinaldehyde (or any aldehyde or ketone with α-hydrogens) is treated with a strong base like lithium diisopropylamide (LDA), it forms the more nucleophilic enolate carbanion.

12. C

Aldol condensations contain two main steps. In the first step, the α-carbon of an aldehyde or ketone is deprotonated, generating the enolate carbanion. This carbanion can then attack another aldehyde or ketone, generating the aldol. In the second step, the aldol is dehydrated, forming a double bond. This double bond is between the α- and β-carbons, so the molecule is an α,β-unsaturated carbonyl.

13. D

Because benzaldehyde lacks an α-proton, it cannot be reacted with base to form the nucleophilic enolate carbanion. Therefore, acetone will act as our nucleophile, and both **choices (A)** and **(B)** can be eliminated. In order to perform this reaction, which is an aldol condensation, acetone will be reacted with a strong base—not a strong acid—in order to extract the α-hydrogen and form the enolate anion, which will act as a nucleophile.

14. B

This is an example of an aldol condensation, but stopped after aldol formation (before dehydration). After the aldol is formed using strong base, the reaction may be halted by the addition of acid. Butanal in strong acid, described in **choice (C)**, would be likely to deprotonate without gaining the hydroxyl group. Methanal in diethyl ether would not be reactive because diethyl ether is not a strong enough base to abstract the α-hydrogen, eliminating **choice (A)**. Reaction of the two aldehydes methanal and ethanal in catalytic base would form 3-hydroxypropanal (which would dehydrate to form propenal), not 3-hydroxybutanal.

15. B

The nomenclature in this question is well above what one needs to be able to draw on the MCAT; however, we can discern that we are forming a ketone and an aldehyde from a single molecule. The hallmark of a reverse aldol reaction is the breakage of a carbon–carbon bond, forming two aldehydes, two ketones, or one of each. In an aldol condensation, **choice (A)**, we would expect to form a single product by combining two aldehydes, two ketones, or one of each. A dehydration reaction, **choice (C)**, should release a water molecule, rather than breaking apart a large organic molecule into two smaller molecules. A nucleophilic attack, **choice (D)**, should feature the formation of a bond between a nucleophile and an electrophile; again, we would not expect to break apart a large organic molecule into two smaller molecules. Note that simply noting how many reactants and products are present in the reaction is sufficient to determine the answer.

Concept Summary 193

Introduction

Carboxylic acids, with both carbonyl and hydroxyl groups, are some of the most reactive organic molecules you'll encounter on Test Day. As we will see in this chapter, these molecules can react as acids (as their name suggests), nucleophiles, and electrophiles, and are integral to many biological processes. Carboxylic acids are found in soaps, oils, preservatives, skin care products, clothing, and—most importantly for the MCAT—amino acids. Carboxylic acids often have strong, unpleasant odors. For example, acetic acid (ethanoic acid) is the main ingredient in vinegar; propionic acid (propanoic acid) gives Swiss cheese its smell; butyric acid (butanoic acid) is found in rancid butter and body odor.

So what makes carboxylic acids so interesting and versatile? First, they're acids, so they like to give away protons—particularly because when they do so, the remaining negative charge resonates between two oxygen atoms, making the anion very stable. This makes carboxylic acids some of the most acidic compounds encountered in organic chemistry, with pK_a values between 3 and 6. Compare this with alcohols, which have an average pK_a around 17. Carboxylic acids are also excellent at hydrogen bonding, which results in large intermolecular forces and high boiling points. Finally, carboxylic acids are ubiquitous in nature and are synthesized by all living organisms.

8.1 Description and Properties ★★

A **carboxylic acid** contains both a carbonyl group and a hydroxyl group, bonded to the same carbon. With three bonds to oxygen atoms, this is one of the most oxidized functional groups encountered in organic chemistry. Carboxylic acids are always terminal groups.

NOMENCLATURE

In the IUPAC system of nomenclature, carboxylic acids are named by adding the suffix ***–oic acid*** to the parent root when the carboxylic acid is the highest-priority functional group. When this is true, the carbonyl carbon becomes carbon number 1. Figure 8.1 shows two examples.

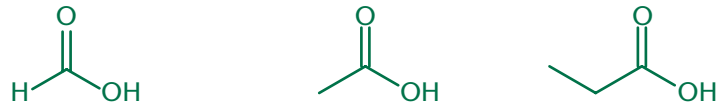
2-methylpentanoic acid　　4-isopropyl-5-oxohexanoic acid

Figure 8.1. IUPAC Names of Carboxylic Acids

Like the other functional groups, many carboxylic acids are also named by their common names. Make note of the common prefixes used in the examples in Figure 8.2.

MCAT Expertise

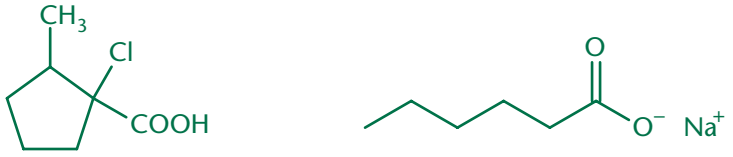
The same common-name prefixes are used for both aldehydes and carboxylic acids: *form–* for one carbon, *acet–* for two, and *propion–* for three.



methanoic acid (formic acid)　　ethanoic acid (acetic acid)　　propanoic acid (propionic acid)

Figure 8.2. IUPAC and Common Names of Carboxylic Acids

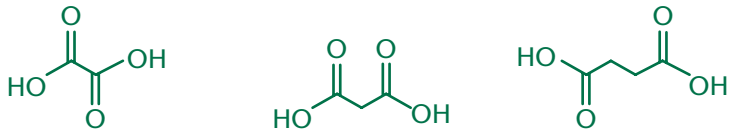
Cyclic carboxylic acids are named by listing the cycloalkane with the suffix ***carboxylic acid***. Salts of carboxylic acids are named beginning with the cation, followed by the name of the acid with the ending ***–oate*** replacing ***–oic acid***. Typical examples are shown in Figure 8.3.



1-chloro-2-methylcyclopentane carboxylic acid　　sodium hexanoate

Figure 8.3. Cyclic Carboxylic Acid and Carboxylic Acid Salt

Finally, **dicarboxylic acids**, which have a carboxylic acid group on each end of the molecule, are common in biological systems. The smallest dicarboxylic acid is *oxalic acid*, with two carbons. The next five straight-chain dicarboxylic acids are *malonic*, *succinic*, *glutaric*, *adipic*, and *pimelic* acids. Their IUPAC names have the suffix ***–dioic acid***: ethanedioic acid, propanedioic acid, butanedioic acid, pentanedioic acid, hexanedioic acid, and heptanedioic acid. Figure 8.4 shows several examples.



ethanedioic acid (oxalic acid) | propanedioic acid (malonic acid) | butanedioic acid (succinic acid)

Figure 8.4. IUPAC and Common Names of Dicarboxylic Acids

PHYSICAL PROPERTIES

Many of the physical properties of carboxylic acids are similar to those of aldehydes and ketones because they both contain carbonyl groups. However, the additional hydroxyl group permits carboxylic acids to hydrogen bond and provides another acidic hydrogen that can participate in reactions.

Hydrogen Bonding

Carboxylic acids are polar because they contain a carbonyl group and can also form hydrogen bonds because they contain a hydrogen bonded to a very electronegative atom (in this case, the hydroxyl oxygen). Carboxylic acids display particularly strong intermolecular attractions because both the hydroxyl oxygen and carbonyl oxygen can participate in hydrogen bonding. As a result, carboxylic acids tend to form **dimers**: pairs of molecules connected by two hydrogen bonds. Multiple hydrogen bonds elevate the boiling and melting points of carboxylic acids past those of corresponding alcohols. Boiling points also increase with increasing molecular weight.

Key Concept

Carboxylic acids are polar and can form hydrogen bonds. Their acidity is due to resonance stabilization and can be enhanced by the addition of electronegative groups or a greater ability to delocalize charge.

Acidity

The hydroxyl hydrogen of a carboxylic acid is quite acidic. This results in a negative charge that remains after the hydrogen is removed and resonance stabilization occurs between both of the electronegative oxygen atoms. Delocalization of the negative charge results in a very stable carboxylate anion, which is demonstrated in Figure 8.5.

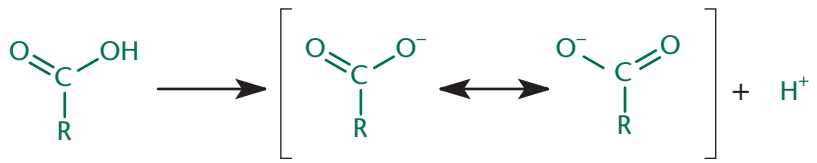


Figure 8.5. Carboxylate Anion Stability
The negative charge from deprotonation is stabilized through resonance.

The more stable the conjugate base is, the easier it is for the proton to leave, and thus, the stronger the acid. Carboxylic acids are relatively acidic, with pK_a values on the order of 4.8 for ethanoic acid and 4.9 for propanoic acid.

However, keep in mind that although these are quite acidic for organic compounds, they do not compare to strong acids like HCl ($pK_a = -8.0$) or even HSO_4^- ($pK_a = 1.99$). Remember, lower pK_a values indicate stronger acids.

Substituents on carbon atoms near a carboxyl group influence anion stability and therefore affect acidity. Groups like $-NO_2$ or halides are electron-withdrawing and increase acidity. In contrast, $-NH_2$ or $-OCH_3$ are electron-donating groups that destabilize the negative charge, decreasing the acidity of the compound. The closer the substituent groups are to the carboxyl group, the greater the effect will be.

In dicarboxylic acids, each –COOH group influences the other –COOH group. Carboxylic acids are electron-withdrawing due to the electronegative oxygen atoms they contain. The net result is that dicarboxylic acids are more acidic than the analogous monocarboxylic acids. However, when one proton is removed from the molecule, the carboxylate anion is formed, resulting in an immediate decrease in the acidity of the remaining carboxylic acid. This makes sense because if the second group were deprotonated, it would create a doubly charged species with two negative charges repelling each other. Due to this instability, the second proton is actually *less* acidic (harder to remove) than the analogous proton of a monocarboxylic acid.

Key Concept

The hydroxyl hydrogen is the most acidic proton on a carboxylic acid. However, in 1,3-dicarbonyls, the α-hydrogen is also quite acidic.

β-dicarboxylic acids are dicarboxylic acids in which each carboxylic acid is positioned on the β-carbon of the other; in other words, there are two carboxylic acids separated by a single carbon. These compounds are notable for the high acidity of the α-hydrogens located on the carbon between the two carboxyl groups ($pK_a \approx 9$–14). Loss of this acidic hydrogen atom produces a carbanion, which is stabilized by the electron-withdrawing effect of both carboxyl groups, as shown in Figure 8.6.

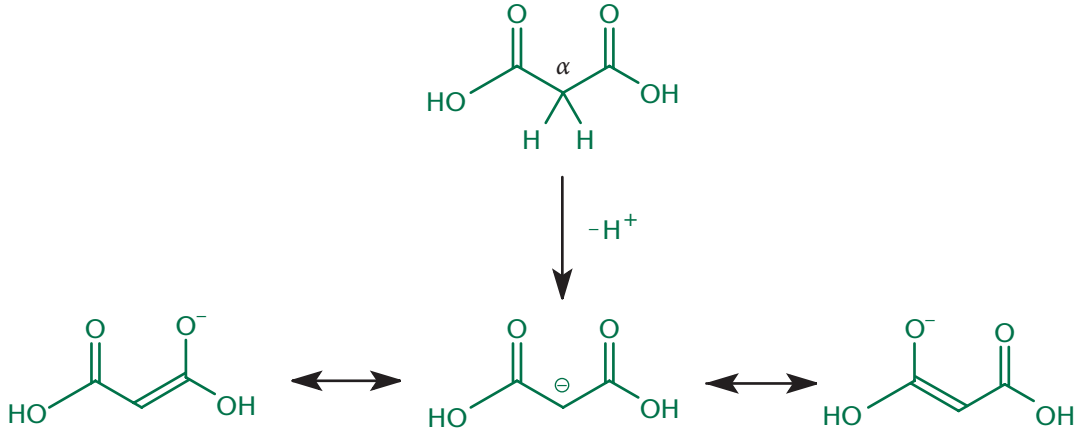

Figure 8.6. Acidity of the α-Hydrogen in β-Dicarboxylic Acids
Note that the α-hydrogen is less acidic than the hydroxyl hydrogens; the hydroxyl groups are left protonated in this example for demonstration purposes only.

Note that this also applies to the α-hydrogens in a β-diketone, β-ketoacids, β-dialdehydes, and other molecules that share the 1,3-dicarbonyl structure shown in Figure 8.7.

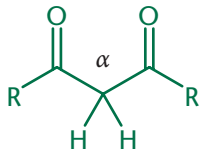

Figure 8.7. General Structure of 1,3-Dicarbonyl Compounds

MCAT Concept Check 8.1:

Before you move on, assess your understanding of the material with these questions.

1. What causes the relatively high acidity of carboxylic acids?

   _____

   _____

2. Between a monocarboxylic acid, a dicarboxylic acid, and a dicarboxylic acid that has been deprotonated once, which will be the most acidic? Why?

   _____

   _____

3. What effects do additional substituents have on the acidity of carboxylic acids?

   _____

   _____

   _____

8.2 Reactions of Carboxylic Acids ★★★

The properties of carboxylic acids make them highly reactive in a number of different categories. Several of the most important reactions are described here.

SYNTHESIS OF CARBOXYLIC ACIDS

As described in earlier chapters, carboxylic acids can be prepared via oxidation of aldehydes and primary alcohols. The oxidant is often a dichromate salt ($Na_2Cr_2O_7$

or $K_2Cr_2O_7$), chromium trioxide (CrO_3), or potassium permanganate ($KMnO_4$), as shown in Figure 8.8, but several other oxidizing agents can also work. Remember that secondary and tertiary alcohols cannot be oxidized to carboxylic acids because they already have at least two bonds to other carbons.

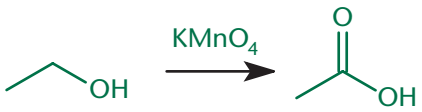

Figure 8.8. Synthesis of a Carboxylic Acid via Oxidation of a Primary Alcohol

There are many other methods of generating carboxylic acids, including organometallic reagents (Grignard reagents) and hydrolysis of nitriles (–C≡N), but these are outside the scope of the MCAT.

NUCLEOPHILIC ACYL SUBSTITUTION

Many of the reactions in which carboxylic acids (and their derivatives) participate proceed via a single mechanism: nucleophilic acyl substitution. This mechanism is similar to nucleophilic addition to an aldehyde or ketone, which was discussed in Chapters 6 and 7 of *MCAT Organic Chemistry Review*. The key difference, however, focuses on the existence of a leaving group in carboxylic acids and their derivatives. In this case, after opening the carbonyl via nucleophilic attack and forming a tetrahedral intermediate, the carbonyl can reform, thereby kicking off the leaving group. This reaction is shown in Figure 8.9.

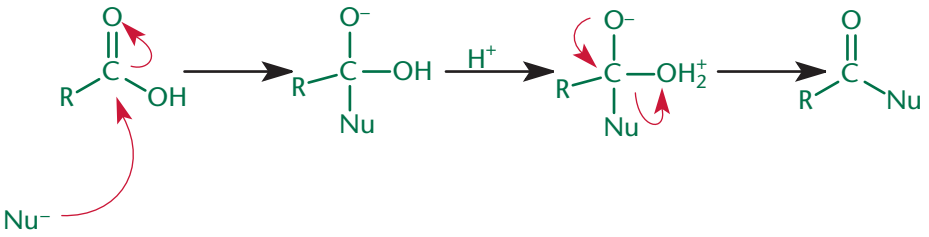

Figure 8.9. Nucleophilic Acyl Substitution
Step 1: Nucleophilic addition; Step 2: Elimination of the leaving group and reformation of the carbonyl.

MCAT Expertise

While you may have learned about other acyl derivatives in your organic chemistry classes, such as acyl halides and nitriles, the official content list for the MCAT restricts its focus to carboxylic acids, amides, esters, and anhydrides.

In these reactions, the nucleophilic molecule replaces the leaving group of an acyl derivative. **Acyl derivatives** encompass all molecules with a carboxylic acid-derived carbonyl, including carboxylic acids, amides, esters, anhydrides, and others. These reactions are favored by a good leaving group. Remember, weak bases, which are often the conjugate bases of strong acids, make good leaving groups. These reactions are also favored in either acidic or basic conditions, which can alter the reactivity of the electrophile and nucleophile.

Amides

Carboxylic acids can be converted into amides if the incoming nucleophile is ammonia (NH_3) or an amine, as shown in Figure 8.10. This can be carried out in either an acidic or basic solution to drive the reaction forward.

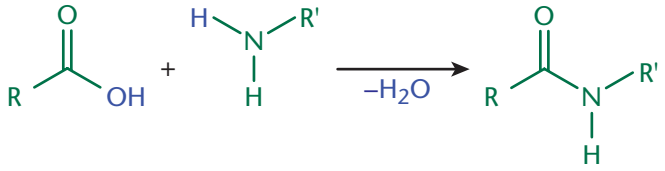

Figure 8.10. Formation of an Amide by Nucleophilic Acyl Substitution

Amides are named by replacing the ***–oic acid*** suffix with ***–amide*** in the name of the parent carboxylic acid. Any alkyl groups on the nitrogen are placed at the beginning of the name with the prefix ***N–***. Amides exist in a resonance state where delocalization of electrons occurs between the oxygen and nitrogen atoms, as shown in Figure 8.11.

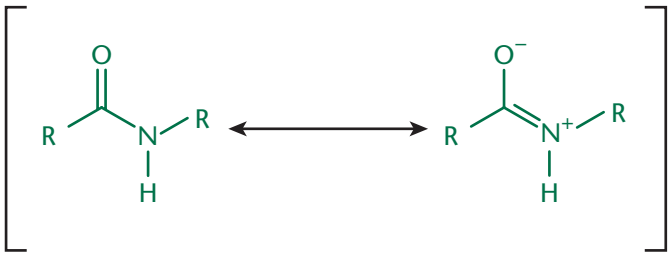

Figure 8.11. Resonance of Amides
Resonance between the carbonyl and lone pair on the nitrogen stabilizes this bond and restricts its motion.

Amides that are cyclic are called **lactams** and are named by replacing ***–oic acid*** with ***–lactam***. They may also be named by indicating the specific carbon that is bonded during cyclization of the compound. Several examples are shown in Figure 8.12.

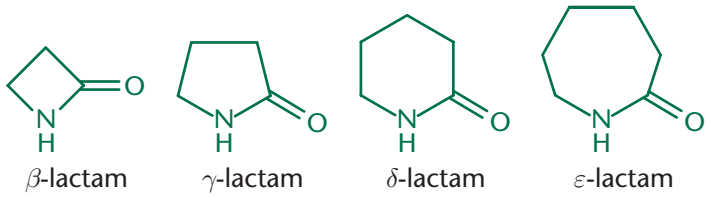

Figure 8.12. Examples of Lactams

Esters

Esters are a hybrid between a carboxylic acid and an ether (ROR′), which can be made by reacting carboxylic acids with alcohols under acidic conditions, as shown in Figure 8.13. **Esterification** is a **condensation** reaction with water as a side product. In acidic solutions, the carbonyl oxygen can be protonated,

Key Concept

Protonating the C=O makes the electrophilic carbon even more ripe for nucleophilic attack.

which enhances the polarity of the bond, thereby placing additional positive charge on the carbonyl carbon and increasing its susceptibility to nucleophilic attack. This condensation reaction occurs most rapidly with primary alcohols.

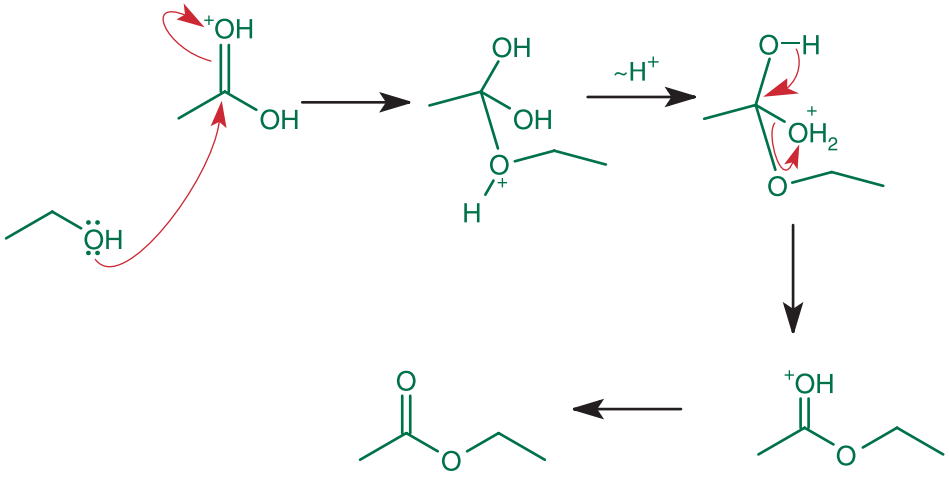

Figure 8.13. Esterification: Reaction of a Carboxylic Acid with an Alcohol

Esters are named in the same manner as salts of carboxylic acids. For example, the ester shown in the reaction in Figure 8.13 has the common name ethyl acetate, or the IUPAC name ethyl ethanoate.

Esters that are cyclic are called **lactones** and are named by replacing ***–oic acid*** with ***–lactone***. Several examples are shown in Figure 8.14.

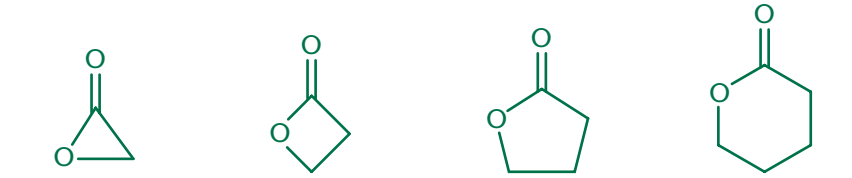

Figure 8.14. Examples of Lactones

Anhydrides

Anhydrides can be formed by the condensation of two carboxylic acids. They are named by replacing the ***acid*** at the end of the name of the parent carboxylic acid with ***anhydride***, whether cyclic or linear. One example is the condensation of two molecules of ethanoic acid to form ethanoic anhydride, as shown in Figure 8.15. Just like the above reactions, anhydride formation occurs via nucleophilic acyl substitution.

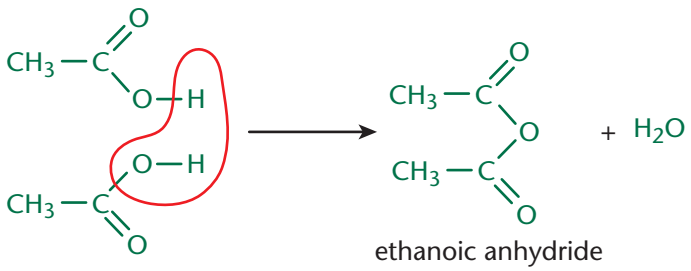

Figure 8.15. Synthesis of an Anhydride via Carboxylic Acid Condensation

REDUCTION

Carboxylic acids can be reduced to primary alcohols by the use of lithium aluminum hydride ($LiAlH_4$). Aldehyde intermediates may be formed in the course of this reaction, but they, too, will be reduced to the alcohol. The reaction occurs by nucleophilic addition of hydride to the carbonyl group. The reaction mechanism is shown in Figure 8.16.

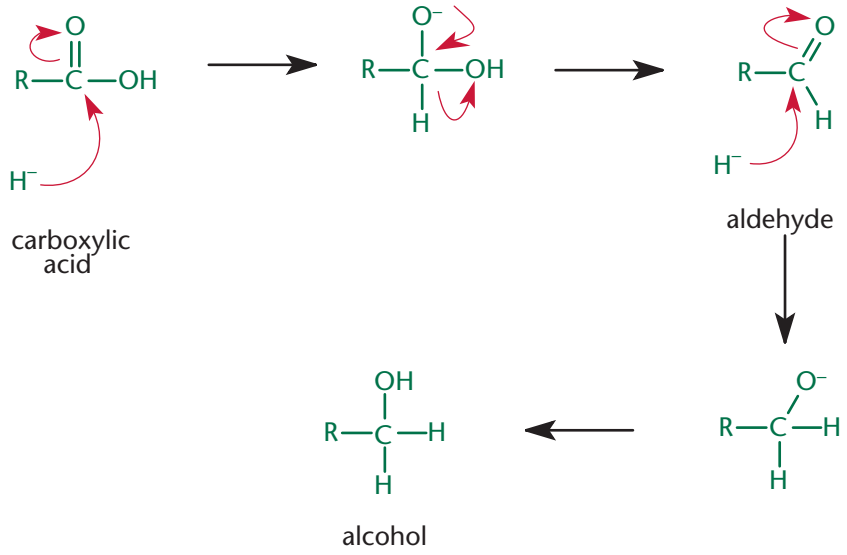

Figure 8.16. Reduction of a Carboxylic Acid to a Primary Alcohol
Reaction occurs by nucleophilic addition of hydride and proceeds through an aldehyde intermediate.

Lithium aluminum hydride is a strong reducing agent that can successfully reduce a carboxylic acid; a gentler reducing agent like sodium borohydride ($NaBH_4$) is not strong enough to reduce carboxylic acids.

Key Concept

Carboxylic acids can be reduced by $LiAlH_4$, but not the less reactive $NaBH_4$.

DECARBOXYLATION

Decarboxylation describes the complete loss of the carboxyl group as carbon dioxide. This is a common way of getting rid of a carbon from the parent chain.

Bridge

Decarboxylation is common in biochemical pathways in the body. *Pyruvate dehydrogenase complex*, described in Chapter 10 of *MCAT Biochemistry Review*, carries out the decarboxylation of pyruvate to help form acetyl-CoA, which can feed into the citric acid cycle.

1,3-dicarboxylic acids and other β-keto acids may spontaneously decarboxylate when heated. Under these conditions, the carboxyl group is lost and replaced with hydrogen. Because both the electrophile and nucleophile are in the same molecule, the reaction proceeds through a six-membered ring in its transition state, as shown in Figure 8.17. The enol that is initially formed from the destruction of the ring tautomerizes to the more stable keto form.

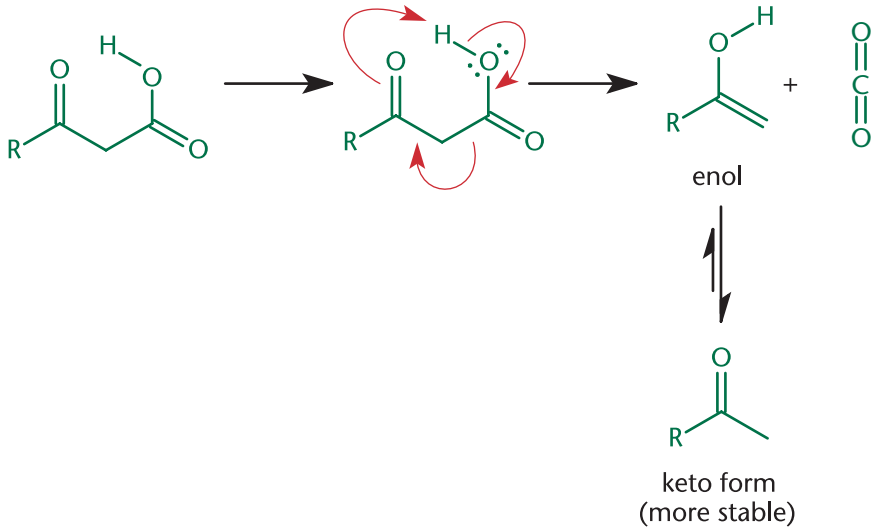

Figure 8.17. Decarboxylation of Carboxylic Acids: Loss of CO_2
The intramolecular reaction proceeds via a six-membered ring transition state, and the product tautomerizes from the enol to the more stable keto form.

SAPONIFICATION

When long-chain carboxylic acids react with sodium or potassium hydroxide, a salt is formed. This process, called **saponification**, occurs by mixing fatty acids with lye (sodium or potassium hydroxide), resulting in the formation of a salt that we know as **soap**. Soaps can solvate nonpolar organic compounds in aqueous solutions because they contain both a nonpolar tail and a polar carboxylate head, as shown in Figure 8.18.

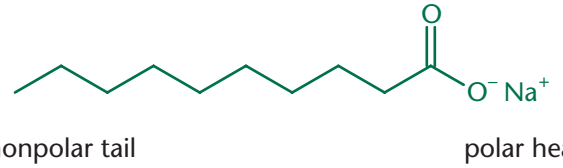

Figure 8.18. Carboxylic Acid Salt (Soap)

When placed in aqueous solution, soap molecules arrange themselves into spherical structures called micelles, as shown in Figure 8.19. The polar heads face outward, where they can be solvated by water, and the nonpolar hydrocarbon chains are

oriented toward the inside of the sphere, protected from the solvent. Nonpolar molecules, such as grease, dissolve in the hydrocarbon interior of the spherical micelle; the micelle as a whole then dissolves in water due to the polarity of its exterior surface.

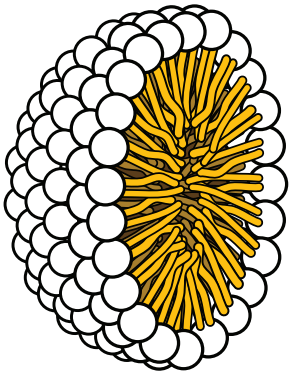

Figure 8.19. Soap Micelle
The polar heads interact with the hydrophilic environment; the nonpolar tails are oriented toward the interior of the micelle.

Bridge

The formation of the phospholipid bilayer, micelles, and liposomes are all contingent on the bipolar nature of carboxylic acids with long hydrocarbon chains. These structures are discussed in Chapter 5 of *MCAT Biochemistry Review*.

MCAT Concept Check 8.2:

Before you move on, assess your understanding of the material with these questions.

1. For each of the derivatives below, list the nucleophile used to form the derivative in an acyl substitution reaction and the name of the cyclic form of that functional group.

Carboxylic Acid Derivative	Formed by Reaction with:	Name of Cyclic Form:
Amide		
Ester		
Anhydride		

2. Briefly describe the mechanism of nucleophilic acyl substitution reactions.

_____

_____

_____

3. Can carboxylic acids be reduced by sodium borohydride? **Yes** or **No**

4. Under what conditions will a carboxylic acid spontaneously decarboxylate?

_____

_____

Conclusion

Acids are an important concept on the MCAT: they can be tested in general chemistry, organic chemistry, and biochemistry. The underlying concept in all three subjects is the same: the more stable the conjugate base is, the more likely it is that the proton will leave. This stability is determined by three factors: periodic trends (electronegativity and, thus, induction), size of the anion, and resonance. Understanding these effects is a major key to success on Test Day. The reactions of carboxylic acids, in particular, are dictated by the polarity of the carbonyl group in conjunction with the ability of the hydroxyl group to act as a leaving group. This allows a diversity of reactions through nucleophilic acyl substitution, reduction by lithium aluminum hydride, decarboxylation, and saponification.

CONCEPT SUMMARY

Description and Properties

- **Carboxylic acids** contain a carbonyl and a hydroxyl group connected to the same carbon. They are always terminal groups.
- Carboxylic acids are indicated with the suffix ***–oic acid***. Salts are named with the suffix ***–oate***, and **dicarboxylic acids** are ***–dioic acids***.
- Physical Properties
  - Carboxylic acids are polar and hydrogen bond very well, resulting in high boiling points. They often exist as **dimers** in solution.
  - The acidity of a carboxylic acid is enhanced by the resonance between its oxygen atoms.
  - Acidity can be further enhanced by substituents that are electron-withdrawing, and decreased by substituents that are electron-donating.
  - **β-dicarboxylic acids**, like other 1,3-dicarbonyl compounds, have an α-hydrogen that is also highly acidic.

Reactions of Carboxylic Acids

- Carboxylic acids can be made by the oxidation of primary alcohols or aldehydes using an oxidizing agent like potassium permanganate ($KMnO_4$), dichromate salts ($Na_2Cr_2O_7$ or $K_2Cr_2O_7$), or chromium trioxide (CrO_3).
- **Nucleophilic acyl substitution** is a common reaction in carboxylic acids.
  - A nucleophile attacks the electrophilic carbonyl carbon, opening the carbonyl and forming a tetrahedral intermediate.
  - The carbonyl reforms, kicking off the leaving group.
  - If the nucleophile is ammonia or an amine, an **amide** is formed. Amides are given the suffix ***–amide***. Cyclic amides are called **lactams**.
  - If the nucleophile is an alcohol, an **ester** is formed. Esters are given the suffix ***–oate***. Cyclic esters are called **lactones**.
  - If the nucleophile is another carboxylic acid, an **anhydride** is formed. Both linear and cyclic anhydrides are given the suffix ***anhydride***.
- Carboxylic acids can be reduced to a primary alcohol with a strong reducing agent like lithium aluminum hydride ($LiAlH_4$).
  - Aldehyde intermediates are formed, but are also reduced to primary alcohols.
  - Sodium borohydride ($NaBH_4$) is a common reducing agent for other organic reactions, but is not strong enough to reduce a carboxylic acid.

- β-dicarboxylic acids and other β-keto acids can undergo spontaneous **decarboxylation** when heated, losing a carbon as carbon dioxide. This reaction proceeds via a six-membered cyclic intermediate.
- Mixing long-chain carboxylic acids (fatty acids) with a strong base results in the formation of a salt we call **soap**. This process is called **saponification**.
  - Soaps contain a hydrophilic carboxylate head and hydrophobic alkyl chain tail.
  - Soaps organize in hydrophilic environments to form **micelles**. A micelle dissolves nonpolar organic molecules in its interior, and can be solvated with water due to its exterior shell of hydrophilic groups.

ANSWERS TO CONCEPT CHECKS

8.1

1. Carboxylic acids are particularly acidic due to the electron-withdrawing oxygen atoms in the functional group and the high stability of the carboxylate anion, which is resonance stabilized by delocalization with two electronegative oxygen atoms.
2. A dicarboxylic acid would be the most acidic, as the second carboxyl group is electron-withdrawing and therefore contributes to even higher stability of the anion after loss of the first hydrogen. However, a monocarboxylic acid is more acidic than a deprotonated dicarboxylic acid because the carboxylate anion is electron-donating and destabilizes the product of the second deprotonation step, resulting in decreased acidity.
3. Electron-withdrawing substituents make the anion more stable and therefore increase acidity. Electron-donating substituents, on the other hand, destabilize the anion, causing the carboxylic acid to be less acidic. The closer the substituent is to the carboxylic acid on the molecule, the stronger the effect will be.

8.2

1.

Carboxylic Acid Derivative	Formed by Reaction with:	Name of Cyclic Form:
Amide	Ammonia (NH_3) or an amine	Lactam
Ester	Alcohol	Lactone
Anhydride	Another carboxylic acid	Anhydride

2. Nucleophilic acyl substitution is the substitution of an attacking nucleophile for the leaving group of an acyl compound, which includes carboxylic acids, amides, esters, and anhydrides. The nucleophile attacks, opening the carbonyl and forming a tetrahedral intermediate. The carbonyl then reforms, kicking off the leaving group. This reaction is favored by acidic or basic conditions.
3. Sodium borohydride is not strong enough to reduce carboxylic acids. Lithium aluminum hydride, however, is strong enough, and reduces carboxylic acids to primary alcohols.
4. 1,3-dicarboxylic acids will spontaneously decarboxylate when heated, due to the stable cyclic intermediate step.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of these compounds would be expected to decarboxylate when heated?

A. 
C. 
B. 
D. 
2. Carboxylic acids have higher boiling points than their corresponding alcohols primarily because:

A. molecular weight is increased by the additional carboxyl group.
B. the pH of the compound is lower.
C. acid salts are soluble in water.
D. hydrogen bonding is much stronger than in alcohols.

3. Which of the following carboxylic acids will be the most acidic?

A. $CH_3CHClCH_2COOH$
B. $CH_3CH_2CCl_2COOH$
C. $CH_3CH_2CHClCOOH$
D. $CH_3CH_2CH_2COOH$

4. Which of the following molecules could be classified as a soap?

A. $CH_3(CH_2)_{19}COOH$
B. CH_3COOH
C. $CH_3(CH_2)_{19}COO^-Na^+$
D. $CH_3COO^-Na^+$

5. What is the final product of the following reaction?

$$CH_3(CH_2)_4CH_2OH \xrightarrow[\text{acetone}]{CrO_3,\ H_2SO_4}$$

A. $CH_3(CH_2)_4CHO$
B. $CH_3(CH_2)_4COOH$
C. $CH_3(CH_2)_4CH_3$
D. $HOOC(CH_2)_4COOH$

6. Carboxylic acids can be reacted in one step to form all of the following compounds EXCEPT:

A. esters.
B. amides.
C. alkenes.
D. alcohols.

7. The reduction of a carboxylic acid using lithium aluminum hydride will yield what final product?

A. An aldehyde
B. An ester
C. A ketone
D. An alcohol

8. Which of the following is true with respect to a micelle in a hydrophilic environment?

A. The interior is hydrophilic.
B. The structure, as a whole, is hydrophobic.
C. It is composed of short-chain fatty acids with polar heads.
D. It can dissolve nonpolar molecules deep in its core.

9. In the presence of an acid catalyst, the major product of butanoic acid and 1-pentanol is:

A. 1-butoxy-1-pentanol.
B. butyl pentanoate.
C. 1-pentoxy-1-butanol.
D. pentyl butanoate.

10. The α-hydrogen of a carboxylic acid is:

I. more acidic than the hydroxyl hydrogen.
II. less acidic than the hydroxyl hydrogen.
III. relatively acidic, as organic compounds go.

A. I only
B. II only
C. I and III only
D. II and III only

11. The reaction of formic acid with sodium borohydride will yield what final product?

A. An aldehyde
B. A carboxylic acid
C. A ketone
D. An alcohol

12. The intramolecular reaction of 5-aminopentanoic acid through nucleophilic acyl substitution would result in a(n):

A. anhydride.
B. lactone.
C. lactam.
D. carboxylic acid.

13. Butanoic anhydride can be produced by the reaction of butanoic acid with which of the following compounds?

A. Butanoic acid
B. Ethanoic acid
C. Butanol
D. Methanal

14. Nucleophilic acyl substitution is favored by:

I. basic solution.
II. acidic solution.
III. leaving groups that are strong bases.

A. I only
B. II only
C. I and II only
D. I, II, and III

15. The reaction of ammonia with caprylic acid, found in coconuts, would produce a(n):

A. ester.
B. anhydride.
C. alcohol.
D. water molecule.

Explanations to Discrete Practice Questions

1. D

This compound is a β-keto acid: a carbonyl functional group at the β-position from a carboxyl group. Decarboxylation occurs with β-keto acids and β-dicarboxylic acids because they can form a cyclic transition state that permits simultaneous hydrogen transfer and loss of carbon dioxide. **Choice (B)** is a diketone and does not have a single carboxyl group. **Choices (A)** and **(C)** are γ- and δ-dicarboxylic acids, respectively, and can decarboxylate but with more difficulty.

2. D

The boiling points of compounds depend on the strength of the attractive forces between molecules. In both alcohols and carboxylic acids, the major form of intermolecular attraction is hydrogen bonding; however, hydrogen bonding is much stronger in carboxylic acids as compared to alcohols because carboxylic acids are more polar and the carbonyl also contributes to hydrogen bonding in addition to the hydroxyl group. The stronger hydrogen bonds elevate the boiling points of carboxylic acids compared to alcohols. Boiling points also depend on molecular weight, **choice (A)**, but in this case, the difference in molecular weight is insignificant compared to the effect of hydrogen bonding. **Choices (B)** and **(C)** are both true but do not explain the difference in boiling points.

3. B

The acidity of carboxylic acids is significantly increased by the presence of highly electronegative functional groups. Their electron-withdrawing effect increases the stability of the carboxylate anion, favoring proton dissociation. This effect increases as the number of electronegative groups on the chain increases, and it also increases as the distance between the acid functionality and electronegative group decreases. This answer has two halogens bonded to it at a smaller distance from the carboxyl group compared to the other answers.

4. C

Soap is a salt of a carboxylate anion with a long hydrocarbon tail. **Choices (A)** and **(B)** are not salts of anionic compounds. **Choice (D)** is sodium acetate, which is a salt but does not contain the long hydrocarbon tail needed to be considered a soap.

5. B

Jones reagent (chromium trioxide in aqueous sulfuric acid) is an oxidizing agent. As such, it oxidizes primary alcohols directly to carboxylic acids. This reagent is too strong an oxidant to give an aldehyde, so **choice (A)** is incorrect; remember that pyridinium chlorochromate (PCC) is a common oxidizing agent used to convert alcohols to aldehydes without progressing to a carboxylic acid. **Choice (D)**, a dicarboxylic acid, cannot form because there is no functional group on the other end of the molecule for the reagent to attack, and it cannot attack an inert alkane. **Choice (C)** represents reduction, not oxidation.

6. C

Carboxylic acids cannot be converted into alkenes in one step. Esters, **choice (A)**, are formed in nucleophilic acyl substitution reactions with alcohols. Amides, **choice (B)**, are formed by nucleophilic acyl substitution reactions with ammonia. Alcohols, **choice (D)**, may be formed using a variety of reducing agents. To form alkenes, carboxylic acids may be reduced to alcohols, which can then be transformed into alkenes by elimination in a second step.

7. D

Lithium aluminum hydride ($LiAlH_4$ or LAH) is a strong reducing agent. LAH can completely reduce carboxylic acids to primary alcohols. Aldehydes are intermediate products of this reaction; therefore, **choice (A)** is incorrect. The other compounds are not created through the reduction of a carboxylic acid.

8. D

Micelles are self-assembled aggregates of soap in which the interior is composed of long hydrocarbon (fatty) tails, which can dissolve nonpolar molecules. The outer surface is covered with carboxylate groups, which makes the overall structure water-soluble. Soaps, in general, are salts of long-chain hydrocarbons with carboxylate head groups.

9. D

The reaction described is esterification, in which the nucleophilic oxygen atom of 1-pentanol attacks the electrophilic carbonyl carbon of butanoic acid, ultimately displacing water to form pentyl butanoate. The acid catalyst is regenerated from 1-pentanol's released proton. C**hoice (A)** reverses the carbon chains, considering the butyl tail to be the esterifying group. Ethers do not form under these conditions, so **choices (B)** and **(C)** are also incorrect.

10. D

The α-hydrogen of a carboxylic acid is relatively acidic as far as organic compounds go, due to resonance stabilization. However, the hydroxyl hydrogen is significantly more acidic because it is able to share the negative charge resulting from deprotonation between both electronegative oxygen atoms in the functional group.

11. B

The reaction of formic acid, which is a simple carboxylic acid, with sodium borohydride, which is a mild reducing agent, will result in no reaction, and therefore will result in maintenance of the carboxylic acid. Sodium borohydride is too mild to reduce carboxylic acids, and therefore cannot produce the primary alcohols that lithium aluminum hydride, a strong reducing agent, would.

12. C

5-aminopentanoic acid contains a carboxylic acid and an amine. If this molecule undergoes intramolecular nucleophilic acyl substitution, it will form a cyclic amide. These molecules are called lactams. Lactones, **choice (B)**, are cyclic esters, not amides.

13. A

Butanoic anhydride is an anhydride with two butane R groups. Anhydrides are produced by the reaction of two carboxylic acids with the loss of a water molecule. Therefore, butanoic anhydride would be produced by the reaction of two molecules of butanoic acid.

14. C

Nucleophilic acyl substitutions are favored in basic solution, which makes the nucleophile more nucleophilic; in acidic solution, which makes the electrophile more electrophilic; and by good leaving groups. However, strong bases do not make good leaving groups; weak bases do.

15. D

Based on its name, caprylic acid must be a carboxylic acid. The reaction between a carboxylic acid and ammonia (NH_3) would produce an amide—which is not one of the options listed. Instead, we should take a look at the type of reaction occurring. The production of an amide from a carboxylic acid and ammonia occurs through a condensation reaction in which a molecule of water is removed as a leaving group.

Concept Summary 216

Introduction

We saw in the previous three chapters that carbonyls are susceptible to attack by everything from water to amines to other carbonyl-containing compounds (in the enol or enolate form). These reactions often result in the formation of carboxylic acid derivatives. Our focus in this chapter will be on describing the carboxylic acid derivatives that appear on the MCAT: amides, esters, and anhydrides. Each of these molecules replaces the –OH on the carboxyl group with another leaving group ($–NR_2$, –OR, and –OCOR, respectively). These each react in similar ways to carboxylic acids. Many of these functional groups are also critical for biochemical processes.

9.1 Amides, Esters, and Anhydrides ★★

Amides, esters, and anhydrides are all carboxylic acid derivatives. Each of these is formed by a **condensation** reaction with a carboxylic acid—a reaction that combines two molecules into one, while losing a small molecule. In this case, the small molecule is water, which is created from the hydroxyl group of the carboxylic acid and a hydrogen associated with the incoming nucleophile.

Key Concept

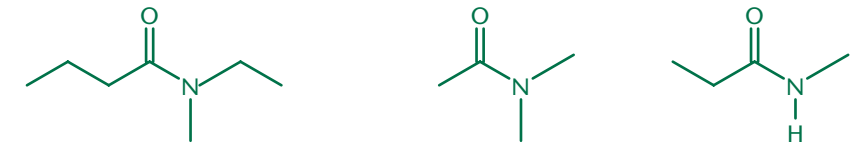
In a condensation reaction, two molecules are combined to form one, with the loss of a small molecule—water, in our case. Carboxylic acid derivatives are formed by this mechanism.

DESCRIPTIONS

For each of the carboxylic acid derivatives described in this section, focus on the relevant nucleophile that forms the derivative and the nomenclature of the functional group. In the next section, we'll focus more directly on the relative reactivity of these compounds.

Amides

Amides are compounds with the general formula $RCONR_2$. They are named by replacing the ***–oic acid*** suffix with ***–amide***. Alkyl substituents on the nitrogen atom are listed as prefixes, and their location is specified with the letter ***N***–. Figure 9.1 shows a few examples.



N-ethyl-*N*-methylbutanamide *N*,*N*-dimethylethanamide *N*-methylpropanamide

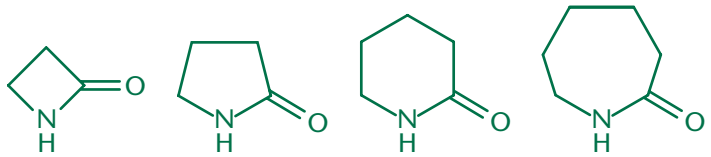
Figure 9.1. Naming Amides

Key Concept

Amides are formed by the condensation reaction of other carboxylic acid derivatives and ammonia or an amine.

Amides are generally synthesized by the reaction of other carboxylic acid derivatives with either ammonia or an amine. Note that loss of hydrogen from the nucleophile is required for this reaction to take place. Thus, only primary and secondary amines will undergo this reaction.

Cyclic amides are called **lactams**. These are named according to the carbon atom bonded to the nitrogen: β-lactams contain a bond between the β-carbon and the nitrogen, γ-lactams contain a bond between the γ-carbon and the nitrogen, and so forth. Structures of lactams are shown in Figure 9.2.



β-lactam γ-lactam δ-lactam ε-lactam

Figure 9.2. Examples of Lactams

Amides may or may not participate in hydrogen bonding depending on the number of alkyl groups they have bonded, and therefore their boiling points may be lower or on the same level as the boiling points of carboxylic acids.

Esters

Key Concept

Esters are formed by the condensation reaction of carboxylic acids or anhydrides with alcohols.

Esters are the dehydration synthesis products of other carboxylic acid derivatives and alcohols. They are named by placing the **esterifying group** (the substituent bonded to the oxygen) as a prefix; the suffix ***–oate*** replaces ***–oic acid***. Several examples are shown in Figure 9.3. As mentioned in the last chapter, ethyl acetate, derived from the condensation of acetic acid and ethanol, is called ethyl ethanoate according to IUPAC nomenclature.

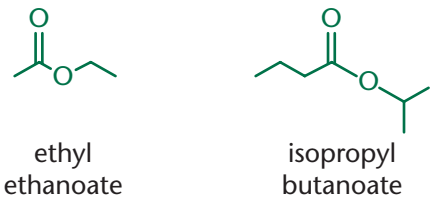


Figure 9.3. Naming Esters

Under acidic conditions, mixtures of carboxylic acids and alcohols will condense into esters. This reaction, called a **Fischer esterification**, is shown in Figure 9.4. Esters can also be obtained from the reaction of anhydrides with alcohols.

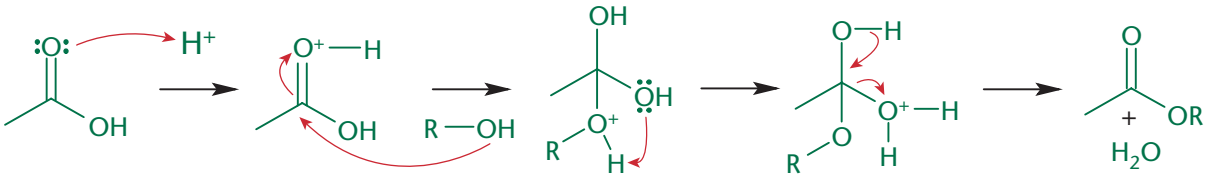

Figure 9.4. Fischer Esterification

Cyclic esters are called **lactones** and are named in the same manner as lactams, with the name of the precursor acid molecule also included. Examples are shown in Figure 9.5.

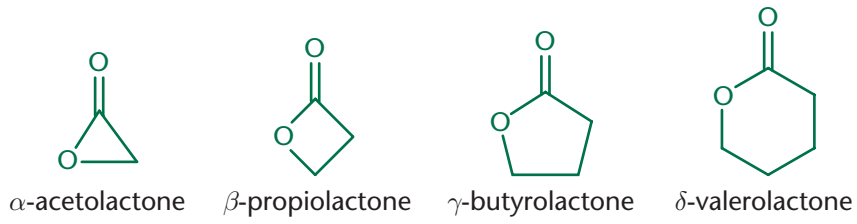

Figure 9.5. Examples of Lactones

Because they lack hydrogen bonding, esters usually have lower boiling points than their related carboxylic acids.

Triacylglycerols, the storage form of fats in the body, are esters of long-chain carboxylic acids (fatty acids) and *glycerol* (1,2,3-propanetriol). **Saponification** is the process by which fats are hydrolyzed under basic conditions to produce soap; saponification of a triacylglycerol is shown in Figure 9.6. Subsequent acidification of the soap regenerates the fatty acids.

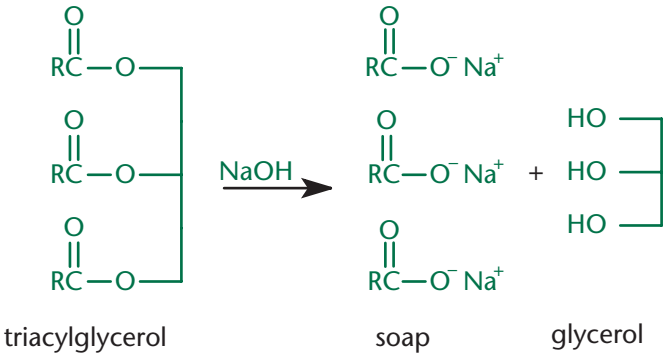

Figure 9.6. Saponification of a Triacylglycerol
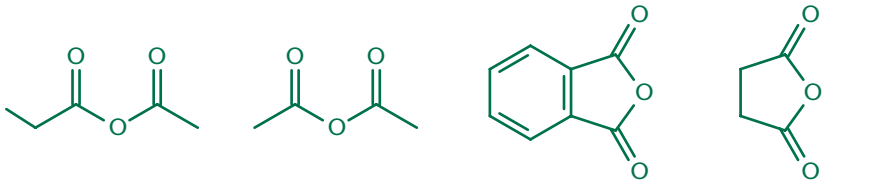
Treating triacylglycerols with NaOH will produce fatty acid salts (soap) as well as glycerol.

Anhydrides

Key Concept

Anhydrides are usually formed by the condensation reaction of two carboxylic acids.

Anhydrides, also called **acid anhydrides**, are the condensation dimers of carboxylic acids. These molecules have the general formula RC(O)OC(O)R. Symmetrical anhydrides are named by substituting the word ***anhydride*** for the word ***acid*** in a carboxylic acid. When anhydrides are asymmetrical, simply name the two chains alphabetically, followed by ***anhydride***, as shown in Figure 9.7. Phthalic and succinic anhydrides are cyclic anhydrides arising from intramolecular condensation or dehydration of diacids; their structures need not be memorized, but recognize them as cyclic anhydrides.



ethanoic propanoic anhydride | ethanoic anhydride (acetic anhydride) | phthalic anhydride | succinic anhydride

Figure 9.7. Naming Anhydrides

Acid anhydrides are synthesized, as mentioned previously, by a condensation reaction between two carboxylic acids, with one molecule of water lost in the condensation, as shown in Figure 9.8.

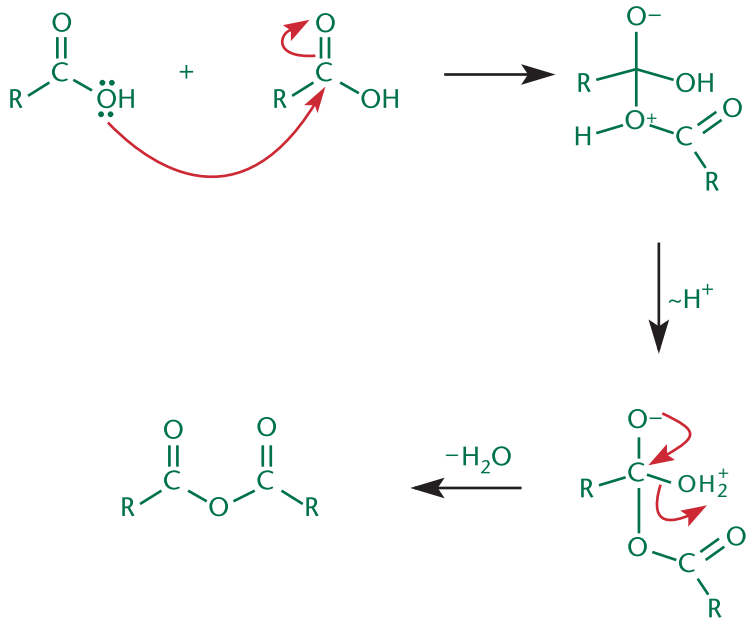


Figure 9.8. Synthesis of an Anhydride via Carboxylic Acid Condensation
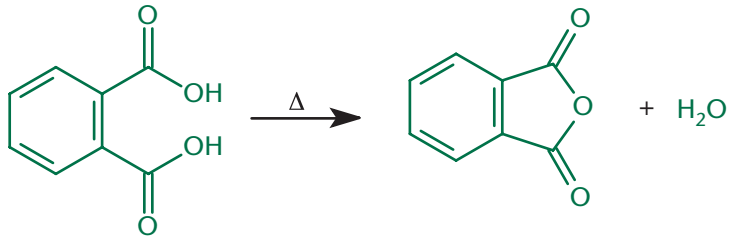
Two molecules of carboxylic acid come together and lose a molecule of water in the formation of an anhydride.

Certain cyclic anhydrides can be formed simply by heating carboxylic acids, as shown in Figure 9.9. The reaction is driven forward by the increased stability of the newly formed ring; as such, only anhydrides with five- or six-membered rings are easily made. Just as with all anhydride formations, the hydroxyl group of one –COOH acts as the nucleophile, attacking the carbonyl on the other –COOH.



ortho-phthalic acid phthalic anhydride

Figure 9.9. Intramolecular Anhydride Formation
Heat and the increased stability of the newly formed ring drive this intramolecular ring formation reaction forward.

Anhydrides often have higher boiling points than their related carboxylic acids, based solely on their much greater weight.

MCAT Concept Check 9.1:
Before you move on, assess your understanding of the material with these questions.

1. For each of the carboxylic acid derivatives below, list the relevant nucleophile that reacts with a carboxylic acid to generate the derivative, the derivative's suffix, and the name of the derivative in cyclic form.

Carboxylic Acid Derivative	Formed from –COOH by…	Suffix	Cyclic Naming
Amide			
Ester			
Anhydride

_____

_____

9.2 Reactivity Principles ★★★

Regardless of the carboxylic acid derivative at hand, there are some rules that govern the reactivity of these molecules.

RELATIVE REACTIVITY OF DERIVATIVES

Key Concept
When considering the reactivity of carboxylic acid derivatives toward nucleophilic attack, anhydrides are the most reactive, followed by esters and carboxylic acids, and then amides.

In a nucleophilic substitution reaction, the reactivity of the carbonyl is determined by its substituents. Anhydrides are most reactive, followed by esters (which are essentially tied with carboxylic acids), then finally amides. This can be explained by the structure of these molecules. Anhydrides, with their resonance stabilization and three electron-withdrawing oxygen atoms, are the most electrophilic. Esters, by comparison, lack one electron-withdrawing carbonyl oxygen and are slightly less reactive. Finally, amides, with an electron-donating amino group, are the least reactive toward nucleophiles.

STERIC EFFECTS

Steric hindrance is always worth keeping in mind when considering reactivity. **Steric hindrance** describes when a reaction does not proceed due to the size of the substituents. A good example of this is in S_N2 reactions, which will not occur

at tertiary carbons. This effect, which might sound detrimental, can be used to our advantage—for example, if we want to push a reaction in an S_N1 direction, rather than S_N2, we can use a tertiary substrate. Another way that this is used synthetically is in the creation of protecting groups. As we saw in Chapter 6 of *MCAT Organic Chemistry Review*, aldehydes and ketones will readily react with strong reducing agents like $LiAlH_4$—but this can be prevented by first reacting the aldehyde or ketone with two equivalents of alcohol, producing a nonreactive acetal or ketal. After we complete the rest of the desired reactions, we can then regenerate the carbonyl with aqueous acid. In the context of carboxylic acid derivatives, the size and substitution of the leaving group can affect the ability of a nucleophile to access the carbonyl carbon, thus affecting the reactivity of the derivative to nucleophilic acyl substitution.

Key Concept

Steric hindrance can be used to control where a reaction occurs in a molecule. Protecting groups may make it too hard for a nucleophile, oxidizing agent, or reducing agent to access or react with a part of the molecule.

ELECTRONIC EFFECTS

There are several electronic effects that must be considered in organic chemistry on the MCAT, and all of them come into play when considering carboxylic acid derivatives. **Induction** refers to the distribution of charge across σ bonds. Electrons are attracted to atoms that are more electronegative, generating a dipole across the σ bond. The less electronegative atom acquires a slightly positive charge, and the more electronegative atom acquires a slightly negative charge. This effect is relatively weak and gets increasingly weaker as one moves further away within the molecule from the more electronegative atom. This effect is responsible for the dipole character of the carbonyl group, as well as the increased dipole character (and therefore susceptibility to nucleophilic attack) of carboxylic acids—which contain an additional oxygen atom in their leaving group. This also explains the overall relative reactivity of anhydrides, esters, and amides toward nucleophilic attack. Anhydrides have two electron-withdrawing groups, which leaves a significant partial positive charge on the electrophilic carbon. This effect is smaller in amides because nitrogen is less electronegative than oxygen, and the dipole is not as strong.

Resonance and conjugation also affect the reactivity of a molecule. **Conjugation** refers to the presence of alternating single and multiple bonds. This setup implies that all of the atoms involved in these bonds are either sp^2- or *sp*-hybridized—and therefore have unhybridized *p*-orbitals. When these *p*-orbitals align, they can delocalize π electrons through resonance, forming clouds of electron density above and below the plane of the molecule. This type of electron sharing is most commonly demonstrated using benzene, as shown in Figure 9.10.

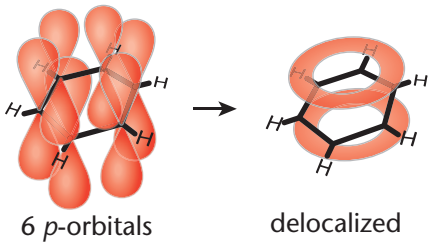

Figure 9.10. Conjugation in Benzene
Parallel unhybridized *p*-orbitals combine to form delocalized electron clouds above and below the plane of the molecule.

In carbonyl-containing compounds, conjugation can be established with the carbonyl group itself. α,β-unsaturated carbonyls or **enones** are common examples, as shown in Figure 9.11.

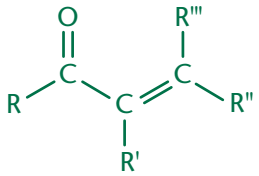

Figure 9.11. Conjugation in a Carbonyl-Containing Compound

This type of electron sharing makes for very stable compounds because these compounds have multiple resonance structures. This characteristic allows for the stabilization of a positive charge once the nucleophile has bonded, making these compounds more susceptible to nucleophilic attack.

Key Concept

Induction is the distribution of charge across σ bonds. Conjugation and resonance are much more powerful effects and occur in systems with alternating single and multiple bonds.

STRAIN IN CYCLIC DERIVATIVES

Lactams and lactones are cyclic amides and esters, respectively. Certain lactams and lactones are more reactive to hydrolysis because they contain more strain. β-lactams, for example, are four-membered cyclic amides and are highly reactive due to significant ring strain; four-membered rings have both torsional strain from eclipsing interactions and angle strain from compressing the normal sp^3 angle of 109.5°. These molecules are part of the core structure of several antibiotic families, as shown in Figure 9.12. The ring strain, and therefore the reactivity, is increased by fusion to a second ring. The four-membered structure of a β-lactam also forces a trigonal pyramidal bond geometry on the nitrogen atom in the ring, which reduces resonance, making hydrolysis more likely.

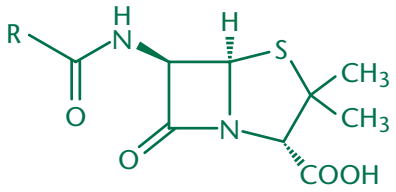

Figure 9.12. Penicillin, a β-Lactam-Containing Antibiotic

Real World

Many antibiotic families contain β-lactams, including the penicillin family, cephalosporins, carbapenems, and monobactams. Many bacteria have developed β-lactamases, which break β-lactam rings, as a resistance mechanism against these antibiotics. Therefore, β-lactams are sometimes given with β-lactamase inhibitors to increase their efficacy.

MCAT Concept Check 9.2:

Before you move on, assess your understanding of the material with these questions.

1. Rank the following molecules by decreasing reactivity to OR^-: acetamide, acetic anhydride, and ethyl acetate.

   1. _____
   2. _____
   3. _____

2. What is responsible for the increased rate of hydrolysis in β-lactams?

_____

_____

3. What properties account for the differences in reactivity seen between anhydrides, esters, and amides with nucleophiles?

_____

_____

_____

9.3 Nucleophilic Acyl Substitution Reactions

Although there are a seemingly infinite number of reactions in which carboxylic acid derivatives can participate, a much smaller group of reactions will appear on the MCAT. As we will observe, these reactions have much in common with those of carboxylic acids and other carbonyl-containing compounds. Many of the properties we have already discussed determine the ways in which these reactions proceed.

ANHYDRIDE CLEAVAGE

As with carboxylic acids, nucleophilic acyl substitution involves nucleophilic attack of the carbonyl carbon with displacement of a leaving group. All carboxylic acid derivatives can participate in nucleophilic substitution reactions at different relative rates. Specifically, anhydrides are most reactive toward nucleophiles, followed by esters, and finally amides. One example of this is the formation of amides from the nucleophilic substitution reaction between ammonia and any carboxylic acid or derivative. The example shown in Figure 9.13 is not only a nucleophilic substitution

reaction, but also a **cleavage reaction** because it splits an anhydride in two. In this reaction, ammonia acts as the nucleophile, one of the carbonyl carbons acts as the electrophile, and a carboxylic acid is the leaving group.

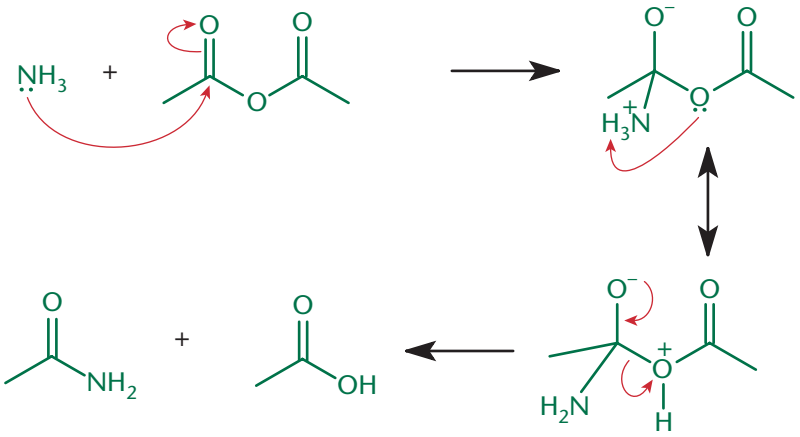

Figure 9.13. Nucleophilic Acyl Substitution: Anhydride to Amide and Carboxylic Acid

Alcohols can also act as nucleophiles toward anhydrides; this nucleophilic substitution reaction will result in the formation of esters and carboxylic acids, as shown in Figure 9.14.

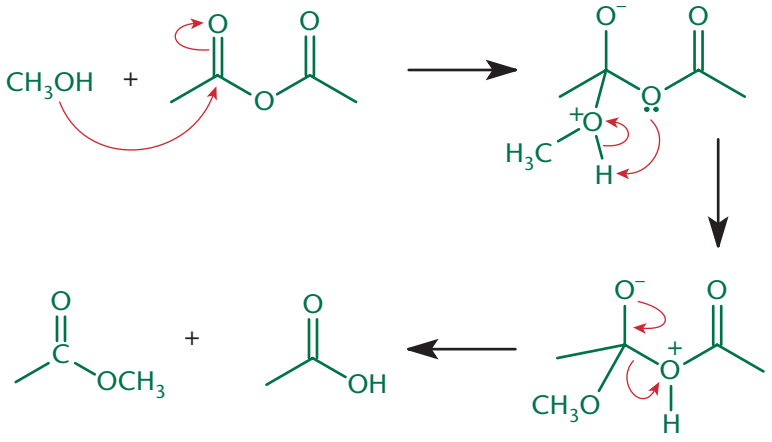

Figure 9.14. Nucleophilic Acyl Substitution: Anhydride to Ester and Carboxylic Acid

Anhydrides can also be reverted to carboxylic acids by exposing them to water, as shown in Figure 9.15. For these reactions to be useful, the anhydride should be symmetric; otherwise, one forms a mixture of products.

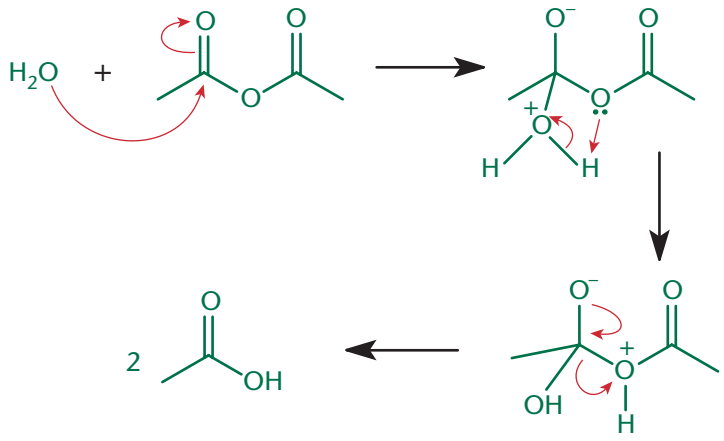

Figure 9.15. Nucleophilic Acyl Substitution: Anhydride to Carboxylic Acids

TRANSESTERIFICATION

Alcohols can act as nucleophiles and displace the esterifying group on an ester. This process is called **transesterification**. In this reaction, one ester is simply transformed to another, as shown in Figure 9.16.

Figure 9.16. Nucleophilic Acyl Substitution: Transesterification
Different alcohol chains are swapped into and out of the esterifying group position.

HYDROLYSIS OF AMIDES

Amides can be hydrolyzed under highly acidic conditions via nucleophilic substitution. The acidic conditions allow the carbonyl oxygen to become protonated, making the molecule more susceptible to nucleophilic attack by a water molecule. The product of this reaction is a carboxylic acid and ammonia. This should be no surprise because this is the reverse of the condensation reaction by which amides are formed. This reaction is shown in Figure 9.17.

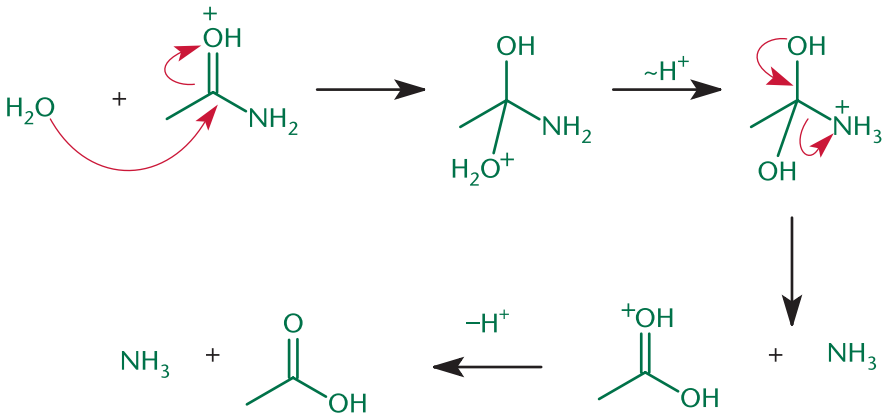

Figure 9.17. Nucleophilic Acyl Substitution: Amide to Carboxylic Acid
Strong acid or base is needed to catalyze the hydrolysis of amides, which are normally quite stable.

Hydrolysis can also occur if conditions are basic enough. The reaction is similar to an acid-catalyzed reaction, except that the carbonyl oxygen is not protonated and the nucleophile is a hydroxide ion. The product of this reaction would be the deprotonated carboxylate anion.

MCAT Concept Check 9.3:
Before you move on, assess your understanding of the material with these questions.

1. In the formation of an amide from ammonia and an anhydride, what serves as the nucleophile? The electrophile?
   - Nucleophile: _____
   - Electrophile: _____

2. Define transesterification.

_____

_____

3. How do strongly acidic and strongly basic conditions catalyze the hydrolysis of an amide?
   - Strongly acidic conditions:

     _____
   - Strongly basic conditions:

     _____

Conclusion

We're sure you've noticed that this chapter covers only a few reactions happening in a wide variety of contexts. The MCAT testmakers don't want you to memorize all the possible reactions; they simply want you to truly understand the trends and the underlying reasons for these reactions. Make sure you know the order of reactivity of the derivatives (from anhydrides, the most, to amides, the least). Also, learn the special reactions of esters and amides. Your study of amides will pay off right away as we explore amino acids and other nitrogen- and phosphorus-containing compounds in the next chapter.

CONCEPT SUMMARY

Amides, Esters, and Anhydrides

- **Amides** are the condensation products of carboxylic acids and ammonia or amines.
  - Amides are given the suffix ***–amide***. The alkyl groups on a substituted amide are written at the beginning of the name with the prefix ***N***–.
  - Cyclic amides are called **lactams**. Lactams are named by the Greek letter of the carbon forming the bond with the nitrogen (β-lactam, γ-lactam, and so on).
- **Esters** are the condensation products of carboxylic acids with alcohols **(Fischer esterification)**.
  - Esters are given the suffix ***–oate***. The **esterifying group** is written as a substituent, without a number.
  - Cyclic esters are called **lactones**. Lactones are named by the number of carbons in the ring and the Greek letter of the carbon forming the bond with the oxygen (α-acetolactone, β-propiolactone, and so on).
  - **Triacylglycerols**, which are a form of fat storage, include three ester bonds between glycerol and fatty acids. **Saponification** is the breakdown of fat using a strong base to form **soap** (salts of long-chain carboxylic acids).
- **Anhydrides** are the condensation dimers of carboxylic acids.
  - Symmetric anhydrides are named for the parent carboxylic acid, followed by ***anhydride***. Asymmetric anhydrides are named by listing the parent carboxylic acids alphabetically, followed by ***anhydride***.
  - Some cyclic anhydrides can be synthesized by heating dioic acids. Five- or six-membered rings are generally stable.

Reactivity Principles

- In nucleophilic substitution reactions, anhydrides are more reactive than esters, which are more reactive than amides.
- **Steric hindrance** describes when a reaction cannot proceed (or significantly slows) because of substituents crowding the reactive site. **Protecting groups**, such as acetals, can be used to increase steric hindrance or otherwise decrease the reactivity of a particular portion of a molecule.
- **Induction** refers to uneven distribution of charge across a σ bond because of differences in electronegativity. The more electronegative groups in a carbonyl-containing compound, the greater its reactivity.
- **Conjugation** refers to the presence of alternating single and multiple bonds, which creates delocalized π electron clouds above and below the plane of

the molecule. Electrons experience **resonance** through the unhybridized *p*-orbitals, increasing stability. Conjugated carbonyl-containing compounds are more reactive because they can stabilize their transition states.

- Increased strain in a molecule can make it more reactive. **β-lactams** are prone to hydrolysis because they have significant ring strain. **Ring strain** is due to torsional strain from eclipsing interactions and angle strain from compressing bond angles below 109.5°.

Nucleophilic Acyl Substitution Reactions

- All carboxylic acid derivatives can undergo nucleophilic substitution reactions. The rates at which they do so are determined by their relative reactivities.
- Anhydrides can be **cleaved** by the addition of a nucleophile.
  - Addition of ammonia or an amine results in an amide and a carboxylic acid.
  - Addition of an alcohol results in an ester and a carboxylic acid.
  - Addition of water results in two carboxylic acids.
- **Transesterification** is the exchange of one esterifying group for another on an ester. The attacking nucleophile is an alcohol.
- **Amides** can be hydrolyzed to carboxylic acids under strongly acidic or basic conditions. The attacking nucleophile is water or the hydroxide anion.

ANSWERS TO CONCEPT CHECKS

9.1

1.

Carboxylic Acid Derivative	Formed from –COOH by…	Suffix	Cyclic Name
Amide	Ammonia or an amine	*–amide*	Lactam
Ester	An alcohol	*–oate*	Lactone
Anhydride	Another carboxylic acid	anhydride	Anhydride

2. A condensation reaction is one in which two molecules are joined with the loss of a small molecule. In all of the examples in this section, the small molecule lost was water.

9.2

1. Anhydrides are the most reactive to nucleophiles, followed by esters, and then amides. Therefore, acetic anhydride will be the most reactive, followed by ethyl acetate, and finally acetamide.
2. β-lactams are susceptible to hydrolysis due to the high level of ring strain, which is due to both torsional strain (eclipsing interactions) and angle strain (deviation from 109.5°).
3. Electronic effects like induction have some effect on the reactivity of the carbonyl in these three functional groups. Differences in resonance also explain the increased reactivity of anhydrides, in particular. Steric effects could also be significant, depending on the specific leaving group present.

9.3

1. Ammonia acts as the nucleophile. One of the carbonyl carbons of the anhydride serves as the electrophile.
2. Transesterification is the exchange of one esterifying group for another in an ester. This reaction requires an alcohol as a nucleophile.
3. Strongly acidic conditions catalyze amide hydrolysis by protonating the oxygen in the carbonyl. This increases the electrophilicity of the carbon, making it more susceptible to nucleophilic attack. Strongly basic conditions greatly increase the concentration of OH^-, which can act as a nucleophile on amide carbonyls.

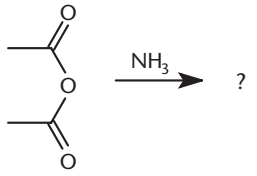
Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

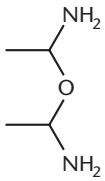
1. Which of the following would be the best method of producing methyl propanoate?

A. Reacting propanoic acid and methanol in the presence of a mineral acid
B. Reacting methanoic acid and propanol in the presence of a mineral acid
C. Reacting propanoic anhydride with an aqueous base
D. Reacting propanoic acid with an aqueous base

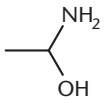
2. What would be the product(s) of the reaction below?



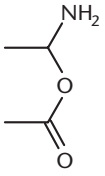
A.



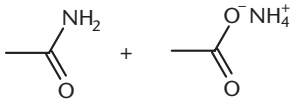
B. 2



C.

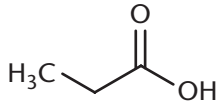


D.

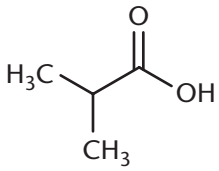


3. Which of the following undergoes a Fischer esterification most rapidly?

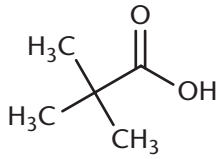
A.



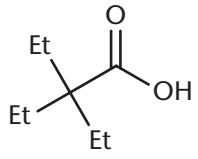
B.



C.



D.



4. Each of the acyl compounds listed below contains a six-membered ring EXCEPT:

A. δ-lactam.
B. cyclohexane carboxylic acid.
C. γ-butyrolactone.
D. the anhydride formed from intramolecular ring closure of pentanedioic acid.

5. Which of the following would be most reactive toward nucleophiles?

A. Propyl ethanoate
B. Propanoic acid
C. Propanamide
D. Propanoic anhydride

6. How might succinic anhydride, shown below, be formed from succinic acid (butanedioic acid)?

A. Catalytic acid
B. Catalytic base
C. Heat
D. Oxidation

7. Which of the following would react most readily with a carboxylic acid to form an amide?

A. Methylamine
B. Triethylamine
C. Diphenylamine
D. Ethylmethylamine

8. If propanamide were treated with water, what product(s) would be observed?

A. Propanamide
B. Propanoic acid
C. Equal concentrations of propanamide and propanoic acid
D. Propyl propanoate

9. β-lactams are:

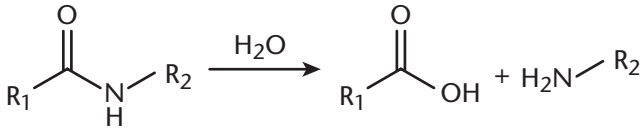
I. cyclic forms of the least reactive type of carboxylic acid derivative.
II. more reactive than their straight-chain counterparts.
III. molecules with high levels of ring strain.

A. I only
B. II only
C. II and III only
D. I, II, and III

10. The acid-catalyzed conversion of propyl ethanoate to benzyl ethanoate is likely:

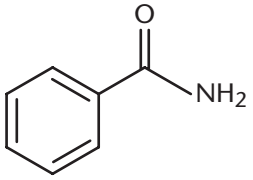
A. reduction.
B. hydrolysis.
C. transesterification.
D. oxidation.

11. The reaction shown, which is important to breakdown of polypeptides, would be favored under what conditions?



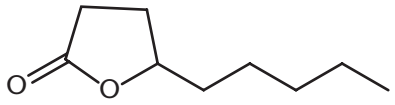
A. Mild heat
B. Acid environment
C. Anhydrous environment
D. Nonpolar solvent

12. A positive charge on the molecule shown would have greater stability than a positive charge on a straight-chain alkane version of the same molecule. What property most explains this effect?



A. Steric hindrance
B. Nitrogen electronegativity
C. Induction
D. Conjugation

13. The molecule shown is:



I. synthesizable from a γ-hydroxycarboxylic acid.

II. a lactone.

III. a form of an ester.

A. I only
B. I and II only
C. II and III only
D. I, II, and III

14. Which reactant could be combined with butanol to form butyl acetate?

A. $(CH_3CO)_2O$ and catalytic acid
B. $(CH_3CH_2CO)_2O$ and catalytic acid
C. $CH_3CH_2CONH_2$ and catalytic acid
D. CH_3CONH_2 and catalytic acid

15. Why should esterification reactions NOT be carried out in water?

A. Carboxylic acids, from which esters are made, are generally insoluble in water.
B. The polar nature of water overshadows the polar nature of the leaving group.
C. The extensive hydrogen bonding of water interferes with the nucleophilic addition mechanism.
D. Water molecules would hydrolyze the desired products back into the parent carboxylic acid.

Explanations to Discrete Practice Questions

1. A

Methyl propanoate is an ester; it can be synthesized by reacting a carboxylic acid with an alcohol in the presence of acid. Here, the parent chain is propanoate, and the esterifying group is a methyl group. **Choice (B)** reverses the nomenclature, and would form propyl methanoate. The other reactions listed would not form esters.

2. D

This question asks for the products when ammonia reacts with acetic anhydride. Recall from the chapter that an amide and a carboxylic acid will be formed. However, the carboxylic acid—an acid—is in the same environment as ammonia—a base. The two will react, forming the ammonium carboxylate shown.

3. A

A Fischer esterification involves reacting a carboxylic acid and an alcohol with an acid catalyst. Under these conditions, the carbonyl carbon is open to attack by the nucleophilic alcohol. The rate of this reaction depends on the amount of steric hindrance around the carbonyl carbon because there must be room for the alcohol to approach the carboxylic acid substrate. **Choices (B)**, **(C)**, and **(D)** all have more crowding around the carbonyl carbon, which will decrease reactivity. The additional alkyl groups in these other choices also donate electron density to the carbonyl carbon, making it slightly less electrophilic.

4. C

This question requires knowledge of the nomenclature of cyclic molecules. A δ-lactam, **choice (A)**, has a bond between the nitrogen and the fourth carbon away from the carbonyl carbon. This ring will have six elements: the nitrogen, the carbonyl carbon, and the four carbons in between. Cyclohexane carboxylic acid, **choice (B)**, has cyclohexane, a six-membered cycloalkane. The anhydride formed from pentanedioic acid, **choice (D)**, will have the five carbons in the parent chain and one oxygen atom closing the ring, meaning there are still six elements. γ-butyrolactone will have five elements because it contains a bond between the ester oxygen and the third carbon away from the carbonyl carbon. The five elements will be the oxygen, the carbonyl carbon, and the three carbons in between.

5. D

With the same R groups, steric influence is the same in each case, so we can therefore rely solely on electronic effects. When this is all that is taken into account, reactivity toward nucleophiles is highest for anhydrides, followed by esters and carboxylic acids, then amides.

6. C

Anhydrides, particularly cyclic anhydrides, will form spontaneously from dicarboxylic acids when heated.

7. A

Methylamine would react readily to form an amide. The less substituted the nucleophile, the easier it will be for the nucleophile to attack the carbonyl carbon and form the amide. In fact, triethylamine, **choice (B)**, would not be able to form an amide at all because it does not have a hydrogen to lose while attaching to the carbonyl carbon.

8. A

Propanamide is an amide; as such, it is the least reactive of the carboxylic acid derivatives discussed in this chapter. Without strong acid or base, propanamide will not be able to undergo nucleophilic acyl substitution and no reaction will occur.

9. D

β-lactams are amides in the form of four-membered rings; amides are generally the least reactive type of carboxylic acid derivative. β-lactams experience significant ring strain from both eclipsing interactions (torsional strain) and angle strain, and are therefore more susceptible to hydrolysis than the linear form of the same molecule.

10. C

As far as we can tell, we are converting one ester to another in this reaction. The fact that this reaction is acid-catalyzed should confirm the suspicion that this is a transesterification reaction.

11. B

This reaction, which is the hydrolysis of an amide, is favored in strong acid. Acid protonates the carbonyl oxygen, which increases the electrophilicity of the carbonyl carbon. This allows water to serve as the nucleophile, attacking the bond and hydrolyzing the molecule.

12. D

This molecule is more stable with a positive charge than a straight-chain alkane due to the conjugation of the benzene ring. This permits delocalization of the charge through resonance. Although induction, **choice (C)**, does have an effect on the stabilization of the molecule, this effect is much less significant than the impact of having a conjugated system. The electronegativity of nitrogen, **choice (B)**, which primarily affects induction, is also not a vital component of the stabilization by this molecule of a positive charge because oxygen is more electronegative. Steric hindrance, **choice (A)**, would affect the reactivity of a molecule, but not its ability to stabilize charge.

13. D

The molecule shown, γ-nonalactone, is a cyclic ester, also called a lactone. This molecule could arise from intramolecular attack in a γ-hydroxycarboxylic acid.

14. A

In order to prepare butyl acetate from butanol, we need to perform a nucleophilic acyl substitution reaction. If the product is an ester, we need to start with a reactant that is more reactive than the ester itself, or the reaction will not proceed. Anhydrides are more reactive than esters, but amides are less reactive, eliminating **choices (C)** and **(D)**. Reaction with propanoic anhydride, as in **choice (B)**, would result in butyl propanoate.

15. D

The presence of water in an esterification reaction would likely revert some of the desired esters back into carboxylic acids. Small carboxylic acids, like formic or acetic acid, are easily dissolved in water, eliminating **choice (A)**. The polarity of water plays little role in affecting the leaving group; if anything, water can be used to increase the electrophilicity of the carbonyl carbon by protonating the carbonyl oxygen—eliminating **choice (B)**. Finally, this is a nucleophilic substitution mechanism, not a nucleophilic addition mechanism, as mentioned in **choice (C)**. Further, hydrogen bonding would likely augment the reaction.

MCAT Expertise

Note that, even though biological molecules—amino acids, proteins, and DNA—are called out in this chapter, the 1-star rating for this chapter only applies to non-biochemical reactions of these molecules. Mastery of these molecules in biological settings is still very important for Test Day success; that content is found in Chapters 1, 2, 3, 6, and 7 of *MCAT Biochemistry Review*.

Introduction

Organic chemistry is the study of carbon-containing molecules. But as you've seen, carbon is not the only element that plays a role in organic molecules; many of the functional groups we've explored up until this point also include hydrogen and oxygen. Together, these three elements make up 93% of the composition of the human body by weight. But other atoms also contribute to biomolecules: nitrogen comprises 3.2% of body weight and phosphorus 1.0%.

In this chapter, we'll take a look at some biologically important molecules that contain nitrogen and phosphorus. In addition to the amides explored in the previous chapter, amino acids also contain nitrogen. These building blocks of proteins are discussed in depth in Chapter 1 of *MCAT Biochemistry Review*; in this chapter, we review their structure and focus on laboratory methods for synthesizing amino acids. Finally, we turn our attention to phosphorus-containing molecules, which often are used to transfer energy—or store genetic information.

10.1 Amino Acids, Peptides, and Proteins ★★

Amino acids are dipolar molecules that come together through a condensation reaction, forming peptides. Larger, folded peptide chains are considered proteins.

DESCRIPTION

Amino acids contain an amino group and a carboxyl group attached to a single carbon atom (the α-carbon). The other two substituents of the α-carbon are a hydrogen atom and a side chain referred to as the **R group**. This structure is shown in Figure 10.1.

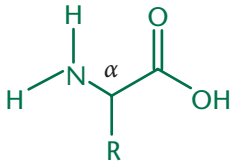

Figure 10.1. Amino Acid Structure

The α-carbon, with its four different groups, is a chiral (stereogenic) center. **Glycine**, the simplest amino acid, is an exception to this rule because its R group is a hydrogen atom. All naturally occurring amino acids in eukaryotes—except for glycine—are optically active, and all are L-isomers. Therefore, by convention, the Fischer projection for an amino acid is drawn with the amino group on the left, as shown in Figure 10.2. L-amino acids have (*S*) configurations, except for **cysteine**, which is (*R*) because of the change in priority caused by the sulfur in its R group.

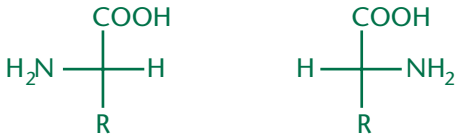

Figure 10.2. L- and D-Amino Acids

PROPERTIES

Amino acids, with their acidic carboxyl group and basic amino group, are **amphoteric** molecules. That is, they can act as both acids and bases. Amino groups can take on a positive charge by being protonated, and carboxyl groups can take on negative charges by being deprotonated. When an amino acid is put into solution, it will take on both of these charges, forming a dipolar ion or ***zwitterion***, as shown in Figure 10.3. How an amino acid acts depends on the pH of the environment. In basic solutions, the amino acid can become fully deprotonated; in acidic solutions, it can become fully protonated.

Bridge

Amino acids are amphoteric molecules, just like water—they can act as both acids and bases. These acid–base characteristics (and titrations of amino acids) are discussed thoroughly in Chapter 1 of *MCAT Biochemistry Review*.

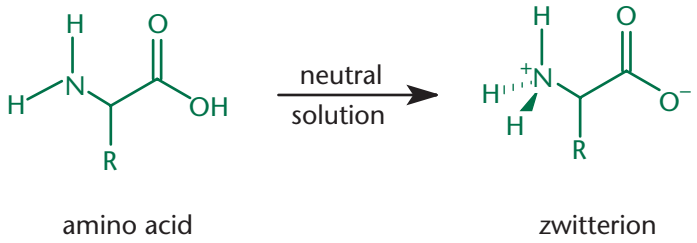

Figure 10.3. Amino Acids Exist as Zwitterions (Dipolar Ions) at Neutral pH

Aside from the zwitterionic properties common to every amino acid, each one has properties defined by its R group, or side chain. The 20 eukaryotic proteogenic amino acids are grouped into five categories: **nonpolar nonaromatic**, **aromatic**, **polar**, **negatively charged** (**acidic**), and **positively charged** (**basic**). Nonpolar nonaromatic amino acids tend to have side chains that are saturated hydrocarbons, like alanine, valine, leucine, and isoleucine; they also include glycine, proline (which is cyclic, with a secondary amine), and methionine (which contains sulfur). Aromatic amino acids include tryptophan, phenylalanine, and tyrosine. Nonpolar amino acids—both nonaromatic and aromatic—are also hydrophobic and tend to be sequestered in the interior of proteins. Polar amino acids tend to have terminal groups containing oxygen, nitrogen, or sulfur. These include serine, threonine, asparagine, glutamine, and cysteine. Negatively charged (acidic) amino acids include aspartic acid and glutamic acid. These amino acids have terminal carboxylate anions in their R groups. Finally, positively charged (basic) amino acids, including arginine, lysine, and histidine, have a protonated amino group in their R groups. Polar, acidic, and basic amino acids are all hydrophilic and tend to form hydrogen bonds with water in aqueous solution.

Amino acids undergo condensation reactions to form **peptide bonds**. The molecules these bonds form, called **polypeptides**, are the base unit of **proteins**. The reverse reaction, hydrolysis of the peptide bond, is catalyzed by a strong acid or base. Both of these reactions are shown in Figure 10.4.

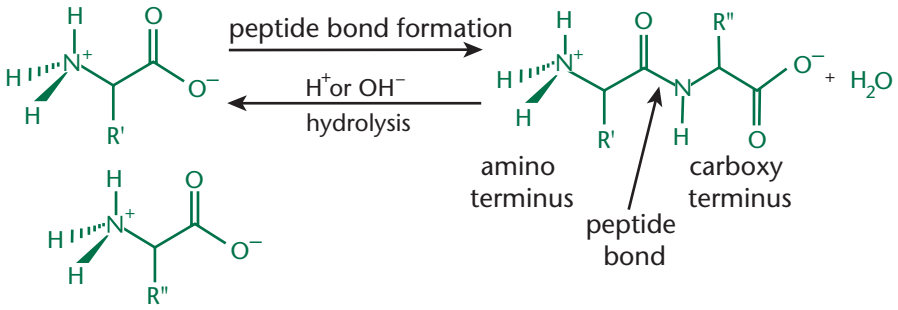

Figure 10.4. Peptide Bond Formation and Cleavage

Key Concept

Rotation is limited around the peptide bond because resonance gives the C–N bond partial double-bond character.

Like other carbonyl-containing functional groups, amides have two resonance structures, as shown in Figure 10.5. The true structure of the amide bond is therefore a hybrid of these two structures, with partial double-bond character between the nitrogen atom and the carbonyl carbon. This double-bond character limits rotation about the C–N bond, which adds to the rigidity and stability of the backbone of proteins. The single bonds on either side of the peptide bond, on the other hand, permit free rotation.

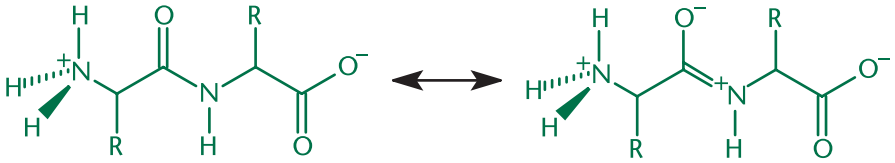

Figure 10.5. Resonance in the Peptide Bond

10.2 Synthesis of α-Amino Acids ★★

Synthesis of amino acids occurs by an astonishing variety of mechanisms *in vivo*. In the lab, several simple reaction mechanisms are exploited to make amino acids neatly and efficiently.

STRECKER SYNTHESIS

In the **Strecker synthesis**, one starts with an aldehyde, ammonium chloride (NH_4Cl), and potassium cyanide (KCN), as shown in Figure 10.6. The carbonyl oxygen is protonated, increasing the electrophilicity of the carbonyl carbon. Then, as seen in Chapter 6 of *MCAT Organic Chemistry Review*, ammonia can attack the carbonyl carbon, forming an **imine**. The imine carbon is also susceptible to nucleophilic addition reactions; thus, the CN^- anion from KCN attacks, forming a **nitrile** group (–C≡N). The final molecule at the end of Step 1 is an ***aminonitrile***—a compound containing an amino group ($–NH_2$) and a nitrile group.

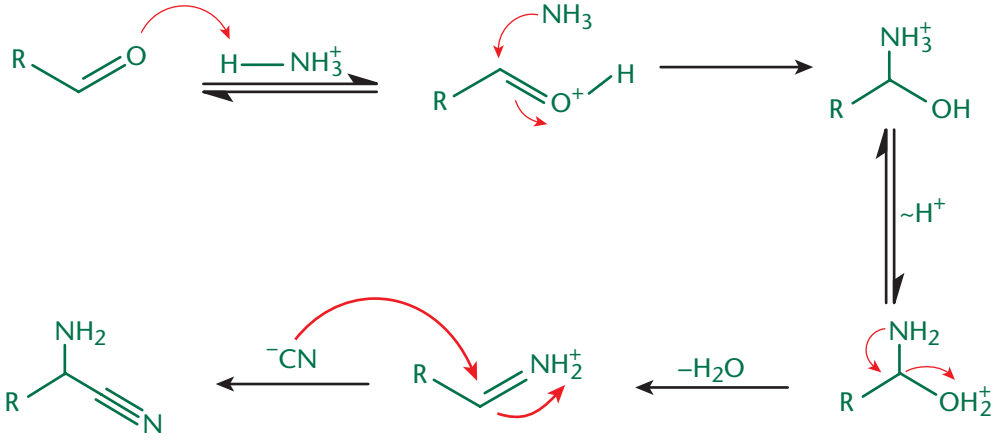

Figure 10.6. Strecker Synthesis: Step 1
An aminonitrile is generated from an aldehyde or ketone.

In Step 2, the nitrile nitrogen is protonated, increasing the electrophilicity of the nitrile carbon. This is similar to protonating the oxygen of a carbonyl. A water molecule attacks, leading to the creation of a molecule with both imine and hydroxyl moieties on the same carbon. This imine is attacked by another equivalent of water. A carbonyl is formed, kicking off ammonia and creating the carboxylic acid functionality. This step, shown in Figure 10.7, is performed in aqueous acid and can be accelerated by the use of heat.

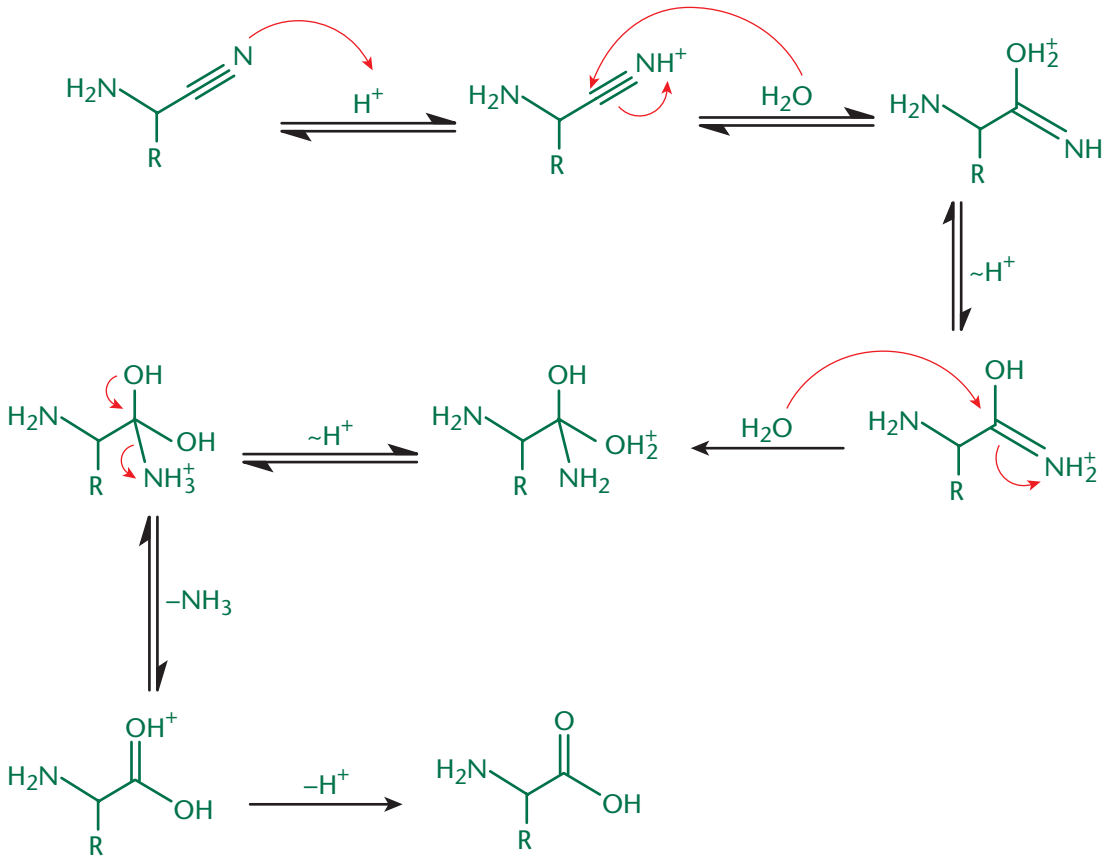

Figure 10.7. Strecker Synthesis: Step 2
An amino acid is generated from the aminonitrile.

The starting material for the Strecker synthesis is a planar carbonyl-containing compound; therefore, the product of this pathway is a racemic mixture. The incoming nucleophiles are equally able to attack from either side of the carbonyl; thus, both L- and D-amino acids can be generated through this process.

GABRIEL SYNTHESIS

Another way of synthesizing amino acids is the **Gabriel (malonic-ester) synthesis**, shown in Figure 10.8.

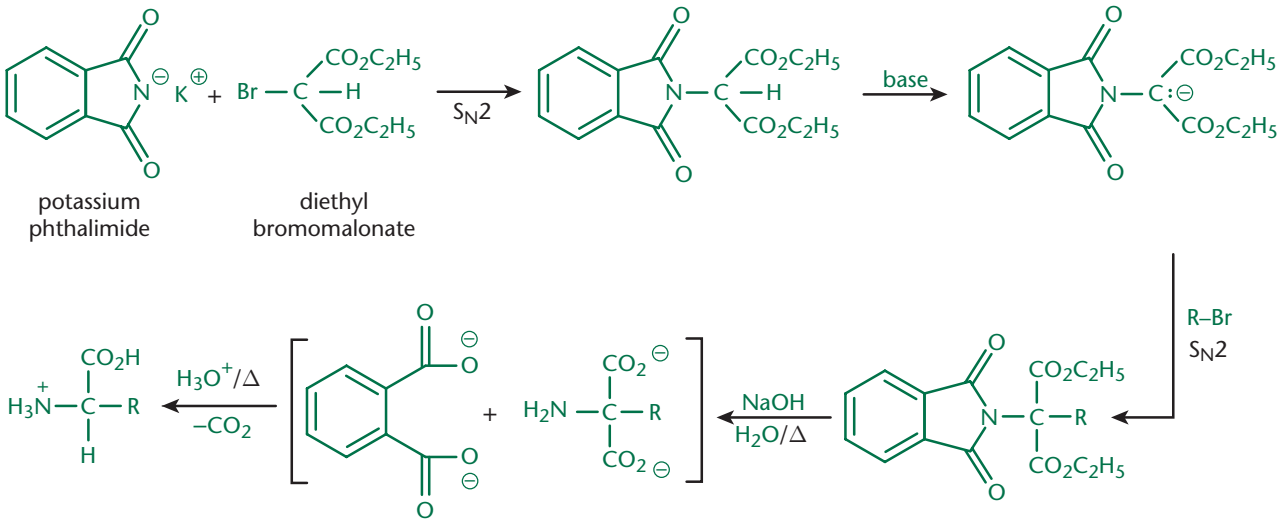

Figure 10.8. Gabriel Synthesis
An amino acid is generated from phthalimide and diethyl bromomalonate, using two S_N2 reactions, hydrolysis, and decarboxylation.

In this method, potassium phthalimide is reacted with diethyl bromomalonate. Phthalimide is acidic and exists in solution as a nucleophilic anion. Diethyl bromomalonate contains a secondary carbon bonded to bromine, a good leaving group. This setup should sound much like the S_N2 reactions discussed in Chapter 4 of *MCAT Organic Chemistry Review*. With phthalimide as the nucleophile, the (secondary) substrate carbon as the electrophile, and bromine as the leaving group, this reaction generates a phthalimidomalonic ester. Consider the benefits of using such a large nucleophile. The bulkiness of this group creates steric hindrance, which prevents the substrate carbon from undergoing multiple substitutions.

Instead, in the presence of base, this carbon (which is the α-carbon between two carbonyls) can easily be deprotonated. The molecule as a whole can then act as a nucleophile, attacking the substrate carbon of a bromoalkane. This is another example of an S_N2 reaction. The nucleophile is the large, deprotonated phthalimidomalonic ester, the electrophile is the substrate carbon, and the leaving group is the bromide anion.

Next, this molecule is hydrolyzed with strong base and heat. Much like converting a cyclic anhydride into a dioic acid, the phthalimide moiety is removed as phthalic acid (with two carboxylic acids). The malonic ester is hydrolyzed to a dicarboxylic acid with an amine on the α-carbon.

Finally, this dicarboxylic acid, which is a 1,3-dicarbonyl, can be decarboxylated through the addition of acid and heat. The loss of a molecule of carbon dioxide results in the formation of the complete amino acid.

Key Concept

Both the Strecker and Gabriel synthesis methods result in a racemic mixture of amino acids.

Like the Strecker synthesis, the Gabriel synthesis starts with a planar molecule; thus, the product is a racemic mixture of L- and D-amino acids.

10.3 Phosphorus-Containing Compounds ★

Phosphoric acid is an extremely important molecule biochemically. This molecule forms the high-energy bonds that carry energy in adenosine triphosphate (ATP).

DESCRIPTION

In a biochemical context, phosphoric acid is sometimes referred to as a **phosphate group** or **inorganic phosphate**, denoted $\mathbf{P_i}$. At physiological pH, inorganic phosphate includes molecules of both hydrogen phosphate (HPO_4^{2-}) and dihydrogen phosphate ($H_2PO_4^-$).

In addition to the energy-carrying nucleotide phosphates, phosphorus is also found in the backbone of DNA in **phosphodiester** bonds linking the sugar moieties of the nucleotides, as shown in Figure 10.9.

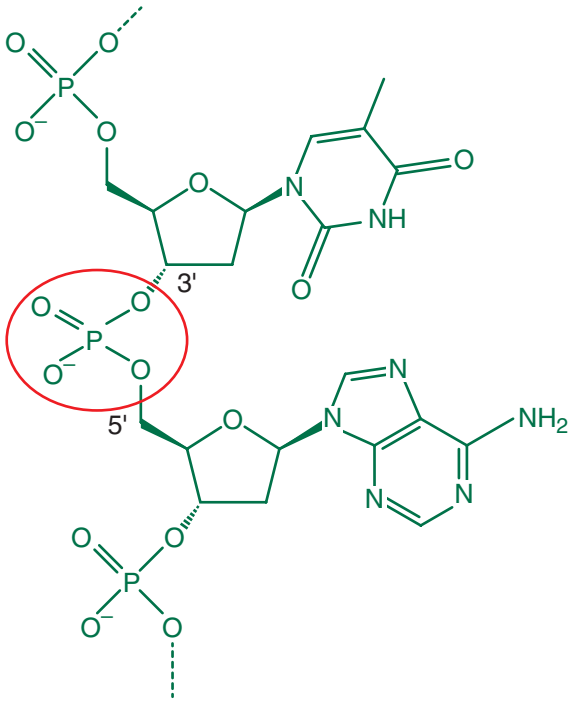

Figure 10.9. Phosphodiester Bond in DNA

When a new nucleotide is joined to a growing strand of DNA by a *DNA polymerase*, it releases an ester dimer of phosphate, referred to as **pyrophosphate** ($P_2O_7^{4-}$), denoted **PP_i**, and shown in Figure 10.10. The hydrolytic release of this molecule provides the energy for the formation of the new phosphodiester bond. Pyrophosphate is unstable in aqueous solution and is hydrolyzed to form two molecules of inorganic phosphate, which can then be recycled to form high-energy bonds in ATP or for other purposes.

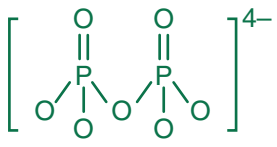

Figure 10.10. Pyrophosphate Anion

Nucleotides, such ATP, GTP, and those in DNA, are referred to as **organic phosphates** due to the presence of the phosphate group bonded to a carbon-containing molecule.

Bridge

DNA replication is an important process for the MCAT. Nucleotide triphosphates are added to the growing daughter strand, with the release of pyrophosphate, PP_i. The process of DNA synthesis is described in Chapter 6 of *MCAT Biochemistry Review*.

PROPERTIES

Phosphoric acid is unique in that it has three acidic hydrogens, each with its own pK_a. Phosphoric acid most properly refers to the form that predominates in strongly acidic conditions, H_3PO_4. In mildly acidic conditions, it loses a proton to become dihydrogen phosphate, $H_2PO_4^-$; it will readily lose a second proton to become hydrogen phosphate, HPO_4^{2-} in weakly basic solutions. The form that exists in strongly basic solutions is phosphate, PO_4^{3-}. The pK_a for the loss of the first hydrogen is 2.15; for the second, 7.20; and for the third, 12.32. At a physiological pH of 7.4, this means that dihydrogen phosphate and hydrogen phosphate predominate in nearly equal proportions. This variety of pK_a values also makes phosphates good buffers because they can pick up or give off protons depending on the pH of the solution.

Key Concept

Phosphoric acid is an excellent buffer because it has three hydrogens with pK_a values that span nearly the entire pH scale.

Adjacent phosphate groups on a nucleotide triphosphate experience a large amount of repulsion because they are negatively charged. This, combined with the ability of phosphate to stabilize up to three negative charges by resonance, means that the energy released when a phosphate or pyrophosphate is cleaved is quite high.

MCAT Concept Check 10.3:

Before you move on, assess your understanding of the material with these questions.

1. What characteristics make inorganic phosphate so useful for energy transfer biologically?

_____

_____

_____

Conclusion

In this chapter, we spent a lot of time looking at biologically active molecules—but did you notice that these molecules are simply applications of the general principles that we have been learning throughout the chapters of this book? By applying your knowledge of the reactions and properties of different types of molecules, you can understand how biological processes work and how complex organic chemistry mechanisms work, like those of the Strecker and Gabriel syntheses. Many of these processes will fall into categories of reactions that we've seen before over and over—nucleophilic substitution, nucleophilic addition, and condensation reactions are just a few examples. The MCAT doesn't require you to memorize tables of reactants or regurgitate hundreds of named reactions from scratch. Instead, the MCAT asks you to look at the bigger picture and understand the trends—which you've now learned!

CONCEPT SUMMARY

Amino Acids, Peptides, and Proteins

- The α-carbon of an amino acid is attached to four groups: an amino group, a carboxyl group, a hydrogen atom, and an **R group**. It is a chiral stereocenter in all amino acids except **glycine**.
- All amino acids in eukaryotes are L-amino acids. They all have (*S*) stereochemistry except **cysteine**, which is (*R*).
- Amino acids are **amphoteric**, meaning they can act as acids or bases.
  - Amino acids get their acidic characteristics from carboxylic acids and their basic characteristics from amino groups.
  - In neutral solution, amino acids tend to exist as **zwitterions** (dipolar ions).
- Amino acids can be classified by their R groups.
  - **Nonpolar nonaromatic amino acids** include alanine, valine, leucine, isoleucine, glycine, proline, and methionine.
  - **Aromatic amino acids** include tryptophan, phenylalanine, and tyrosine. Both nonpolar nonaromatic and aromatic amino acids tend to be hydrophobic and reside in the interior of proteins.
  - **Polar amino acids** include serine, threonine, asparagine, glutamine, and cysteine.
  - **Negatively charged amino acids** contain carboxylic acids in their R groups and include aspartic acid and glutamic acid.
  - **Positively charged amino acids** contain amines in their R groups and include arginine, lysine, and histidine.
  - Nonpolar nonaromatic and aromatic amino acids tend to be hydrophobic and reside in the interior of proteins.
  - Polar, negatively charged (acidic), and positively charged (basic) amino acids tend to be hydrophilic and reside on the surface of proteins, making hydrogen bonds with the aqueous environment.
- **Peptide bonds** form by condensation reactions and can be cleaved hydrolytically.
  - Resonance of the peptide bond restricts motion about the C–N bond, which takes on partial double-bond character.
  - Strong acid or base is needed to cleave a peptide bond.
- **Polypeptides** are made up of multiple amino acids linked by peptide bonds. **Proteins** are large, folded, functional polypeptides.

Synthesis of α-Amino Acids

- Biologically, amino acids are synthesized in many ways. In the lab, certain standardized mechanisms are used.
- The **Strecker synthesis** generates an amino acid from an aldehyde.
  - An aldehyde is mixed with ammonium chloride (NH_4Cl) and potassium cyanide. The ammonia attacks the carbonyl carbon, generating an imine. The imine is then attacked by the cyanide, generating an aminonitrile.
  - The aminonitrile is hydrolyzed by two equivalents of water, generating an amino acid.
- The **Gabriel synthesis** generates an amino acid from potassium phthalimide, diethyl bromomalonate, and an alkyl halide.
  - Phthalimide attacks the diethyl bromomalonate, generating a phthalimidomalonic ester.
  - The phthalimidomalonic ester attacks an alkyl halide, adding an alkyl group to the ester.
  - The product is hydrolyzed, creating phthalic acid (with two carboxyl groups) and converting the esters into carboxylic acids.
  - One carboxylic acid of the resulting 1,3-dicarbonyl is removed by decarboxylation.

Phosphorus-Containing Compounds

- Phosphorus is found in **inorganic phosphate** ($\mathbf{P_i}$), a buffered mixture of hydrogen phosphate (HPO_4^{2-}) and dihydrogen phosphate ($H_2PO_4^-$).
- Phosphorus is found in the backbone of DNA, which uses **phosphodiester bonds**. In forming these bonds, a **pyrophosphate** ($\mathbf{PP_i}$, $P_2O_7^{4-}$) is released. Pyrophosphate can then be hydrolyzed to two inorganic phosphates.
- Phosphate bonds are high energy because of large negative charges in adjacent phosphate groups and resonance stabilization of phosphates.
- **Organic phosphates** are carbon-containing compounds that also have phosphate groups. The most notable examples are nucleotide triphosphates (such as ATP or GTP) and DNA.
- Phosphoric acid has three hydrogens, each with a unique pK_a. The wide variety in pK_a values allows phosphoric acid to act as a buffer over a large range of pH values.

ANSWERS TO CONCEPT CHECKS

10.1

1. All amino acids, except glycine, have chiral α-carbons. Because the R group of glycine is a hydrogen atom, it is not chiral and therefore is not optically active.
2. Amphoteric molecules can act as acids or bases. Carboxylic acids give amino acids their acidic properties because they can be deprotonated. Amino groups give amino acids their basic properties because they can be protonated.
3. Peptide bonds are formed by a condensation reaction, in which water is lost, and cleaved hydrolytically by strong acid or base.
4. The C–N bond of an amide is planar because it has partial double-bond character due to resonance. Double bonds exist in a planar conformation and restrict movement.

10.2

1. An aldehyde, ammonium chloride (NH_4Cl), and potassium cyanide (KCN) are used to make the aminonitrile; water is used to hydrolyze the aminonitrile to form the amino acid.
2. Strecker synthesis is a condensation reaction (formation of an imine from a carbonyl-containing compound and ammonia, with loss of water), followed by nucleophilic addition (addition of the nitrile group), followed by hydrolysis.
3. Gabriel synthesis begins with potassium phthalimide and diethyl bromomalonate, followed by an alkyl halide. Water is then used to hydrolyze the resulting compound to form the amino acid. While acids and bases are used at various times as catalysts, they are not main reactants.
4. Gabriel synthesis proceeds through two S_N2 reactions, hydrolysis, and decarboxylation.

10.3

1. Inorganic phosphate contains a very negative charge. When bonded to other phosphate groups in a nucleotide triphosphate, this creates repulsion with adjacent phosphate groups, increasing the energy of the bond. Further, inorganic phosphate can be resonance-stabilized.
2. Organic phosphates are carbon-containing molecules with phosphate groups; the most common examples are nucleotides, like those in DNA, ATP, or GTP.
3. The three hydrogens in phosphoric acid have very different pK_a values. This allows phosphoric acid to pick up or give off protons in a wide pH range, making it a good buffer over most of the pH scale.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Which of the following amino acids does not have an L-enantiomer?

A. Cysteine
B. Threonine
C. Glutamic acid
D. Glycine

2. Which of the following would be formed if methyl bromide were reacted with phthalimide and followed by hydrolysis with an aqueous base?

A. $C_2H_5NH_2$
B. CH_3NH_2
C. $(C_2H_5)_3N$
D. $(CH_3)_4N^+Br^-$

3. Which of the following amino acids contain(s) sulfur?

I. Cysteine
II. Serine
III. Methionine

A. I only
B. I and III only
C. II and III only
D. I, II, and III

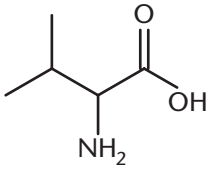
4. Nylon, a polyamide, is produced from hexanediamine and a substance *X*. This substance *X* is most probably a(n):

A. amine.
B. carboxylic acid.
C. ketone.
D. alcohol.

5. Intermediates in the Strecker synthesis include all of the following nitrogen-containing functional groups EXCEPT a(n):

A. nitrile.
B. imine.
C. amide.
D. amine.

6. A biochemist is synthesizing valine, shown below, using the Strecker synthesis. Which of the following carbonyl-containing compounds would be an appropriate starting reactant in this synthesis?



A. 2-Propanone
B. Propanal
C. 2-Methylpropanal
D. Butanal

7. Why is the C–N bond of an amide planar?

I. It has partial double-bond character.
II. It is sp^3-hybridized.
III. It has some sp^2 character.

A. I only
B. II only
C. I and II only
D. I and III only

8. Which of the primary methods of amino acid synthesis results in an optically active solution?

A. The Strecker synthesis only
B. The Gabriel synthesis only
C. Both the Strecker and Gabriel syntheses
D. Neither the Strecker nor the Gabriel syntheses

9. During the Gabriel synthesis, phthalimide serves as the:

A. nucleophile.
B. base.
C. leaving group.
D. electrophile.

10. Each of the following reaction types occurs during the Gabriel synthesis EXCEPT:

A. decarboxylation.
B. nucleophilic substitution.
C. dehydration.
D. hydrolysis.

11. At physiological pH, which two forms of phosphoric acid have the highest concentrations?

A. H_3PO_4 and $H_2PO_4^-$
B. $H_2PO_4^-$ and HPO_4^{2-}
C. HPO_4^{2-} and PO_4^{3-}
D. PO_4^{3-} and H_3PO_4

12. In aqueous solution, pyrophosphate will likely:

A. form insoluble complexes.
B. be stable and inert.
C. degrade into inorganic phosphate.
D. decrease the polarity of the solvent.

13. What would be the charge of aspartic acid at pH 7?

A. Neutral
B. Negative
C. Positive
D. There is not enough information to answer the question.

14. When a bond is created between two nucleotide triphosphates in DNA synthesis, the small molecule released from this reaction is:

A. pyrophosphate.
B. inorganic phosphate.
C. ATP.
D. organic phosphate.

15. The hydrogens of phosphoric acid have pK_a values that:

A. allow high buffering capacity over a small pH range.
B. allow moderate buffering capacity over a large pH range.
C. allow low buffering capacity over a small pH range.
D. do not allow buffering.

Explanations to Discrete Practice Questions

1. D

Glycine's R group is a hydrogen atom; this amino acid is therefore achiral because the central carbon is not bonded to four different substituents. The other amino acids are all chiral and therefore have both L- and D-enantiomers.

2. B

This reaction is similar to the Gabriel synthesis. Phthalimide acts as a nucleophile, the methyl carbon acts as an electrophile, and bromide acts as the leaving group. Therefore, the reaction between methyl bromide and phthalimide results in the formation of methyl phthalimide. Subsequent hydrolysis then yields methylamine.

3. B

Cysteine is well known for containing a sulfur atom because it is able to form disulfide bridges; however, methionine also contains a sulfur atom in its R group.

4. B

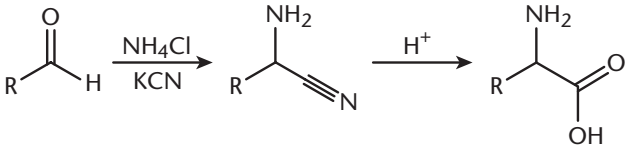
An amide is formed from an amine and a carboxyl group or its acyl derivatives. In this question, an amine is already given; the compound to be identified must be an acyl compound. The only acyl compound among the choices given is a carboxylic acid.

5. C

During the Strecker synthesis, ammonia attacks a carbonyl, forming an imine, **choice (B)**. This imine is attacked by cyanide, forming an amine, **choice (D)**, and a nitrile, **choice (A)**. Amide bonds are formed between amino acids, but do not appear during the Strecker synthesis.

6. C

The Strecker synthesis creates an amino acid from an aldehyde. The carbonyl carbon ultimately becomes the α-carbon of the amino acid. Any remaining alkyl chain becomes the R group, as shown below. The starting compound is therefore 2-methylpropanal (isobutyraldehyde).



7. D

One resonance structure of a C–N bond in an amide has the double bond between the C and N, not between the C and O. Thus, the C–N bond of an amide has some sp^2 character, and sp^2-hybridized atoms exhibit planar geometry.

8. D

Both the Strecker and Gabriel syntheses contain planar intermediates, which can be attacked from either side by a nucleophile. This results in a racemic mixture of enantiomers, and the solution will therefore be optically inactive.

9. A

During the Gabriel synthesis, phthalimide attacks a secondary carbon in diethyl bromomalonate. The secondary carbon is the electrophile, **choice (D)**, and bromide is the leaving group, **choice (C)**.

10. C

The Gabriel synthesis includes two nucleophilic substitution steps, followed by hydrolysis and decarboxylation. Dehydration—the loss of a water molecule—is not a part of this reaction.

11. B

The pK_{a2} of phosphoric acid is close to physiological pH; therefore, $\left[H_2PO_4^-\right] \approx \left[HPO_4^{2-}\right]$ at this pH.

12. C

Pyrophosphate is unstable in aqueous solution and will degrade to form two equivalents of inorganic phosphate. The solvent is water, which should retain its polarity regardless of the presence of solutes, eliminating **choice (D)**. Pyrophosphate and inorganic phosphate are small, charged molecules which are relatively soluble, eliminating **choice (A)**.

13. B

The amino acid in question is aspartic acid, which is an acidic amino acid because it contains an extra carboxyl group. At neutral pH, both of the carboxyl groups are ionized, so there are two negative charges on the molecule. Only one of the charges is neutralized by the positive charge on the amino group, so the molecule has an overall negative charge.

14. A

As DNA is synthesized, it forms phosphodiester bonds, releasing pyrophosphate, PP_i. Pyrophosphate is an inorganic phosphate-containing molecule, but it is not the single phosphate group commonly referred to as inorganic phosphate, **choice (B)**. The DNA molecule itself is referred to as an organic phosphate, **choice (D)**.

15. B

Phosphoric acid has three hydrogens with pK_a values spread across the pH range. This allows some degree of buffering over almost the entire standard pH range from 0 to 14.

Concept Summary **260**

Introduction

If we are given an unknown compound, one of the most efficient ways to identify it and determine its properties is by using spectroscopy. **Spectroscopy** measures the energy differences between the possible states of a molecular system by determining the frequencies of electromagnetic radiation absorbed by the molecules. These possible states are quantized energy levels associated with different types of molecular motion, such as molecular rotation, vibration of bonds, electron absorption, and nuclear spin transitions. Different types of spectroscopy measure different types of molecular properties, allowing us to identify the presence of specific functional groups and to detect the connectivity (backbone) of a molecule.

In a medical context, spectroscopy is important in magnetic resonance imaging (MRI). MRI scanners actually measure ^{1}H–NMR spectra of water molecules in different environments in the body. They then converts these signals into greyscale, allowing excellent visualization of the body, especially soft tissue.

One of the big advantages of laboratory spectroscopy is that only a small quantity of a sample is needed. Also, the sample may be reused after a test is performed. The downside of spectroscopy is that it's difficult to do without special equipment—but as long as you have a chemistry lab available, these are some of the best techniques to identify compounds.

11.1 Infrared Spectroscopy ★★

Infrared (**IR**) **spectroscopy** measures molecular vibrations, which can be seen as bond stretching, bending, or combinations of different vibrational modes. To record an IR spectrum, infrared light is passed through a sample, and the absorbance is measured. By determining what bonds exist within a molecule, we hope to infer the functional groups in the molecule.

Key Concept

Wavenumbers (cm^{-1}) are an analog of frequency. $f = \frac{c}{\lambda}$, whereas wavenumber $= \frac{1}{\lambda}$.

INTRAMOLECULAR VIBRATIONS AND ROTATIONS

The infrared light range runs from λ = 700 nm to 1 mm, but the useful absorptions for spectroscopy occur at wavelengths of 2500 to 25,000 nm. On an IR spectrum, we use an analog of frequency called **wavenumber**. The standard range corresponding to 2500 to 25,000 nm is 4000 to 400 cm^{-1}. When light of these wavenumbers is absorbed, the molecules enter excited vibrational states. Four types of vibration that can occur are shown in Figure 11.1. Others include twisting and folding.

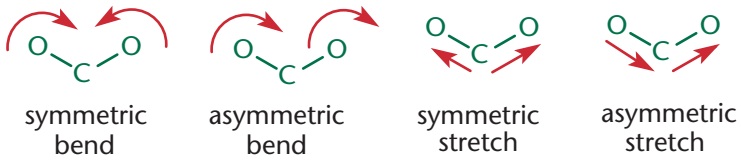

Figure 11.1. Molecular Vibrations Measured by Infrared (IR) Spectroscopy
Bond bending and stretching; twisting and folding can also occur.

More complex vibration patterns, caused by the motion of the molecule as a whole, can be seen in the 1500 to 400 cm^{-1} range. This is called the **fingerprint region** because the specific absorbance pattern is characteristic of each individual molecule. Spectroscopy experts can use this region to identify a substance, but you won't ever need to use it on the MCAT.

Key Concept

Symmetric stretches do not show up in IR spectra because they involve no net change in dipole movement.

For an absorption to be recorded, the vibration must result in a change in the bond dipole moment. This means that molecules that do not experience a change in dipole moment, such as those composed of atoms with the same electronegativity or molecules that are symmetrical, do not exhibit absorption. For example, we cannot get an absorption from O_2 or Br_2, but we can from HCl or CO. Symmetric bonds, such as the triple bond in acetylene (C_2H_2), will also be silent.

CHARACTERISTIC ABSORPTIONS

For the MCAT, you only need to memorize a few absorptions. The first is the hydroxyl group, O–H, which absorbs with a broad (wide) peak at around one of two frequencies: 3300 cm^{-1} for alcohols, and 3000 cm^{-1} for carboxylic acids. The carbonyl of a carboxylic acid pulls some of the electron density out of the O–H bond, shifting the absorption to a lower wavenumber. The second is the carbonyl, which absorbs around 1700 cm^{-1} with a sharp (deep) peak. In Table 11.1, notice how the bond between any atom and hydrogen always has a relatively high absorption frequency and how, as we add more bonds between carbon atoms, the absorption frequency increases. N–H bonds are in the same region as O–H bonds (around 3300 cm^{-1}), but have a sharp peak instead of a broad one. You should be able to identify these three peaks in an IR spectrum. If you need to identify other peaks on Test Day, a list or table of peak wavenumbers will be provided.

Functional Group	Wavenumber (cm^{-1})	Vibration
Alkanes	2800–3000	C–H
	1200	C–C
Alkenes	3080–3140	=C–H
	1645	C=C
Alkynes	3300	≡C–H
	2200	C≡C
Aromatic	2900–3100	C–H
	1475–1625	C–C
Alcohols	3100–3500	O–H (broad)
Ethers	1050–1150	C–O
Aldehydes	2700–2900	(O)C–H
	1700–1750	C=O
Ketones	1700–1750	C=O
Carboxylic Acids	1700–1750	C=O
	2800–3200	O–H (broad)
Amines	3100–3500	N–H (sharp)

Table 11.1. Absorption Frequencies

MCAT Expertise

Infrared spectroscopy is best used for identification of functional groups. The most important peaks to know are:

- O–H (broad around 3300 cm^{-1})
- N–H (sharp around 3300 cm^{-1})
- C=O (sharp around 1750 cm^{-1})

We can learn a great deal of information from an IR spectrum; for the MCAT, all of the information comes from the frequencies between 1400 and 4000 cm^{-1}. Everything lower (in the fingerprint region) is out of scope. IR spectra are plotted as percent **transmittance**, the amount of light that passes through the sample and reaches the detector, *vs*. wavenumber.

Key Concept

In an IR spectrum, percent transmittance is plotted *vs*. frequency. The equation relating absorbance, *A*, and percent transmittance, % *T*, is $A = 2 - \log \%T$; this means that maximum absorptions appear as the bottoms of valleys on the spectrum.

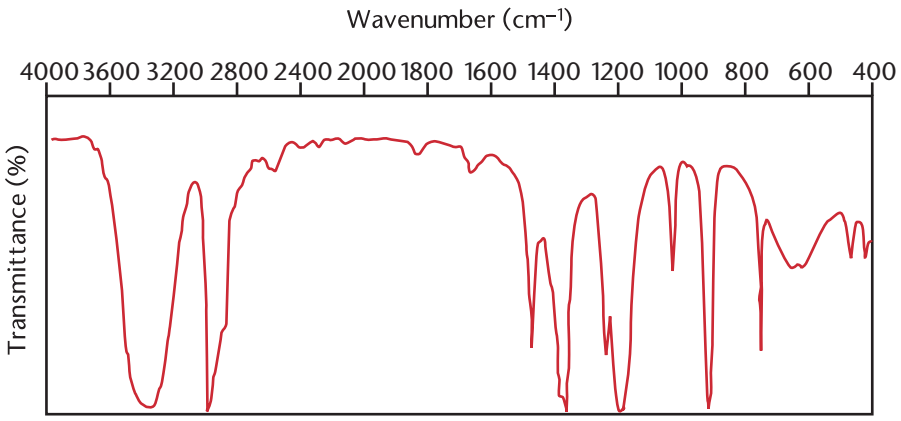

Figure 11.2. IR Spectrum of an Aliphatic Alcohol
Broad peak at 3300 cm^{-1}: –OH

Figure 11.2 shows the IR spectrum for an aliphatic alcohol: the large broad peak at 3300 cm^{-1} is due to the presence of a hydroxyl group, whereas the sharper peak at 3000 cm^{-1} is due to the carbon–hydrogen bonds in the alkane portion of the molecule, as listed in Table 11.1.

MCAT Concept Check 11.1:

Before you move on, assess your understanding of the material with these questions.

1. What does infrared (IR) spectroscopy measure? What is IR spectroscopy generally used for?

   _____

   _____

   _____

2. What two peaks would you expect to see in the IR spectrum of a carboxylic acid?

   - _____
   - _____

11.2 Ultraviolet Spectroscopy ★★

Although you will never have to interpret **ultraviolet** (**UV**) **spectroscopy** data on the MCAT, it is fair game for discussion. A basic understanding of how it works and when it is used will suffice. UV spectra are obtained by passing ultraviolet light through a sample that is usually dissolved in an inert, nonabsorbing solvent, and recording the absorbance. The absorbance is then plotted against wavelength. The absorbance is caused by electronic transitions between orbitals. The biggest piece of information we get from this technique is the wavelength of maximum absorbance, which tells us the extent of conjugation within conjugated systems: the more conjugated the compound, the lower the energy of the transition and the greater the wavelength of maximum absorbance.

MCAT Expertise

UV spectroscopy is most useful for studying compounds containing double bonds and/or heteroatoms with lone pairs that create conjugated systems. For the MCAT, that is all you need to know.

ELECTRON TRANSITIONS

UV spectroscopy works because molecules with π-electrons or nonbonding electrons can be excited by ultraviolet light to higher-energy antibonding orbitals. Molecules with a lower energy gap between **highest occupied molecular orbital** (**HOMO**) and **lowest unoccupied molecular orbital** (**LUMO**) are more easily excited and can absorb longer wavelengths (lower frequencies) with lower energy.

CONJUGATED SYSTEMS

Conjugated molecules, or molecules with unhybridized *p*-orbitals, can also be excited by ultraviolet light. Conjugation shifts the absorption spectrum, resulting in higher maximum wavelengths (lower frequencies). For example, benzene has three broad absorbances, which mark the energy level transitions; these are found at 180, 200, and 255 nm wavelengths. Larger conjugated molecules may even absorb light in the visible range, leading to color. Because the technique for UV spectroscopy can also be used at visible wavelengths, it is sometimes called *UV–Vis spectroscopy*.

MCAT Concept Check 11.2:
Before you move on, assess your understanding of the material with these questions.

1. What types of molecules can be detected by UV spectroscopy?

   _____

   _____

2. In UV spectroscopy, what is the HOMO? What is the LUMO? How are they related to absorption wavelength?
   - HOMO:

     _____
   - LUMO:

     _____
   - Relation to absorption wavelength:

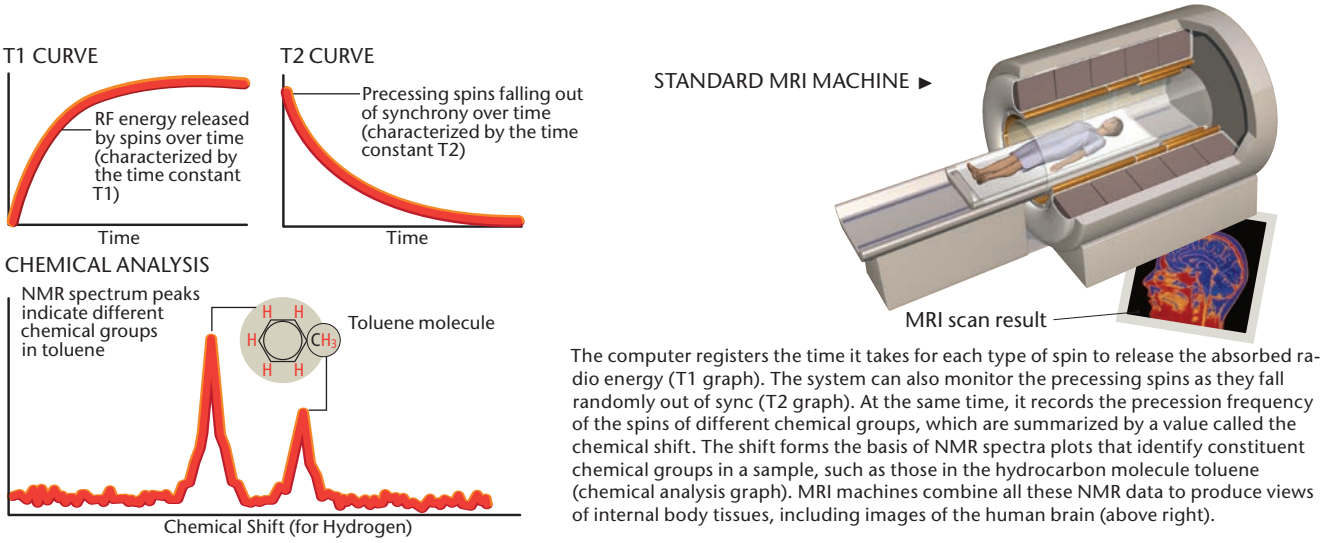
     _____

11.3 Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (**NMR**) spectroscopy is the most important spectroscopic technique to understand for the MCAT. NMR spectroscopy is based on the fact that certain atomic nuclei have magnetic moments that are oriented at random. When such nuclei are placed in a magnetic field, their magnetic moments tend to align either with or against the direction of this applied field. Nuclei with magnetic moments that are aligned with the field are said to be in the **α-state** (lower energy). The nuclei can then be irradiated with radiofrequency pulses that match the energy gap between the two states, which will excite some lower-energy nuclei into the **β-state** (higher energy). The absorption of this radiation leads to excitation at different frequencies,

depending on an atom's magnetic environment. In addition, the nuclear magnetic moments of atoms are affected by nearby atoms that also possess magnetic moments.

Magnetic resonance imaging (**MRI**) is a noninvasive diagnostic tool that uses proton NMR, as shown in Figure 11.3. Multiple cross-sectional scans of the patient's body are taken, and the various chemical shifts of absorbing protons are translated into specific shades of grey. This produces a picture that shows the relative density of specific types of protons; for instance, a dark area on a T1-weighted MRI tends to correspond to water, whereas a light area indicates fattier tissue. Comparison with normal MRI then allows the diagnostician to detect abnormalities in the scanned region. We mention this to explain the relevance of NMR spectroscopy to medicine; the MCAT will not test you on the details of how MRI works.



The computer registers the time it takes for each type of spin to release the absorbed radio energy (T1 graph). The system can also monitor the precessing spins as they fall randomly out of sync (T2 graph). At the same time, it records the precession frequency of the spins of different chemical groups, which are summarized by a value called the chemical shift. The shift forms the basis of NMR spectra plots that identify constituent chemical groups in a sample, such as those in the hydrocarbon molecule toluene (chemical analysis graph). MRI machines combine all these NMR data to produce views of internal body tissues, including images of the human brain (above right).

Figure 11.3. Magnetic Resonance Imaging (MRI)

Key Concept

TMS provides a reference peak. The signal for its ^{1}H atoms is assigned $\delta = 0$.

Bridge

Nuclei with odd mass numbers, odd atomic numbers, or both, will have a magnetic moment when placed in a magnetic field. Not all nuclei have magnetic moments (^{12}C, for example). Atomic numbers and mass numbers are discussed in more detail in Chapter 1 of *MCAT General Chemistry Review*.

A typical NMR spectrum is a plot of frequency *vs.* absorption of energy. Because different NMR spectrometers operate at different magnetic field strengths, a standardized method of plotting the NMR spectrum as been adopted. This standardized method, which is the only one seen on the MCAT, uses an arbitrary variable called **chemical shift** (**δ**), with units of **parts per million** (**ppm**) of spectrometer frequency. The chemical shift is plotted on the *x*-axis, and it increases toward the left (referred to as **downfield**). To make sure that we know just how far downfield compounds are, we use **tetramethylsilane** (**TMS**) as the calibration standard to mark 0 ppm; when counting peaks, make sure to skip the TMS peak.

Nuclear magnetic resonance is most commonly used to study ^{1}H nuclei (protons), although any atom possessing a nuclear spin (with an odd atomic number, odd mass number, or both) can be studied, such as ^{13}C, ^{19}F, ^{17}O, ^{31}P, and ^{59}Co. The MCAT, however, only tests knowledge of ^{1}H–NMR.

PROTON NMR (^{1}H–NMR)

Most hydrogen (^{1}H) nuclei come into resonance 0 to 10 ppm downfield from TMS. Each distinct set of nuclei gives rise to a separate peak. This means that if multiple protons are **chemically equivalent**, having the same magnetic environment, they will lead to the same peak. For example, Figure 11.4 depicts the ^{1}H–NMR of dichloromethyl methyl ether, which has two distinct sets of ^{1}H nuclei. The single proton attached to the dichloromethyl group (H_a) is in a different magnetic environment from the three protons on the methyl group (H_b), so the two classes will resonate at different frequencies. The three protons on the methyl group are chemically equivalent and resonate at the same frequency because this group rotates freely, and on average, each proton sees an identical magnetic environment.

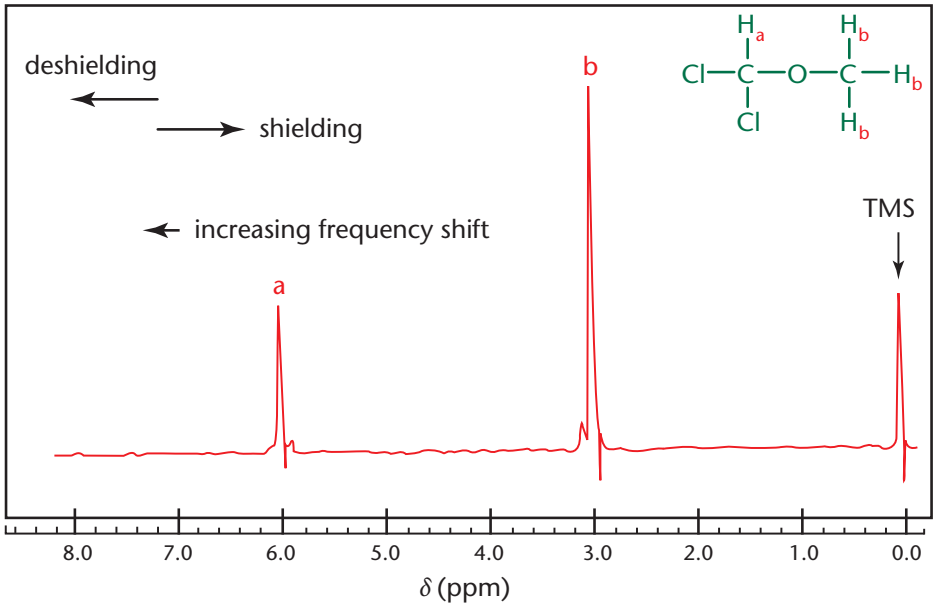


Figure 11.4. ^{1}H–NMR Spectrum of Dichloromethyl Methyl Ether
Peak a: Dichloromethyl proton; Peak b: Methyl protons.

The peak on the left (a) is from the single dichloromethyl proton, and the taller middle peak is from the three methyl protons (b). The height of each peak is proportional to the number of protons it contains. Specifically, if we were to analyze the area under the peaks, called the **integration**, we would find that the ratio of (a) to (b) is 1:3, corresponding exactly to the ratio of protons that produced each peak.

Now that we know which peak is which, let's talk about their respective positions on the spectrum. We can see that the peak for the single proton (a) is fairly far downfield compared with the other protons. This is because it is attached to a carbon with two electronegative chlorine atoms and an oxygen atom. These atoms pull electron density away from the surrounding atoms, thus **deshielding** the proton from the magnetic field. The more the proton's electron density is pulled away, the less it can

MCAT Expertise

To determine how many peaks will be in the spectrum, see if you can describe protons differently using words. In the dichloromethyl methyl ether shown in Figure 11.4, one could call H_a the *hydrogen on the carbon with two chlorides* and all three H_b hydrogens the *ones in the methyl group*. It would not be possible to describe each of these three hydrogens as distinct from each other because they rotate freely in space.

Key Concept

- Each peak or group of peaks that are part of a multiplet represents a single group of equivalent protons
- The relative area of each peak reflects the ratio of the protons producing each peak
- The position of the peak (upfield or downfield) is due to shielding or deshielding effects and reflects the chemical environment of the protons

shield itself from the applied magnetic field, resulting in a reading further downfield. With this same reasoning, we know that if we had an electron-donating group, such as the silicon atom in TMS, it would help shield the ^1H nuclei and give it a position further upfield. This is why tetramethylsilane is used as the reference or calibration peak; everything else in proton NMR will be more deshielded than it.

Mnemonic

When dealing with ^1H–NMR on the MCAT, think of a proton as being surrounded by a shield of electrons. As we add electronegative atoms or have resonance structures that pull electrons away from the proton, we **D**eshield and move **D**ownfield.

Now, let's make it a little more interesting. Consider a compound containing protons that are within three bonds of each other: in other words, a compound in which there are hydrogens on two adjacent atoms. When we have two protons in such close proximity to each other that are not magnetically identical, **spin–spin coupling** (**splitting**) occurs. Let's use the molecule in Figure 11.5 to demonstrate this concept.

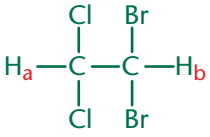

Figure 11.5. 1,1-Dibromo-2,2-dichloroethane

Notice the two protons, H_a and H_b, on 1,1-dibromo-2,2-dichloroethane. Because of their proximity, the magnetic environment of H_a can be affected by H_b, and vice-versa. Thus, at any given time, H_a can experience two different magnetic environments because H_b can be in either the α- or the β-state. The different states of H_b influence the nucleus of H_a, causing slight upfield and downfield shifts. There is approximately a 50% chance that H_b will be in either of the two states, so the resulting absorption is a **doublet**: two peaks of identical intensity, equally spaced around the true chemical shift of H_a. H_a and H_b will both appear as doublets because each one is coupled with one other hydrogen. To determine the number of peaks present (as doublets, triplets, and so on), we use the ***n* + 1 rule**: if a proton has n protons that are three bonds away, it will be split into $n + 1$ peaks. (One caveat: do *not* include protons attached to oxygen or nitrogen.) The magnitude of this splitting, measured in hertz, is called the **coupling constant**, ***J***.

Key Concept

The splitting of the peak represents the number of adjacent hydrogens. A peak will be split into $n + 1$ subpeaks, where n is the number of adjacent hydrogens.

Let's try a molecule that has even more coupled protons. In 1,1-dibromo-2-chloroethane, shown in Figure 11.6, the H_a nucleus is affected by two nearby H_b nuclei, which together can be in one of four different states: $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, or $\beta\beta$.

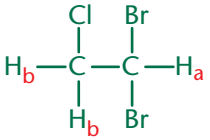

Figure 11.6. 1,1-Dibromo-2-chloroethane

Although there are technically four different states, $\alpha\beta$ has the same effect as $\beta\alpha$, so both of these resonances occur at the same frequency. This means we will have

three unique frequencies, $\alpha\alpha$, $\alpha\beta$ or $\beta\alpha$, and $\beta\beta$. H_a will thus appear as three peaks (a **triplet**) centered on the true chemical shift, with an area ratio of 1:2:1.

Now let's move on to H_b. Because both hydrogens are attached to the same carbon, which can freely rotate, they will be magnetically identical. These hydrogens are three bonds away from one other hydrogen, H_a. This means that they will appear as a doublet. Because there are two of them, the integration for the doublet representing H_b will be larger than the triplet for H_a.

Table 11.2 shows the ratios for up to seven adjacent hydrogens, but it isn't necessary to memorize this table for the MCAT. Just remember to follow the $n + 1$ rule for the proton of interest to determine the number of peaks. In addition, peaks that have more than four shifts will generally be referred to generically as a **multiplet**.

Number of Adjacent Hydrogens	Total Number of Peaks	Area Ratios
0	1	1
1	2	1:1
2	3	1:2:1
3	4	1:3:3:1
4	5	1:4:6:4:1
5	6	1:5:10:10:5:1
6	7	1:6:15:20:15:6:1
7	8	1:7:21:35:35:21:7:1

Table 11.2. Area Ratios for Peaks Split by Adjacent Hydrogens

Table 11.3 indicates the chemical shift ranges of several different types of protons. It is unnecessary to memorize this table, as it is fairly low-yield information. The values that are useful to memorize are the outliers like the deshielded aldehyde at 9 to 10 ppm, and the even more deshielded carboxylic acid between 10.5 and 12 ppm. Another popular peak on the MCAT is the hydrogen of an aromatic ring, which lies between 6.0 and 8.5 ppm. It is also worthwhile to know the general ranges for hydrogens on sp^3-hybridized carbons (0.0 to 3.0 ppm; higher if electron-withdrawing groups are present), sp^2-hybridized carbons (4.6 to 6.0 ppm), and *sp*-hybridized carbons (2.0 to 3.0 ppm). When electronegative groups are present, they pull electron density away from the protons. The more electron density that is pulled away from the proton, the more deshielded it will be and the further downfield the proton will appear.

Key Concept

Proton NMR is good for:

- Determining the relative number of protons and their relative chemical environments
- Showing how many adjacent protons there are by splitting patterns
- Inferring certain functional groups

MCAT Expertise

On Test Day, just counting the number of peaks and unique hydrogens may be enough to get you the correct answer. (Remember *not* to count the peak for TMS, though!) If you need to consider shifts, the main ones for Test Day are:

- Alkyl groups: 0 to 3 ppm
- Alkynes: 2 to 3 ppm
- Alkenes: 4.6 to 6 ppm
- Aromatics: 6 to 8.5 ppm
- Aldehydes: 9 to 10 ppm
- Carboxylic acids: 10.5 to 12 ppm

Type of Proton	Approximate Chemical Shift δ (ppm) Downfield from TMS
RCH_3	0.9
R_2CH_2	1.25
R_3CH	1.5
RC=CH	4.6–6.0
RC≡CH	2.0–3.0
Ar–H	6.0–8.5
RCHX	2.0–4.5
RCHOH/RCHOR	3.4–4.0
RCHO	9.0–10.0
$RCOCH_3$	2.0–2.5
RCHCOOH/RCHCOOR	2.0–2.6
ROH	1.0–5.5
ArOH	4.0–12.0
RCOOH	10.5–12.0
RNH_2	1.0–5.0

Table 11.3. Proton Chemical Shift Ranges

MCAT Concept Check 11.3:

Before you move on, assess your understanding of the material with these questions.

1. What does nuclear magnetic resonance (NMR) spectroscopy measure? What is NMR spectroscopy generally used for?

   _____

   _____

   _____

2. What are the units for chemical shift on a standardized NMR spectrum?

   _____

3. What does it mean for a proton to be deshielded? How does this affect its peak in NMR spectroscopy?

   _____

   _____

4. What is spin–spin coupling?

_____

_____

_____

Conclusion

This chapter was full of numbers and values, but the most important thing to know about spectroscopy on the MCAT is that you don't need to know a lot of numbers. The numbers that you *do* need to know have already been stressed heavily in this chapter. Know that infrared (IR) spectroscopy is best for identifying the presence (or, more importantly, the absence) of functional groups. A cursory understanding of ultraviolet (UV) spectroscopy and its association with conjugation will suffice. Nuclear magnetic resonance (NMR) spectroscopy—specifically, proton (^{1}H) NMR— also helps us figure out the arrangement of functional groups. Know how to interpret IR and NMR spectra: IR spectra have three important peaks (O–H, C=O, and N–H), but NMR spectra can be far more complex. The MCAT can test the chemical shift of deshielded protons, which will be downfield, or toward the left of the spectrum. Make sure that you can interpret peak splitting, which is due to interference from neighboring hydrogens, and peak integration, which is proportional to the number of magnetically identical hydrogens.

Spectroscopy is often tested on the MCAT in the context of experiment-based passages. As you continue studying the reaction chemistry discussed in Chapters 4 through 10 of *MCAT Organic Chemistry Review*, consider what these products would yield in different spectroscopic modalities.

This chapter focused on one method of identifying compounds based on structural characteristics and interactions with electromagnetic energy, but spectroscopy is not the only method for characterizing organic molecules. In the next chapter, we explore another side of laboratory techniques: separation and purification schemes. These utilize physical differences between molecules to allow us to isolate and describe them.

CONCEPT SUMMARY

Infrared Spectroscopy

- **Infrared** (**IR**) **spectroscopy** measures **absorption** of infrared light, which causes molecular vibration (stretching, bending, twisting, and folding).
- IR spectra are generally plotted as **percent transmittance** *vs.* **wavenumber** $\left(\frac{1}{\lambda}\right)$.
  - The normal range of a spectrum is 4000 to 400 cm^{-1}.
  - The **fingerprint region** is between 1500 and 400 cm^{-1}. It contains a number of peaks that can be used by experts to identify a compound.
- To appear on an IR spectrum, vibration of a bond must change the bond dipole moment. Certain bonds have characteristic absorption frequencies, which allow us to infer the presence (or absence) of particular functional groups.
  - The O–H peak is a broad peak around 3300 cm^{-1}. Molecules with O–H include alcohols, water, and carboxylic acids; the carboxylic acid O–H peak will be shifted around 3000 cm^{-1}.
  - The N–H peak is a sharp peak around 3300 cm^{-1}. Molecules with N–H include some amines, imines, and amides.
  - The C=O peak is a sharp peak around 1750 cm^{-1}. Molecules with C=O include aldehydes, ketones, carboxylic acids, amides, esters, and anhydrides.

Ultraviolet Spectroscopy

- Ultraviolet (UV) spectroscopy measures absorption of ultraviolet light, which causes movement of electrons between molecular orbitals.
- UV spectra are generally plotted as percent transmittance or absorbance *vs.* wavelength.
- To appear on a UV spectrum, a molecule must have a small enough energy difference between its **highest occupied molecular orbital** (**HOMO**) and its **lowest unoccupied molecular orbital** (**LUMO**) to permit an electron to move from one orbital to the other.
  - The smaller the difference between HOMO and LUMO, the longer the wavelengths a molecule can absorb.
  - **Conjugation** occurs in molecules with unhybridized *p*-orbitals. Conjugation shifts the absorption spectrum to higher maximum wavelengths (lower frequencies).

Nuclear Magnetic Resonance Spectroscopy

- **Nuclear magnetic resonance** (**NMR**) **spectroscopy** measures alignment of nuclear spin with an applied magnetic field, which depends on the magnetic

environment of the nucleus itself. It is useful for determining the structure (connectivity) of a compound, including functional groups.

- Nuclei may be in the lower-energy **α-state** or higher-energy **β-state**; radiofrequency pulses push the nucleus from the α-state to the β-state, and these frequencies can be measured.

- Magnetic resonance imaging is a medical application of NMR spectroscopy.
- NMR spectra are generally plotted as frequency *vs.* absorption of energy. They are standardized by using **chemical shift** (δ), measured in parts per million (ppm) of spectrophotometer frequency.
  - NMR spectra are calibrated using **tetramethylsilane** (**TMS**), which has a chemical shift of 0 ppm.
  - Higher chemical shifts are located to the left (**downfield**); lower chemical shifts are located to the right (**upfield**).
- Proton (^{1}H) NMR is the most common.
  - Each unique group of protons has its own peak.
  - The **integration** (area under the curve) of this peak is proportional to the number of protons contained under the peak.
  - **Deshielding** of protons occurs when electron-withdrawing groups pull electron density away from the nucleus, allowing it to be more easily affected by the magnetic field. Deshielding moves a peak further downfield.
  - When hydrogens are on adjacent atoms, they interfere with each other's magnetic environment, causing **spin–spin coupling** (**splitting**). A proton's (or group of protons') peak is split into $n + 1$ subpeaks, where n is the number of protons that are three bonds away from the proton of interest.
  - Splitting patterns include **doublets**, **triplets**, and **multiplets**.
  - Protons on sp^3-hybridized carbons are usually in the 0 to 3 ppm range (but higher if electron-withdrawing groups are present). Protons on sp^2-hybridized carbons are usually in the 4.6 to 6.0 ppm range. Protons on *sp*-hybridized carbons are usually in the 2.0 to 3.0 ppm range.
  - Aldehydic hydrogens tend to appear between 9 to 10 ppm.
  - Carboxylic acid hydrogens tend to appear between 10.5 and 12 ppm.
  - Aromatic hydrogens tend to appear between 6.0 and 8.5 ppm.

ANSWERS TO CONCEPT CHECKS

11.1

1. IR spectroscopy measures absorption of infrared light by specific bonds, which vibrate. These vibrations cause changes in the dipole moment of the molecule that can be measured. Once the bonds in a molecule are determined, one can infer the presence of a number of functional groups to determine the identity of the molecule.
2. A carboxylic acid would have a broad O–H peak around 2800–3200 cm^{-1} and a sharp carbonyl peak at 1700–1750 cm^{-1}.

11.2

1. Molecules with π or nonbonding electrons, and conjugated systems, will give absorbances on a UV spectroscopy plot.
2. HOMO is the highest occupied molecular orbital; LUMO is the lowest unoccupied molecular orbital. The smaller the difference in energy between the two, the longer the wavelengths that can be absorbed by the molecule.

11.3

1. NMR measures alignment of the spin of a nucleus with an applied magnetic field. It is most often used for identifying the different types and magnetic environments of protons in a molecule, which allows us to infer the connectivity (backbone) of a molecule.
2. The units for chemical shift with a standardized NMR spectrum are parts per million (ppm).
3. Deshielding occurs in molecules that have electronegative atoms that pull electron density away from the hydrogens being measured. This results in a downfield (leftward) shift of the proton peak.
4. Spin–spin coupling occurs when two protons close to one another have an effect on the other's magnetic environment. This results in the splitting of peaks into doublets, triplets, or multiplets, depending on the environment.

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. IR spectroscopy is most useful for distinguishing:

A. double and triple bonds.
B. C–H bonds.
C. chirality of molecules.
D. relative percentage of enantiomers in mixtures.

2. Oxygen (O_2) does not exhibit an IR spectrum because:

A. it has no molecular motions.
B. it is not possible to record IR spectra of a gaseous molecule.
C. molecular vibrations do not result in a change in the dipole moment.
D. molecular oxygen contains four lone pairs overall.

3. If IR spectroscopy were employed to monitor the oxidation of benzyl alcohol to benzaldehyde, which of the following would provide the best evidence that the reaction was proceeding as planned?

A. Comparing the fingerprint region of the spectra of starting material and product
B. Noting the change in intensity of the peaks corresponding to the benzene ring
C. Noting the appearance of a broad absorption peak in the region of 3100–3500 cm^{-1}
D. Noting the appearance of a strong absorption in the region of 1750 cm^{-1}

4. Which of the following chemical shifts could correspond to an aldehydic proton signal in a ^{1}H–NMR spectrum?

A. 9.5 ppm
B. 7.0 ppm
C. 11.0 ppm
D. 1.0 ppm

5. The isotope ^{12}C is not useful for NMR because:

A. it is not abundant in nature.
B. its resonances are not sensitive to the presence of neighboring atoms.
C. it has no magnetic moment.
D. the signal-to-noise ratio in the spectrum is too low.

6. In ^{1}H–NMR, splitting of spectral lines is due to:

A. coupling between a carbon atom and protons attached to that carbon atom.
B. coupling between a carbon atom and protons attached to adjacent carbon atoms.
C. coupling between adjacent carbon atoms.
D. coupling between protons on adjacent carbon atoms.

7. Compared to IR and NMR spectroscopy, UV spectroscopy is preferred for detecting:

A. aldehydes and ketones.
B. unconjugated alkenes.
C. conjugated alkenes.
D. aliphatic acids and amines.

8. Considering only the 0 to 4.5 ppm region of a ^{1}H–NMR spectrum, how could ethanol and isopropanol be distinguished?

A. They cannot be distinguished from ^{1}H–NMR alone.
B. A triplet and quartet are observed for ethanol, whereas a doublet and septet are observed for isopropanol.
C. A triplet and quartet are observed for isopropanol, whereas a doublet and septet are observed for ethanol.
D. The alcohol hydrogen in ethanol will appear within that region, whereas the alcohol hydrogen in isopropanol will appear downfield of that region.

9. Before absorbing an ultraviolet photon, electrons can be found in:

A. the HOMO only.
B. the LUMO only.
C. both the HOMO and the LUMO.
D. neither the HOMO nor the LUMO.

10. In an IR spectrum, how does extended conjugation of double bonds affect the absorbance band of carbonyl (C=O) stretches compared with normal absorption?

A. The absorbance band will occur at a lower wavenumber.
B. The absorbance band will occur at a higher wavenumber.
C. The absorbance band will occur at the same wavenumber.
D. The absorbance band will disappear.

11. Wavenumber is directly proportional to:

A. wavelength.
B. frequency.
C. percent transmittance.
D. absorbance.

12. Two enantiomers will:

A. have identical IR spectra because they have the same functional groups.
B. have identical IR spectra because they have the same specific rotation.
C. have different IR spectra because they are structurally different.
D. have different IR spectra because they have different specific rotations.

13. In a molecule containing a carboxylic acid group, what would be expected in a ^{1}H–NMR spectrum?

A. A deshielded hydrogen peak for the hydroxyl hydrogen, shifted left
B. A deshielded hydrogen peak for the hydroxyl hydrogen, shifted right
C. A shielded hydrogen peak for the hydroxyl hydrogen, shifted left
D. A shielded hydrogen peak for the hydroxyl hydrogen, shifted right

14. The coupling constant, J, is:

A. the value of $n + 1$ when determining splitting in NMR spectra.
B. measured in parts per million (ppm).
C. corrected for by calibration with tetramethylsilane.
D. a measure of the degree of splitting caused by other atoms in the molecule.

15. The IR spectrum of a fully protonated amino acid would likely contain which of the following peaks?

I. A sharp peak at 1750 cm^{-1}
II. A sharp peak at 3300 cm^{-1}
III. A broad peak at 3300 cm^{-1}

A. I only
B. I and II only
C. II and III only
D. I, II, and III

Explanations to Discrete Practice Questions

1. A

Infrared spectroscopy is most useful for distinguishing between different functional groups. Almost all organic compounds have C–H bonds, **choice (B)**, so except for fingerprinting a compound, these absorptions are not useful. Little information about the optical properties of a compound, such as **choices (C)** and **(D)**, can be obtained by IR spectroscopy.

2. C

Because molecular oxygen is homonuclear (composed of only one element) and diatomic, there is no net change in its dipole moment during vibration or rotation; in other words, the compound does not absorb in a measurable way in the infrared region. IR spectroscopy is based on the principle that, when the molecule vibrates or rotates, there is a change in dipole moment. **Choice (A)** is incorrect because oxygen does have molecular motions; they are just not detectable in IR spectroscopy. **Choice (B)** is incorrect because it is possible to record the IR of a gaseous molecule as long as it shows a change in its dipole moment when it vibrates. **Choice (D)** is incorrect because lone pairs do not have an effect on the ability to generate an IR spectrum of a compound.

3. D

In this reaction, the functional group is changing from a hydroxyl to an aldehyde. This means that a sharp peak will appear around 1750 cm^{-1}, which corresponds to the carbonyl functionality. **Choice (C)** is the opposite of what occurs; the reaction will be characterized by the disappearance of the O–H peak at 3100 to 3500 cm^{-1}, not its appearance. Comparing the fingerprint regions, as in **choice (A)**, will provide evidence that a reaction is occurring, but is not as useful for knowing that the reaction that occurred was indeed the one that was desired.

4. A

The peak at 9.5 ppm corresponds to an aldehydic proton. This signal lies downfield because the carbonyl oxygen is electron-withdrawing and deshields the proton. **Choice (C)** corresponds to a carboxyl proton and is even further downfield because the acidic proton is deshielded to a greater degree than the aldehydic proton. **Choice (B)** corresponds to aromatic protons. **Choice (D)** is characteristic of an alkyl proton on an sp^3-hybridized carbon.

5. C

This isotope has no magnetic moment and will therefore not exhibit resonance with an applied magnetic field. Nuclei with odd mass numbers (^1H, ^{11}B, ^{13}C, ^{15}N, ^{19}F, and so on) or those with an even mass number but an odd atomic number (^2H, ^{10}B) will have a nonzero magnetic moment.

6. D

Spin–spin coupling (splitting) is due to influence on the magnetic environment of one proton by protons on the adjacent atom. These protons are three bonds away from each other. Splitting in other NMR spectra can include coupling with carbon atoms, but not in ^1H–NMR.

7. C

Most conjugated alkenes have an intense ultraviolet absorption. Aldehydes, ketones, acids, and amines, mentioned in **choices (A)** and **(D)**, all absorb in the ultraviolet range. However, other forms of spectroscopy (mainly IR and NMR) are more useful for precise identification. Isolated alkenes, **choice (B)**, can rarely be identified by UV spectroscopy.

8. B

The region in question often gives information about the types of alkyl groups present. Specifically, ethanol will give a characteristic triplet for the methyl group (which is coupled to $–CH_2–$) and a quartet for $–CH_2–$ (which is coupled to the methyl group). Isopropanol will have a septet for the –CH– group (which is coupled to both methyl groups combined) and a doublet for the two methyl groups (which are coupled to –CH–). In both cases, the proton in the alcohol does not participate in coupling. The alcohol hydrogen likely lies downfield for both compounds because it is bonded to such an electronegative element.

9. A

The HOMO is the highest occupied molecular orbital. Only after absorbing ultraviolet light is an electron is excited from the HOMO to the LUMO, the lowest unoccupied molecular orbital.

10. A

Carbonyl groups (C=O) in conjugation with double bonds tend to absorb at lower wavenumbers because the delocalization of π electrons causes the C=O bond to lose double-bond character, shifting the stretching frequency closer to C–O stretches. Remember that higher-order bonds tend to have higher absorption frequencies, so loss of double-bond character should decrease the absorption frequency of the group.

11. B

Wavenumber $\left(\frac{1}{\lambda}\right)$ is directly proportional to frequency $\left(\frac{c}{\lambda}\right)$. It is inversely proportional to wavelength, **choice (A)**, and has no proportionality to percent transmittance or absorbance, **choices (C)** and **(D)**.

12. A

Enantiomers will have identical IR spectra because they have the same functional groups and will therefore have the exact same absorption frequencies. Enantiomers have opposite specific rotations, but specific rotation actually has no effect on the IR spectrum.

13. A

The oxygen of the hydroxyl group will deshield the hydroxyl hydrogen, shifting it downfield, or left. Hydrogens in carboxylic acids can have some of the most downfield absorbances, around 10.5 to 12 ppm.

14. D

The coupling constant is a measured of the degree of splitting introduced by other atoms in a molecule, and is the frequency of the distance between subpeaks. It is measured in hertz, eliminating **choice (B)**. The coupling constant is independent of the value of $n + 1$, and is not changed by calibration with tetramethylsilane, eliminating **choices (A)** and **(B)**.

15. B

Amino acids in their fully protonated form contain all three of the peaks that should be memorized for Test Day: C–O, N–H, and O–H. While statements I and II correctly give the peaks for the C=O bond (sharp peak at 1750 cm^{-1}) and the N–H bond (sharp peak at 3300 cm^{-1}), the peak for the O–H bond is in the wrong place. In a carboxylic acid, the C=O bond withdraws electron density from the O–H bond, shifting the absorption frequency down to about 3000 cm^{-1}. Statement III is therefore incorrect.

Concept Summary 285

Introduction

We've spent a lot of time discussing how to theoretically get various products from a range of reagents. However, as we're sure you've learned in your organic chemistry labs, chemistry isn't as straightforward in the real world as it is on paper. Much of the time spent in the lab is dedicated to the isolation and purification of the desired product after the reaction has occurred. Throughout this chapter, we will discuss several techniques for this. Good news, though—there isn't a lab practical on the MCAT, of course! All you need to understand is when these techniques are used and how they work.

MCAT Expertise

Purification and separation techniques are procedures that exploit different physical properties. These show up on the MCAT to test your knowledge of the basic principles of each of these techniques.

12.1 Solubility-Based Methods ★★

One of the simplest ways to separate out a desired product is through **extraction**, the transfer of a dissolved compound (the desired product) from a starting solvent into a solvent in which the product is more soluble. Extraction is based on the fundamental concept that *like dissolves like*. This principle tells us that a polar substance will dissolve best in polar solvents, and a nonpolar substance will dissolve best in nonpolar solvents. These characteristics can be taken advantage of in order to extract only the desired product, leaving most of the impurities behind in the first solvent.

Key Concept

Like dissolves like is a fundamental concept on the MCAT. Remember that polar substances will associate with other polar substances, and nonpolar with nonpolar.

EXTRACTION

When we perform **extractions**, it is important to make sure that the two solvents are **immiscible**, meaning that they form two layers that do not mix, like water and oil. The two layers are temporarily mixed by shaking so that solute can pass from one solvent to the other. For example, in a solution of isobutyric acid and diethyl ether, shown in Figure 12.1, we can extract the isobutyric acid with water. Isobutyric acid, with its polar carboxyl group, is more soluble in a polar solvent like water than in a nonpolar solvent like ether. When the two solvents are mixed together, isobutyric acid will transfer

MCAT Expertise

Think of the organic and aqueous layers as being like the oil and water in salad dressings: you can shake the mixture to increase their interaction, but ultimately they will separate again.

to the water layer, which is called the **aqueous phase** (**layer**). The nonpolar ether layer is called the **organic phase** (**layer**).

isobutyric acid diethyl ether

Figure 12.1. Isobutyric Acid and Diethyl Ether
Isobutyric acid is more polar than diethyl ether and can exhibit hydrogen bonding, so it will congregate in the aqueous layer; diethyl ether will remain in the organic layer.

After the two layers are mixed together, how do we then get the desired product out? The water (aqueous) and ether (organic) phases will separate on their own, given time to do so. In order to isolate these two phases, we use a piece of equipment called a **separatory funnel**, as shown in Figure 12.2. Gravitational forces cause the denser layer to sink to the bottom of the funnel, where it can then be removed by turning the stopcock at the bottom. It is more common for the organic layer to be on top, although the opposite can also occur. Remember that the position of the layers is determined by their relative densities.

Key Concept

Extraction depends on the rules of solubility and *like dissolves like*. Remember the three intermolecular forces that affect solubility:

1. Hydrogen bonding: Compounds that can do this, such as alcohols or acids, will move most easily into the aqueous layer
2. Dipole–dipole interactions: These compounds are less likely to move into the aqueous layer
3. Van der Waals (London) forces: With only these interactions, compounds are least likely to move into the aqueous layer

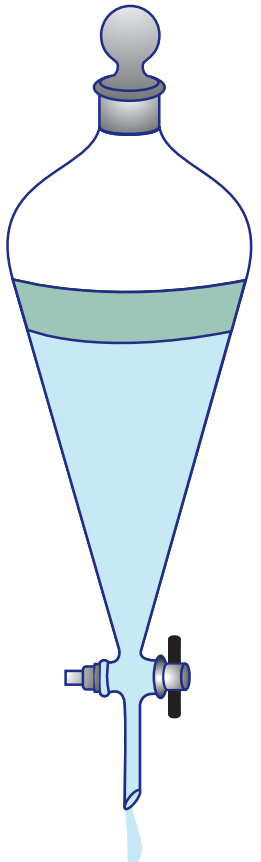

Figure 12.2. Separatory Funnel
Used to separate solvents based on their relative densities; the denser solvent is always drained first.

In this example, we'll assume that the aqueous layer is more dense and settles to the bottom of the separatory funnel. Once we drain the aqueous layer from the separatory funnel, we repeat the extraction several times. Additional water is added to the separatory funnel; it is shaken and allowed to settle, and the aqueous layer is once again drained off. This is done in order to extract as much of the isobutyric acid from the ether layer as possible because it does not completely transfer with the first extraction. Multiple extractions with fresh water are more effective for obtaining the most product, rather than a single extraction with a larger volume of water. You can imagine this as analogous to laundering dirty clothes several times, rather than laundering them with more water—the cleaner each volume of water is, the less dirt is likely to be left on the clothes afterward. Once the desired product has been isolated in the solvent, we can obtain the product alone by evaporating the solvent, usually by using a **rotary evaporator (rotovap)**.

Another way to take advantage of solubility properties is to perform the reverse of the extraction we just described in order to remove unwanted impurities. In this case, a small amount of solute is used to extract and remove impurities, rather than the compound of interest. This process is called a **wash**.

Bridge

You can use the properties of acids and bases to your advantage in extraction:

$$HA + base \rightarrow A^- + H\text{–}base^+$$

When the acid dissociates, the anion formed will be more soluble in the aqueous layer than the original protonated acid because it is charged. Thus, adding a base will help to extract an acid into the aqueous phase.

OTHER METHODS

In addition to extraction, filtration and recrystallization make use of solubility characteristics to separate compounds from a mixture.

Filtration

Filtration isolates a solid from a liquid. In the chemistry lab, one pours a liquid–solid mixture onto a paper filter that allows only the solvent to pass through, much like a coffee filter. At the end of filtration, one is left with the solid, called the **residue**, and the flask full of liquid that passed through the filter, known as the **filtrate**.

Filtration can be modified depending on whether the substance of interest is the solid or is dissolved in the filtrate. **Gravity filtration**, in which the solvent's own weight pulls it through the filter, is more commonly used when the product of interest is in the filtrate. Hot solvent is generally used to keep the product dissolved in liquid. **Vacuum filtration**, in which the solvent is forced through the filter by a vacuum connected to the flask, is more often used when the solid is the desired product.

Recrystallization

Recrystallization is a method for further purifying crystals in solution. In this process, we dissolve our product in a minimum amount of hot solvent and let it recrystallize as it cools. The solvent chosen for this process should be one in which the product is soluble only at high temperatures. Thus, when the solution cools, only the desired product will recrystallize out of solution, excluding the impurities.

MCAT Concept Check 12.1:
Before you move on, assess your understanding of the material with these questions.

1. What must be true about the two solvents used for an extraction to work?

   _____

   _____

2. When doing an extraction, would it be better to do three extractions with 10 mL of solvent, or one extraction with 30 mL?

   _____

3. Would acid dissolve better in aqueous acid or aqueous base? Why?

   _____

   _____

12.2 Distillation ★★

Extraction requires two solvents that are immiscible in order to separate the product. But what happens when the product itself is a liquid that is soluble in the solvent? This is where distillation comes in handy. **Distillation** takes advantage of differences in boiling point to separate two liquids by evaporation and condensation. The liquid with the lower boiling point will vaporize first, and the vapors will rise up the distillation column to condense in a water-cooled condenser. This **condensate** then drips down into a vessel. The end product is called the **distillate**. The heating temperature is kept low so that the liquid with the higher boiling point will not be able to boil and therefore will remain liquid in the initial container. This is the process that is used to make liquor at a distillery. Because ethanol boils at a lower temperature than water, we can use distillation to make beverages with high ethanol contents.

SIMPLE DISTILLATION

Simple distillation, as the name indicates, is the least complex version of distillation. It proceeds precisely as described above. This technique should only be used to separate liquids that boil below 150°C and have at least a 25°C difference in boiling points. These restrictions prevent the temperature from becoming so high that the compounds degrade and provide a large enough difference in boiling points that the second compound won't accidentally boil off into the distillate. The apparatus for this technique consists of a **distilling flask** containing the combined liquid solution, a **distillation column** consisting of a thermometer and a **condenser**, and a **receiving flask** to collect the distillate. The setup is the same as that shown in Figure 12.3, except that there will be no vacuum adaptor.

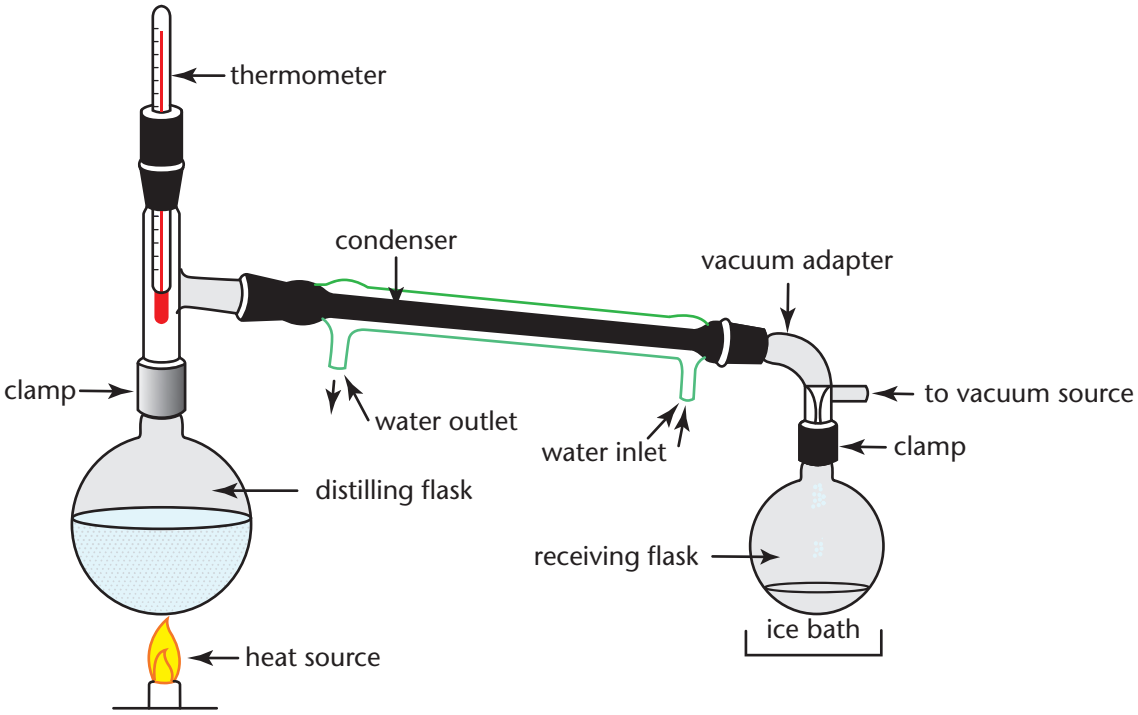

Figure 12.3. Vacuum Distillation
The initial solution is placed in the heated distilling flask, where the components of the solution with the lowest boiling points will vaporize first. The vapor then condenses in the water-cooled condenser, and this distillate drips into the receiving flask.

VACUUM DISTILLATION

We use **vacuum distillation** whenever we want to distill a liquid with a boiling point over 150°C. By using a vacuum, we lower the ambient pressure, thereby decreasing the temperature that the liquid must reach in order to have sufficient vapor pressure to boil. This allows us to distill compounds with higher boiling points at lower temperatures so that we do not have to worry about degrading the product. The apparatus for vacuum distillation is shown in Figure 12.3.

Bridge

Remember from Chapter 7 of *MCAT General Chemistry Review* that liquids boil when their vapor pressure equals ambient pressure. In vacuum distillation, we lower the ambient pressure so that the liquid can boil at lower temperatures.

FRACTIONAL DISTILLATION

To separate two liquids with similar boiling points (less than 25°C apart), we use **fractional distillation**. In this technique, a fractionation column connects the distillation flask to the condenser, as shown in Figure 12.4. A fractionation column is a column in which the surface area is increased by the inclusion of inert objects like glass beads or steel wool. As the vapor rises up the column, it condenses on these

surfaces and refluxes back down until rising heat causes it to evaporate again, only to condense again higher in the column. Each time the condensate evaporates, the vapor consists of a higher proportion of the compound with the lower boiling point. By the time the top of the column is reached, only the desired product drips down to the receiving flask.

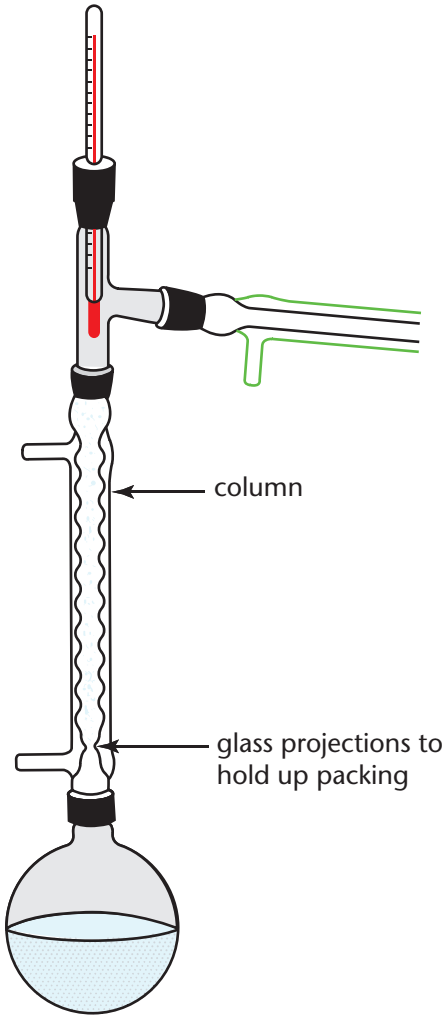

Figure 12.4. Fractional Distillation
With increased surface area in the distillation column, the distillate has more places to condense on its way up the column. This allows for more refined separation of liquids with fairly close boiling points.

MCAT Concept Check 12.2:
Before you move on, assess your understanding of the material with these questions.

1. Distillation separates compounds based on what property?

_____

2. If we are given a solution of ether, with a boiling point of 308 K, and methylene chloride, with a boiling point of 313 K, which type of distillation should be used to separate them?

_____

3. If we are given a solution of bromobenzene, with a boiling point of 156°C, and camphor, with a boiling point of 204°C, which type of distillation should be used to separate them?

_____

12.3 Chromatography

Chromatography is another tool that uses physical and chemical properties to separate and identify compounds from a complex mixture. In all forms of chromatography discussed here, the concept is identical: the more similar a compound is to its surroundings (whether by polarity, charge, or other characteristics), the more it will stick to and move slowly through its surroundings.

The process begins by placing the sample onto a solid medium called the **stationary phase**, or **adsorbent**. We then run the **mobile phase**, usually a liquid (or a gas in gas chromatography) through the stationary phase. This will displace (**elute**) the sample and carry it through the stationary phase. Depending on the characteristics of the substances in the sample and the polarity of the mobile phase, it will adhere to the stationary phase with differing strengths, causing the different substances to migrate at different speeds. This is called **partitioning**, and it represents an equilibrium between the two phases. Different compounds will have different **partitioning coefficients** and will elute at different rates. This results in separation within the stationary phase, allowing us to isolate each substance individually.

There are many different media that can be used as the stationary phase, each one exploiting different properties that allow us to separate out the desired compound. On the MCAT, the property most commonly used is polarity. For instance, thin-layer chromatography (TLC), which we will shortly discuss, uses silica gel, a highly polar substance, as its stationary phase. Cellulose, another polar substance, may also

Key Concept

Chromatography separates compounds based on how strongly they adhere to the solid, or stationary, phase (or in other words, how easily they come off into the mobile phase).

be used. This means that any polar compound will adhere to the gel well and thus move through (elute) slowly. When using column chromatography, size and charge both have a role in how quickly a compound moves through the stationary phase. Chromatography can use even strong interactions, such as antibody–ligand binding.

As mentioned earlier, chromatography is based on the speed at which compounds move through media. In practice, however, we will measure either how far each substance travels in a given amount of time (such as in TLC) or how long it takes to elute (as in column or gas chromatography).

The types of chromatography that we will discuss include thin-layer and paper chromatography, column chromatography, gas chromatography (also called gas–liquid chromatography), and high-performance liquid chromatography, or HPLC.

THIN-LAYER AND PAPER CHROMATOGRAPHY

Thin-layer chromatography and **paper chromatography** are extremely similar techniques, varying only in the medium used for the stationary phase. For thin-layer chromatography, a thin layer of silica gel or alumina adherent to an inert carrier sheet is used. For paper chromatography, as the name suggests, the medium used is paper, which is composed of cellulose.

For these techniques, the sample that we want to separate is placed directly onto the adsorbent itself; this is called **spotting** because we apply a small, well-defined spot of the sample directly onto the silica or paper plate. The plate is then **developed**, which involves placing the adsorbent upright in a developing chamber, usually a beaker with a lid or a wide-mouthed jar. At the bottom of this jar is a shallow pool of solvent, called the **eluent**. The spots of sample must be above the level of the solvent, or else they will dissolve into the pool of solvent rather than running up the plate. When set up correctly, the solvent will creep up the plate by capillary action, carrying the various compounds in the sample with it at varying rates. When the solvent front nears the top of the plate, the plate is removed from the chamber and allowed to dry.

As mentioned before, TLC is often done with silica gel, which is polar and hydrophilic. The mobile phase, on the other hand, is usually an organic solvent of weak to moderate polarity, so it doesn't bind well to the gel. Because of this, nonpolar compounds dissolve in the organic solvent and move quickly as the solvent moves up the plate, whereas the more polar molecules stick to the gel. Thus, the more nonpolar the sample is, the further up the plate it will move, as shown in Figure 12.5.

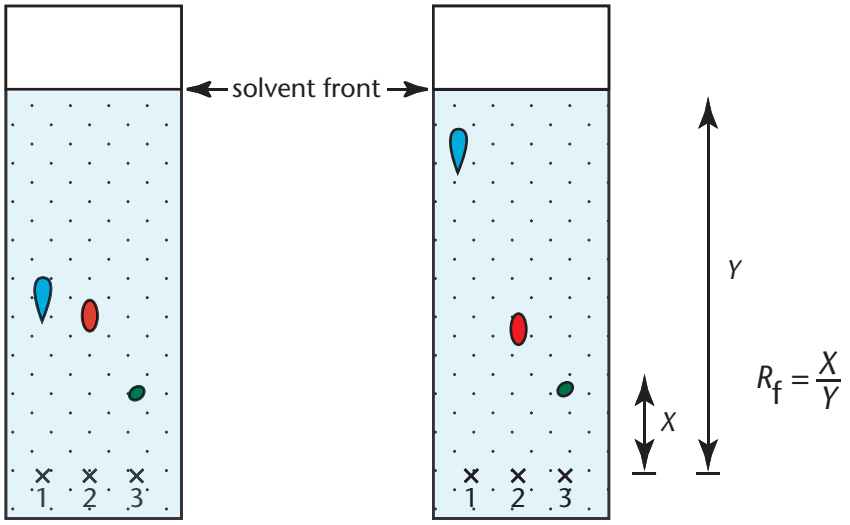

Figure 12.5. Thin-Layer Chromatography
Samples are placed at the "X" marks. As the nonpolar solvent moves up the plate via capillary action, the samples that are nonpolar move further up the plate along with the solvent, while the samples that are polar do not move as far.

Reverse-phase chromatography is the exact opposite. In this technique, the stationary phase used is nonpolar, so polar molecules move up the plate quickly, while nonpolar molecules stick more tightly to the stationary phase.

The spots of individual compounds are usually white, which makes them difficult or impossible to see on the white paper or TLC plate. To get around this problem, the developed plate can be placed under ultraviolet light, which will show any compounds that are ultraviolet-sensitive. Alternatively, iodine, phosphomolybdic acid, or vanillin can be used to stain the spots, although this will destroy the compounds such that they cannot be recovered.

When TLC is performed, compounds are generally identified using the **retardation factor (R_f)**, which is relatively constant for a particular compound in a given solvent. The R_f is calculated using the equation:

$$R_f = \frac{\text{distance spot moved}}{\text{distance solvent front moved}}$$

Equation 12.1

Because its value is relatively constant, the R_f value can be used to identify unknown compounds.

This technique is most frequently performed on a small scale to identify unknown compounds. It can also be used on a larger scale as a means of purification, a technique called **preparative TLC**. As the large plate develops, the larger spot of sample splits into bands of individual compounds, which can then be scraped off and washed to yield pure compounds.

COLUMN CHROMATOGRAPHY

The principles behind column chromatography are the same as for thin-layer chromatography, although there are some differences. First, **column chromatography** uses an entire column filled with silica or aluminum beads as an adsorbent, allowing for much greater separation. The setup for this is shown in Figure 12.6. In addition, thin-layer chromatography uses capillary action to move the solvent up the plate, whereas column chromatography uses gravity to move the solvent and compounds down the column. To speed up the process, one can force the solvent through the column using gas pressure, a technique called flash column chromatography. In column chromatography, the solvent polarity can also be changed to help elute the desired compound.

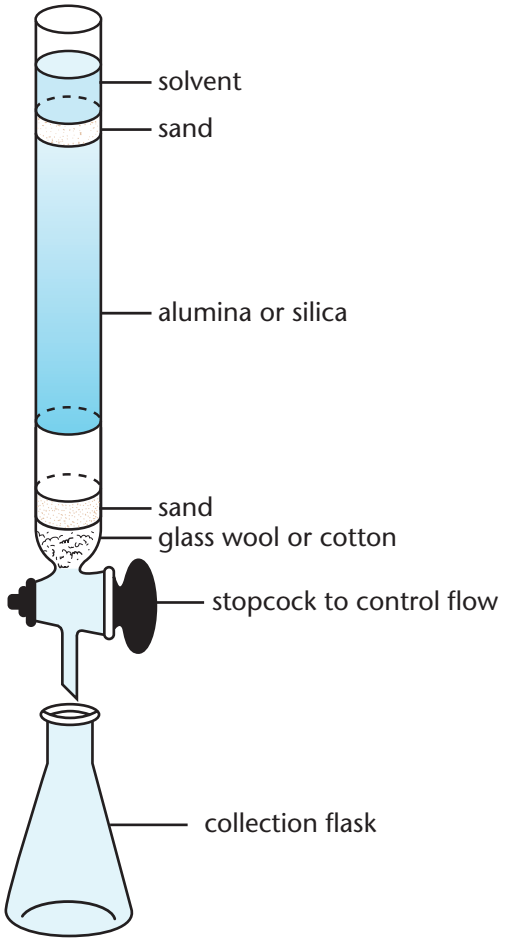

Figure 12.6. Column Chromatography
Sample is added to the top of the column, and a solvent is poured over it. The more similar the sample is to the mobile phase, the faster it elutes; the more similar it is to the stationary phase, the more slowly it will elute (if at all).

Eventually, the solvent drips out of the end of the column, and the different fractions that leave the column can be collected over time. Each fraction will contain different compounds. After collection, the solvent can be evaporated, leaving behind the compounds of interest. Column chromatography is particularly useful in biochemistry because it can be used to separate and collect macromolecules such as proteins or nucleic acids. There are several techniques that can be used to isolate specific materials, which are described in the following paragraphs, as well as in Chapter 3 of *MCAT Biochemistry Review*.

Ion-Exchange Chromatography

In **ion-exchange chromatography**, the beads in the column are coated with charged substances so that they attract or bind compounds that have an opposite charge. For instance, a positively charged compound will attract and hold a negatively charged backbone of DNA or protein as it passes through the column, either increasing its retention time or retaining it completely. After all other compounds have moved through the column, a salt gradient is used to elute the charged molecules that have stuck to the column.

Size-Exclusion Chromatography

In **size-exclusion chromatography**, the beads used in the column contain tiny pores of varying sizes. These tiny pores allow small compounds to enter the beads, thus slowing them down. Large compounds can't fit into the pores, so they will move around them and travel through the column faster. It is important to remember that in this type of chromatography, the small compounds are slowed down and retained longer—which may be counterintuitive. The size of the pores may be varied so that molecules with different molecular weights can be fractionated. A common approach in protein purification is to use an ion-exchange column followed by a size-exclusion column.

Affinity Chromatography

In **affinity chromatography**, a protein of interest is bound by creating a column with high affinity for that protein. This can be accomplished by coating beads with a receptor that binds the protein or a specific antibody to the protein; in either case, the protein is retained in the column. Common stationary phase molecules include nickel, which is used in separation of genetically engineered proteins with histidine tags, antibodies or antigens, and enzyme substrate analogues, which mimic the natural substrate for an enzyme of interest. Once the protein is retained in the column, it can be eluted by washing the column with a free receptor (or target or antibody), which will compete with the bead-bound receptor and ultimately free the protein from the column. Eluents can also be created with a varying pH or salinity level that disrupts the bonds between the ligand and the protein of interest. The only drawback of the elution step is that the recovered substance can be bound to the eluent. If, for example, the eluent was an inhibitor of an enzyme, it could be difficult to remove.

GAS CHROMATOGRAPHY

Gas chromatography (GC) is another method that can be used for qualitative separation. GC, also known as **vapor-phase chromatography (VPC)**, is similar to the other types of chromatography and is shown in Figure 12.7. The main conceptual difference is that the eluent is a gas (usually helium or nitrogen) instead of a liquid. The adsorbent is a crushed metal or polymer inside a 30-foot column. This column is coiled and kept inside an oven to control its temperature. The mixture is then injected into the column and vaporized. The gaseous compounds travel through the column at different rates because they adhere to the adsorbent in the column to different degrees and will separate in space by the time they reach the end of the column. The injected compounds must be **volatile**: low melting-point, sublimable solids or vaporizable liquids. The compounds are registered by a detector, which records them as a peak on a chart.

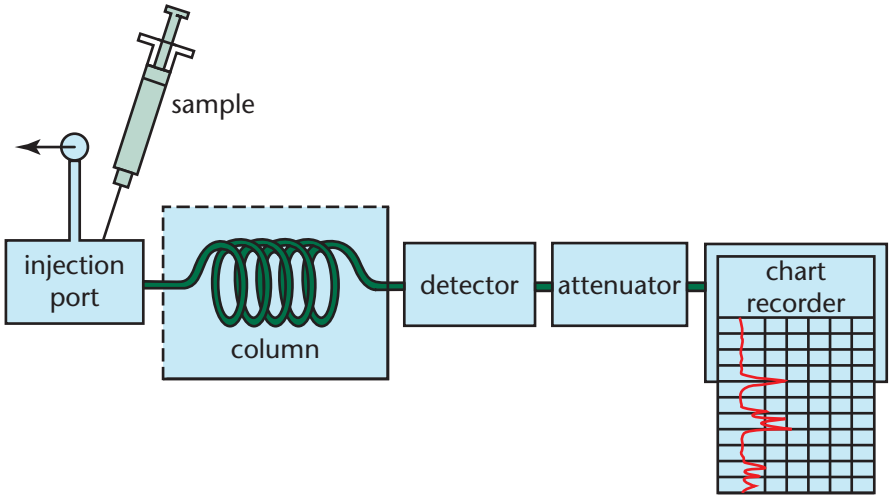

Figure 12.7. Gas Chromatography
The sample is injected into the column and moves with the gaseous mobile phase through a stationary liquid or solid phase; a computer identifies the sample components.

It is common to separate molecules using GC and then to inject the pure molecules into a **mass spectrometer** for molecular weight determination. **Mass spectrometry** involves the ionization and fragmentation of compounds; these fragments are then run through a magnetic field, which separates them by mass-to-charge ratio. The total molecular weight can thus be determined, or the relative concentrations of the different fragments can be calculated and compared against reference values to identify the compound.

HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

High-performance liquid chromatography (HPLC) was previously called high-pressure liquid chromatography. As the name suggests, the eluent is a

liquid, and it travels through a column of a defined composition. There are a variety of stationary phases that can be chosen depending on the target molecule and the quantity of material that needs to be purified. This is fairly similar to column chromatography because the various compounds in solution will react differently with the adsorbent material. In the past, very high pressures were used, but recent advances allow for much lower pressures—hence the change in name. In HPLC, a small sample is injected into the column, and separation occurs as it flows through. The compounds pass through a detector and are collected as the solvent flows out of the end of the apparatus. The interface is similar to that used for GC because the entire process is computerized, but uses liquid under pressure instead of gas. Because the whole process is under computer control, sophisticated solvent gradients as well as temperature can be applied to the column to help resolve the various compounds in the sample—hence the higher performance of HPLC over regular column chromatography.

MCAT Concept Check 12.3:

Before you move on, assess your understanding of the material with these questions.

1. What properties of molecules do thin-layer chromatography, paper chromatography, and standard column chromatography take advantage of to separate compounds?

_____

2. What are the three specialized types of column chromatography? What does each use in order to separate the sample?

Type of Column Chromatography	Method for Separating Sample

3. In what way is gas chromatography distinct from all of the other techniques we have discussed?

_____

4. What is the major historical distinction between HPLC and column chromatography? What is the major distinction now?
   - Historical distinction:

     _____
   - Current distinction:

     _____

Conclusion

Don't forget, the MCAT won't ask you to get into your lab coat and extract the product of a reaction! As long as you understand the principles governing these techniques and when you should apply them, you'll be in great shape. Remember that separation and purification techniques exploit physical properties of compounds, such as polarity, solubility, size and shape, and charge, to obtain a purified product. These properties can be traced back to intermolecular forces or properties of the molecules themselves. Having a variety of tools and methods to separate and collect a purified product is essential in practical organic chemistry, and choosing the proper techniques often requires knowledge and consideration of the desired product. When you look at the bigger picture, these methods may be easier to conceptualize than to actually apply in the lab!

Despite the subject's compelling relevance to everyday life, college organic chemistry often terrifies and alienates its students. The MCAT, on the other hand, doesn't ask you to memorize tables of reactants or regurgitate hundreds of named reactions from scratch. Instead, the MCAT asks you to look at the bigger picture, to know trends, and to participate in the logic of chemistry. We hope that studying for the MCAT has given you a chance to rediscover organic chemistry—to focus on the *how* and the *why*, instead of the *what*. Organic chemistry, like the MCAT as a whole, should be seen not as an obstacle but as an opportunity. So work hard, have some fun along the way, and keep thinking about where you're heading—you can almost feel that white coat.

CONCEPT SUMMARY

Solubility-Based Methods

- **Extraction** combines two immiscible liquids, one of which easily dissolves the compound of interest.
  - The polar (water) layer is called the **aqueous phase** and dissolves compounds with hydrogen bonding or polarity.
  - The nonpolar layer is called the **organic phase** and dissolves nonpolar compounds.
  - Extraction is carried out in a separatory funnel. One phase is collected, and the solvent is then evaporated.
  - Acid–base properties can be used to increase solubility.
- A **wash** is the reverse of extraction, in which a small amount of solute that dissolves impurities is run over the compound of interest.
- **Filtration** isolates a solid **(residue)** from a liquid **(filtrate)**.
  - **Gravity filtration** is used when the product of interest is in the filtrate. Hot solvent is used to maintain solubility.
  - **Vacuum filtration** is used when the product of interest is the solid. A vacuum is connected to the flask to pull the solvent through more quickly.
- In **recrystallization**, the product is dissolved in a minimum amount of hot solvent. If the impurities are more soluble, the crystals will reform while the flask cools, excluding the impurities.

Distillation

- **Distillation** separates liquids according to differences in their boiling points; the liquid with the lowest boiling point vaporizes first and is collected as the **distillate**.
- **Simple distillation** can be used if the boiling points are under 150°C and are at least 25°C apart.
- **Vacuum distillation** should be used if the boiling points are over 150°C to prevent degradation of the product.
- **Fractional distillation** should be used if the boiling points are less than 25°C apart because it allows more refined separation of liquids by boiling point.

Chromatography

- All forms of **chromatography** use two phases to separate compounds based on physical or chemical properties.
  - The **stationary phase** or **adsorbent** is usually a polar solid.

- The **mobile phase** runs through the stationary phase and is usually a liquid or gas. This **elutes** the sample through the stationary phase.
- Compounds with higher affinity for the stationary phase have smaller **retardation factors** and take longer to pass through, if at all; compounds with higher affinity for the mobile phase elute through more quickly. Compounds therefore get separated from each other, called **partitioning**.

- **Thin-layer** and **paper chromatography** are used to identify a sample.
  - The stationary phase is a polar material, such as silica, alumina, or paper.
  - The mobile phase is a nonpolar solvent, which climbs the card through capillary action.
  - The card is **spotted** and **developed**; R_f values can be calculated and compared to reference values.
  - **Reverse-phase chromatography** uses a nonpolar card with a polar solvent.
- **Column chromatography** utilizes polarity, size, or affinity to separate compounds based on their physical or chemical properties.
  - The stationary phase is a column containing silica or alumina beads.
  - The mobile phase is a nonpolar solvent, which travels through the column by gravity.
  - In **ion-exchange chromatography**, the beads are coated with charged substances to bind compounds with opposite charge.
  - In **size-exclusion chromatography**, the beads have small pores which trap smaller compounds and allow larger compounds to travel through faster.
  - In **affinity chromatography**, the column is made to have high affinity for a compound by coating the beads with a receptor or antibody to the compound.
- **Gas chromatography** separates vaporizable compounds according to how well they adhere to the adsorbent in the column.
  - The stationary phase is a coil of crushed metal or a polymer.
  - The mobile phase is a nonreactive gas.
  - Gas chromatography may be combined in sequence with **mass spectrometry**, which ionizes and fragments molecules and passes these fragments through a magnetic field to determine molecular weight or structure.
- **High-performance liquid chromatography (HPLC)** is similar to column chromatography but uses sophisticated computer-mediated solvent and temperature gradients. It is used if the sample size is small or if forces such as capillary action will affect results. It was formerly called high-pressure liquid chromatography.

ANSWERS TO CONCEPT CHECKS

12.1

1. The two solvents must be immiscible and must have different polarity or acid–base properties that allow a compound of interest to dissolve more easily in one than the other.
2. It is better to do three washes with 10 mL than to do one with 30 mL; more of the compound of interest would be extracted with multiple sequential extractions than one large one.
3. Acid dissolves better in aqueous base because it will dissociate to form the conjugate base and, being more highly charged, will become more soluble. Note that *like dissolves like* applies to polarity; acids and bases dissolve more easily in solutions with the opposite acid–base characteristics.

12.2

1. Distillation takes advantage of differences in boiling points in order to separate solutions of miscible liquids.
2. A solution of ether and methylene chloride, which have very close boiling points, can be separated by using fractional distillation.
3. Vacuum distillation would be the best technique to separate two chemicals with such high boiling points because the decreased ambient pressure will allow them to boil at a lower temperature.

12.3

1. Each of these methods separates compounds using charge and polarity.
2.

Type of Column Chromatography	Method for Separating Sample
Ion-exchange	Column is given a charge, which attracts molecules with the opposite charge
Size-exclusion	Small pores are used; smaller molecules are trapped, while larger molecules pass through the column
Affinity	Specific receptors or antibodies can trap the target in the column; the target must then be washed out using other solutions

3. As the name suggests, gas chromatography is simply the same technique of mobile and stationary phases performed with a gaseous eluent (instead of liquid). The stationary phase is usually a crushed metal or polymer.
4. Historically, HPLC was performed at high pressures, whereas column chromatography uses gravity to pull the solution through the column. Now, HPLC is performed with sophisticated and variable solvent and temperature gradients, allowing for much more specific separation of compounds than column chromatography; high pressures are no longer required.

EQUATIONS TO REMEMBER

(12.1) **Retardation factor:** $R_f = \frac{\text{distance spot moved}}{\text{distance solvent front moved}}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Fractional distillation under atmospheric pressure would most likely be used to separate which of the following compounds?

A. Methylene chloride (boiling point of 40°C) and water (boiling point of 10°C)
B. Ethyl acetate (boiling point of 77°C) and ethanol (boiling point of 80°C)
C. Aniline (boiling point of 184°C) and benzyl alcohol (boiling point of 205°C)
D. Aniline (boiling point of 184°C) and water (boiling point of 100°C)

2. Which of the following compounds would be most effective in extracting benzoic acid from a diethyl ether solution?

A. Tetrahydrofuran
B. Aqueous hydrochloric acid
C. Aqueous sodium hydroxide
D. Water

Questions 3 and 4 refer to the following table:

Compound	Retardation Factor in Ether
Benzyl alcohol	0.10
Benzyl acetate	0.26
p-Nitrophenol	0.23
1-Naphthalene-methanol	0.40

3. What would be the effect on the R_f values if thin-layer chromatography (TLC) were run with hexane rather than ether as the eluent?

A. No effect
B. Increase tenfold
C. Double
D. Decrease

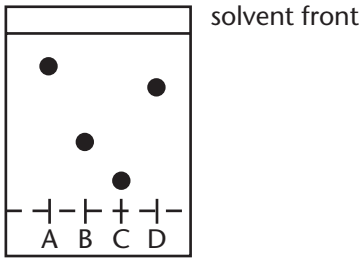
4. If these compounds were separated by column chromatography with ether on silica gel, which would elute first?

A. Benzyl alcohol
B. Benzyl acetate
C. *p*-Nitrophenol
D. 1-Naphthalenemethanol

5. Which of the following would be the best procedure for extracting acetaldehyde from an aqueous solution?

A. A single extraction with 100 mL of ether
B. Two successive extractions with 50 mL portions of ether
C. Three successive extractions with 33.3 mL portions of ether
D. Four successive extractions with 25 mL portions of ether

6. Four compounds, I, II, III, and IV, are separated by chromatographic techniques. Compound III is the most polar, II the least polar, and I and IV have intermediate polarity. The solvent system is 85:15 ethanol:methylene chloride. Which spot on the card below likely belongs to compound III?



A. A
B. B
C. C
D. D

7. Suppose an extraction with methylene chloride $\left(\rho = 1.33 \frac{g}{mL}\right)$ is performed, with the desired compound initially in brine $\left(\rho = 1.04 \frac{g}{mL}\right)$. In a separatory funnel, which layer will be the organic layer?

A. The top layer
B. The bottom layer
C. No layers are observed; methylene chloride and brine are miscible.
D. More information is needed to answer the question.

8. Silica gel is often used in thin-layer chromatography. What property does silica gel probably possess that makes it useful for this purpose?

A. Acidity
B. Polarity
C. Specifically sized pores
D. Aqueous solubility

9. A mixture of sand, benzoic acid, and naphthalene in ether is best separated by:

A. filtration, followed by acidic extraction, followed by recrystallization.
B. filtration, followed by basic extraction, followed by evaporation.
C. extraction, followed by distillation, followed by gas chromatography.
D. filtration, followed by size-exclusion column chromatography, followed by extraction.

10. Simple distillation could be used to separate which of the following compounds?

A. Toluene (boiling point of 111°C) and water (boiling point of 100°C)
B. Naphthalene (boiling point of 218°C) and butyric acid (boiling point of 163°C)
C. Propionaldehyde (boiling point of 50°C) and acetic acid (boiling point of 119°C)
D. Benzene (boiling point of 80°C) and isopropyl alcohol (boiling point of 83°C)

11. In order to separate a biological effector from solution, which chromatographic technique would be the most effective?

A. Thin-layer chromatography
B. Ion-exchange chromatography
C. Affinity chromatography
D. Size-exclusion chromatography

12. Given a solution of insulin (molecular weight = 5.8 kD) and titin (molecular weight = 3816 kD), which chromatographic technique would be the most effective for separating out usable molecules of titin?

A. Thin-layer chromatography
B. Ion-exchange chromatography
C. Affinity chromatography
D. Size-exclusion chromatography

13. The gas eluent in gas chromatography and the liquid eluent in paper chromatography are examples of which component of these systems?

A. Stationary phase
B. Mobile phase
C. Column
D. Fraction

14. During gravity filtration, a student forgets to heat the solution before running it through the filter. After capturing the filtrate, the student analyzes the sample via infrared (IR) spectroscopy and finds none of the desired product in the filtrate. What likely occurred to the student's product?

A. The product degraded because of a prolonged filtration time.
B. The product evaporated with collection of the filtrate.
C. The product precipitated and is present in the residue.
D. The product was dissolved in the solvent.

15. Lactoferrin, a milk protein, is a valuable antimicrobial agent that is extracted from pasteurized, defatted milk utilizing a column containing a charged resin. This is an example of which of the following chromatographic techniques?

A. Thin-layer chromatography
B. Ion-exchange chromatography
C. Affinity chromatography
D. Size-exclusion chromatography

Explanations to Discrete Practice Questions

1. B

Fractional distillation is the most effective procedure for separating two liquids that boil within a few degrees of each other. Ethyl acetate and ethanol boil well within 25°C of each other and thus would be good candidates for fractional distillation. Fractional distillation could also be used for the liquids in **choice (C)**, but would require lower pressures because of their high boiling points.

2. C

By extracting with sodium hydroxide, benzoic acid will be converted to its sodium salt, sodium benzoate. Sodium benzoate, unlike its conjugate acid, will dissolve in an aqueous solution. The aqueous layer simply has to be acidified afterward to retrieve benzoic acid. **Choice (A)** is incorrect because diethyl ether and tetrahydrofuran are both nonpolar and are miscible. Hydrochloric acid will not transform benzoic acid into a soluble salt, so **choice (B)** is incorrect. Finally, **choice (D)** is incorrect because protonated benzoic acid has limited solubility in water.

3. D

Hexane is less polar than ether and, therefore, is less likely to displace polar compounds adsorbed to the silica gel. This would decrease the distance these polar compounds would travel, decreasing R_f values.

4. D

In column chromatography, as in TLC, the less polar compound travels most rapidly. This means that 1-naphthalenemethanol,with the highest R_f value, would travel most rapidly and would be the first to elute from the column.

5. D

It is more effective to perform four successive extractions with small amounts of ether than to perform one extraction with a large amount of ether.

6. A

This is an example of reverse-phase chromatography. The solvent system is polar, which means that the most polar compound will travel the furthest up the card, resulting in the largest R_f. This gives compound III the largest R_f, which corresponds to spot A.

7. B

Because methylene chloride is denser than brine (salt water), the organic layer will settle at the bottom of the funnel. Methylene chloride is nonpolar, so it cannot mix with brine, eliminating **choice (C)**.

8. B

Silica gels are polar. Polarity is used to selectively attract specific solutes within a nonpolar solvent phase. Although silica gels have other properties, this is the most important to TLC.

9. B

In this question, three substances must be separated using a combination of techniques. The first step should be the most obvious: remove the sand by filtration. The remaining compounds—benzoic acid and naphthalene—are still dissolved in ether. If the solution is extracted with aqueous base, the benzoate anion is formed and becomes dissolved in the aqueous layer, while naphthalene, a nonpolar compound, remains in the ether. Finally, evaporation of the ether will yield purified naphthalene.

10. C

This is the only option that would be effectively separated by a simple distillation. **Choice (B)** would require vacuum distillation because the boiling points are over 150°C. In **choices (A)** and **(D)**, the boiling points are within 25°C of each other and would therefore require fractional distillation in order to be separated.

11. C

Affinity chromatography, using the target for the biological effector or a specific antibody, would work best in this case. It will specifically bind the protein of interest and keep it in the column.

12. D

Because this solution is composed of a much larger molecule and a much smaller molecule, size-exclusion chromatography would effectively remove the smaller insulin molecule into the fraction retained in the column and allow the titin to be eluted. Affinity chromatography, **choice (C)**, could also be used, but comes with a risk of rendering the titin unusable; the eluent run through an affinity chromatography column often binds to the target molecule.

13. B

Each of these is the mobile phase of the system, in which the solutes are dissolved and move. The stationary phase in gas chromatography is usually a crushed metal or polymer; the stationary phase in paper chromatography is paper.

14. C

Warm or hot solvent is generally used in gravity filtration to keep the desired product soluble. This allows the product to remain in the filtrate, which can then be collected. In this case, the student likely used solvent that was too cold, and the product crystallized out. The product should be present in the residue.

15. B

Because the lactoferrin proteins are likely to be charged, as is the resin described in the question, this is an example of ion-exchange chromatography. The charged protein molecules will stick to the column, while the remainder of the milk washes through and can later be washed off of the column and collected.

Glossary

α-Carbon—The carbon adjacent to a carbonyl; in amino acids, the chiral stereocenter in all amino acids except glycine.

α-Hydrogen—Hydrogen atoms connected to α-carbons adjacent to carbonyls.

α-State—A magnetic state seen in NMR spectroscopy in which nuclei have magnetic moments that are aligned with an incident magnetic field, thus having lower energy.

Absolute conformation—The exact spatial arrangement of atoms or groups in a chiral molecule around a single chiral atom, designated by (*R*) or (*S*).

Acetal—A functional group that contains a carbon atom bonded to two –OR groups, an alkyl chain, and a hydrogen atom.

Achiral—A molecule that either does not contain a chiral center or contains chiral centers and a plane of symmetry; as such, it has a superimposable mirror image.

Acid dissociation constant (K_a)—A measurement of the strength of an acid in solution; the higher the K_a, the lower the pK_a and the stronger the acid.

Affinity chromatography—A special type of column chromatography in which a column is customized to bind a substance of interest.

Aldol condensation—A reaction in which an aldehyde or ketone acts as both the electrophile and nucleophile, resulting in the formation of a carbon–carbon bond in a new molecule called an aldol.

Aldehyde—A functional group containing a carbonyl and a hydrogen (RCOH); always found at the end of a chain.

Alkane—A simple hydrocarbon molecule with the formula C_nH_{2n+2}.

Amide—A functional group containing a carbonyl and an amino group ($RCONR_2$).

Amino acids—Dipolar compounds that contain an amine and a carboxylic acid attached to a single carbon (the α-carbon); the building blocks of peptides.

Amphoteric—Describes molecules that can act as both acids and bases.

Angle strain—Increased energy that results when bond angles deviate from their ideal values.

Anhydride—A functional group containing two carbonyls separated by an oxygen atom (RCOOCOR); often the condensation dimer of a carboxylic acid.

***Anti* conformation**—A type of staggered conformation in which the two largest groups are antiperiplanar to each other; the most energetically favorable conformation.

Antibonding orbital—A higher-energy, less stable orbital that results from the overlap of wave functions with opposite signs.

Antiperiplanar—A conformation in which substituents are in the same plane, but on opposite sides of a bond.

Axial—Describes groups on a cyclic molecule that are perpendicular to the plane of the molecule, pointing straight up or down.

Azimuthal quantum number (l)—Describes the subshell in which an electron is found; possible values range from 0 to $n - 1$, with $l = 0$ representing the *s* subshell, $l = 1$ representing *p*, $l = 2$ representing *d*, and $l = 3$ representing *f*.

β-lactam—Four-membered cyclic amides that are more reactive to hydrolysis than linear amides or

larger cyclic amides; often used as the backbone for antibiotics.

***β*-state**—A magnetic state seen in NMR spectroscopy in which nuclei have been irradiated with radiofrequency pulses to bring them to a higher-energy state.

Bonding orbital—A lower-energy, more stable orbital that results from the overlap of wave functions with the same sign.

Carbonyl—A double bond between a carbon and an oxygen.

Carboxylic acid—A functional group that contains a carbonyl and a hydroxyl group on the same carbon (RCOOH).

Carboxylic acid derivative—A compound that can be created from a carboxylic acid by nucleophilic acyl substitution; includes anhydrides, esters, amides, and others.

Chemical properties—Characteristics of compounds that change chemical composition during a reaction; determine how a molecule will react with other molecules.

Chemical shift (*δ*)—An arbitrary variable used to plot NMR spectra; measured in parts per million (ppm).

Chemoselectivity—A reaction's preference for one location over another within a molecule.

Chiral—A molecule or carbon atom bonded to four different groups and without a plane of symmetry; thus, it is not superimposable on its mirror image and has an enantiomer.

Chiral center—Atoms that are chiral within a molecule.

Chromatography—A tool used to separate compounds based on how strongly they adhere to a stationary phase or travel with a mobile phase.

Cis—A molecule in which the two substituents are on the same side of an immovable bond.

***Cis–trans* Isomers**—Diastereomers with different arrangements of substituents around an immovable bond.

Column chromatography—A type of chromatography that uses a column filled with silica or alumina beads as an adsorbent, allowing for separation; uses gravity to move the solvent and compounds down the column.

Condensation reaction—A reaction that combines two molecules into one, with the loss of a small molecule.

Configuration—The spatial arrangement of the atoms or groups in a molecule.

Configurational isomers—Isomers that can only interconvert by breaking bonds; include enantiomers, diastereomers, and *cis–trans* isomers.

Conformational isomers—Isomers that are the same molecule, just at different points in their natural rotation about a σ bond.

Conjugation—Alternating single and multiple bonds that create a system of parallel unhybridized *p*-orbitals; thus, electrons can be shared between these orbitals, forming electron clouds above and below the plane of the molecule and stabilizing the molecule.

Constitutional isomers—Molecules that have the same molecular formulas but different connectivity; also called structural isomers.

Coordinate covalent bond—A covalent bond in which both electrons in the bond come from the same starting atom.

Coupling—In NMR spectroscopy, a phenomenon that occurs when there are protons in such close proximity to each other that their magnetic moments affect each other's appearance in the NMR spectrum by subdividing the peak into subpeaks; also called splitting.

Coupling constant (*J*)—The magnitude of splitting in NMR spectroscopy, measured in hertz.

Covalent—One of two types of chemical bonds in which electrons are shared between atoms.

Cyanohydrin—A functional group containing a nitrile (–C≡N) and a hydroxyl group.

***d*-orbital**—An atomic orbital that is composed of four symmetrical lobes and contains two nodes.

Decarboxylation—The complete loss of a carboxyl group as carbon dioxide.

Deprotection—Reversion of a protecting group to its original functional group.

Deprotonation—The removal of a hydrogen cation (H^+) from a molecule.

Deshielding—The phenomenon of atoms pulling electron density away from surrounding atoms; in NMR spectroscopy, pulls a group further downfield on the spectrum.

Developing chamber—A beaker with a lid or wide-mouthed jar used in thin-layer chromatography.

Dialcohols—Alcohols with two hydroxyl groups that are commonly used as protecting groups for aldehyde or ketone carbonyls; also called diols.

Diastereomers—Non-mirror-image configurational isomers that differ at at least one—but not all—chiral carbons; have different chemical and physical properties.

Distillate—The liquid evaporated, condensed, and collected during distillation.

Distillation—A separation and purification technique that takes advantage of differences in boiling point to separate two liquids by vaporization and condensation.

Doublet—Two peaks of identical intensity in an NMR spectrum that are equally spaced around the true chemical shift of a group of protons; results from splitting by another hydrogen.

Downfield—Movement toward the left in an NMR spectrum.

Electron-donating—Describes groups that push additional electron density toward another atom; stabilizes positive charges and destabilizes negative charges while decreasing acidity.

Electron-withdrawing—Describes groups that pull electron density away from another atom; stabilizes negative charges and destabilizes positive charges while increasing acidity.

Electrophile—"Electron-loving" atoms with a positive charge or positive polarization that can accept an electron pair when forming new bonds with a nucleophile.

Eluent—The solvent used in chromatography, after it has passed through the stationary phase.

Elute—To displace with solvent, as in thin-layer chromatography.

Enantiomers—Nonsuperimposable mirror images of a chiral molecule; have all the same physical and chemical properties except for rotation of plane-polarized light and reactions in a chiral environment.

Enol—The resonance form of a carbonyl that has a carbon–carbon double bond (*ene*) and an alcohol (*–ol*).

Equatorial—Describes groups on a cyclic molecule that are in the plane of the molecule.

Ester—A functional group containing a carbonyl and an alkoxy group (RCOOR).

Extraction—The transfer of a dissolved compound from a starting solvent into a solvent in which the product is more soluble.

Fingerprint region—In an IR spectrum, the region of 1500 to 400 cm^{-1} where more complex vibration patterns, caused by the motion of the molecule as a whole, can be seen; it is characteristic of each individual molecule.

Fischer esterification—The formation of an ester from a carboxylic acid and an alcohol in acidic conditions.

Fischer projection—A system to represent three-dimensional molecules in which horizontal lines indicate bonds that project out from the plane of the page (wedges) and vertical lines indicate bonds going into the plane of the page (dashes); points of intersection represent carbon atoms.

Flash column chromatography—A technique that speeds up column chromatography by forcing the solvent through the column by increasing pressure with a nonreactive gas.

Fractional distillation—A modified form of distillation used to separate two liquids with similar boiling points (less than 25°C apart); uses a

fractionation column, which contains inert materials onto which the liquids can condense and reflux back into the reaction vial, allowing more refined separation.

Fraction—A volume of eluted fluid from column chromatography; each fraction contains different compounds that are collected as they leave the column.

Gabriel (malonic-ester) synthesis—A method of synthesizing amino acids that uses potassium phthalimide and diethyl bromomalonate followed by an alkyl halide; two substitution reactions are followed by hydrolysis and decarboxylation.

Gas chromatography (GC)—A type of chromatography used to separate vaporizable compounds; the stationary phase is a crushed metal or polymer, and the mobile phase is a nonreactive gas.

***Gauche* conformation**—A type of staggered conformation in which the two largest groups are 60° apart.

Geminal diol—A functional group with two hydroxyl groups on the same carbon; also called a hydrate.

Hemiacetal—A functional group that contains a carbon atom bonded to one –OR group, one –OH group, an alkyl chain, and a hydrogen atom.

Hemiketal—A functional group that contains a carbon atom bonded to one –OR group, one –OH group, and two alkyl chains.

Heterolysis—Cleavage of a bond in which both electrons are given to the same atom.

High-performance liquid chromatography (HPLC)—A form of chromatography in which a small sample is put into a column that can be manipulated with sophisticated solvent gradients to allow very refined separation and characterization; formerly called high-pressure liquid chromatography.

Highest occupied molecular orbital (HOMO)—The highest-energy molecular orbital containing electrons; in UV spectroscopy, electrons are excited from the HOMO to the LUMO.

Hydride reagent—Reducing reagents containing hydride anions (H^-).

Hydrogen bonding—An intermolecular force that results from the extreme polarity of the bonds when hydrogen atoms are attached to highly electronegative atoms (N, O, or F).

Hydrolysis—The breaking of a molecule using water.

Hydroxyl group—An –OH group; seen in alcohols, hemiacetals and hemiketals, carboxylic acids, water, and other compounds.

Hydroxyquinone—A compound containing a quinone (conjugated ring with carbonyls) and a hydroxyl group.

Imine—A double bond between a carbon and a nitrogen.

Immiscible—Describes two solvents that will not mix with or dissolve each other.

Induction—The pull of electron density across sigma bonds.

Infrared (IR) spectroscopy—A technique that measures molecular vibrations at different frequencies, from which specific bonds can be determined; functional groups can be inferred based on this information.

Inorganic phosphate (P_i)—Derived from phosphoric acid, the molecule that forms high-energy bonds for energy transfer in nucleotide triphosphates like ATP; also used for enzyme regulation.

Ion-exchange chromatography—A special type of column chromatography in which the beads in the column are coated with charged substances so that they attract or bind compounds with an opposite charge.

Ionic—One of two types of chemical bonds in which electrons are transferred from one atom to another.

Isomers—Molecules with the same molecular formula but different chemical structures.

Jones oxidation—An oxidation reaction in which primary alcohols are oxidized to carboxylic acids and secondary alcohols are oxidized to ketones; requires CrO_3 dissolved with dilute sulfuric acid in acetone.

Ketal—A functional group that contains a carbon atom bonded to two –OR groups and two alkyl chains.

Ketone—A functional group containing a carbonyl with two alkyl groups (RCOR); always found within a chain.

Lactam—A cyclic amide; named according to the Greek letter of the carbon closing the ring.

Lactone—A cyclic ester; named according to the Greek letter of the carbon closing the ring and for the straight-chain form of the compound.

Leaving group—The molecular fragment that retains electrons after heterolysis; must be stable in solution.

Lewis acid—An electron acceptor in the formation of a covalent bond.

Lewis base—An electron donor in the formation of a covalent bond.

Lowest unoccupied molecular orbital (LUMO)—The lowest-energy molecular orbital that does not contain electrons; in UV spectroscopy, electrons are excited from the HOMO to the LUMO.

Magnetic quantum number (m_l)—Describes the orbital in which an electron is found; possible values range from $-l$ to $+l$.

***Meso* compound**—A molecule that has chiral centers but is not optically active because it has an internal plane of symmetry.

Mesylate—A compound containing the functional group $-SO_3CH_3$, derived from methanesulfonic acid.

Michael addition—A reaction in which a carbanion attacks an α,β-unsaturated carbonyl.

Mobile phase—A liquid (or a gas in gas chromatography) that is run through the stationary phase in chromatography.

Molecular orbital—The resulting electron structure when two atomic orbitals combine.

Multiplet—Peaks that have more than four shifts in NMR spectroscopy.

Newman projection—A method of visualizing a compound in which the line of sight is down a carbon–carbon bond axis.

Node—In orbital structure, an area where the probability of finding an electron is zero.

Nonbonded strain—Increased energy that results when nonadjacent atoms or groups compete for the same space; also called steric strain.

Nuclear magnetic resonance (NMR) spectroscopy—A technique that measures the alignment of magnetic moments from certain molecular nuclei with an external magnetic field; can be used to determine the connectivity and functional groups in a molecule.

Nucleophiles—"nucleus-loving" atoms with either lone pairs or π bonds that can be used to form new bonds with electrophiles.

Nucleophilic acyl substitution—The substitution of a nucleophile for the leaving group of a carboxylic acid or carboxylic acid derivative.

Optical isomers—A type of configurational isomers that have different spatial arrangements of substituents, which affects the rotation of plane-polarized light.

Organic phosphates—Organic molecules—usually nucleotides—that have a variable number of phosphate groups attached.

Oxidation—Loss of electrons causing an increase in oxidation state; increasing bonds to oxygen or other heteroatoms in a molecule.

Oxidation state—An indication of the hypothetical charge that an atom would have if all of its bonds were completely ionic.

Oxidizing agent—An element or compound that accepts an electron from another species, thereby being reduced in the process.

***p*-orbital**—An atomic orbital that is composed of two lobes located symmetrically about the nucleus and contains a node.

Paper chromatography—A type of chromatography that uses paper as the stationary phase.

Partitioning—When components in a sample adhere differentially to the mobile and stationary phases of a chromatographic setup; this causes the different substances to migrate at different speeds through the stationary phase.

Peptide bond—An amide bond formed between two amino acids through a condensation (nucleophilic acyl substitution) reaction.

Phenol—An alcohol with an aromatic ring, which has slightly more acidic hydroxyl hydrogens than other alcohols.

Phosphodiester bond—The type of bond linking the sugar moieties of adjacent nucleotides in DNA.

Physical properties—Characteristics of compounds that do not change chemical composition, such as melting point, boiling point, solubility, odor, color, and density.

Pi (π) Bond—The bonding molecular orbital formed when two parallel *p*-orbitals share electrons; exists as electrons clouds above and below the sigma (σ) bond between the two nuclei.

Polarity—An uneven distribution of charge caused by atoms in the same molecule having different electronegativities.

Polypeptide—A molecule formed from multiple amino acids connected by peptide bonds.

Preparative thin-layer chromatography—Large-scale use of thin-layer chromatography (TLC) as a means of purification; as the large plate develops, the larger spot of sample splits into bands of individual compounds, which can then be scraped off and washed to yield pure compounds.

Principal quantum number (n)—Describes the shell in which an electron is found; values range from 1 to ∞.

Protonation—The addition of a hydrogen cation (H^+) to a molecule.

Pyrophosphate (PP_i)—The ester dimer of phosphate $\left(P_2O_7^{4-}\right)$; released when a new nucleotide is joined to a growing strand of DNA by DNA polymerase.

Quinone—A compound produced by the oxidation of a phenol containing a conjugated ring with ketones.

R group—In general, an alkyl chain; in amino acid chemistry, the variable side chain on the α-carbon.

Racemic mixture—A mixture where both (+) and (–) enantiomers are present in equal concentrations.

Reduction—Gain of electrons causing a decrease in oxidation state; decreasing bonds to oxygen or other heteroatoms in a molecule.

Relative configuration—The spatial arrangement of groups in a chiral molecule compared to another chiral molecule.

Resonance—Delocalization of π electrons which increases stability of a molecule.

Resonance structure—A possible arrangement of π electrons in a molecule; the actual electronic structure of a molecule is the weighted average of resonance structures, based on their stability.

Retro-aldol reaction—The reverse of an aldol condensation reaction, in which a carbon–carbon bond is cleaved with heat and base, yielding two aldehydes, two ketones, or one of each.

Reverse-phase chromatography—The opposite of traditional thin-layer chromatography, in which the stationary phase is nonpolar and the mobile phase is polar.

Retardation factor (R_f)—A ratio used in thin-layer chromatography to identify a compound; calculated as how far the compound traveled relative to how far the solvent front traveled.

Ring strain—Energy created in a cyclic molecule by angle strain, torsional strain, and nonbonded strain; determines if a ring is stable enough to stay intact.

***s*-orbital**—An atomic orbital that is spherical and symmetrical, centered on the nucleus.

Saponification—The process by which fats are hydrolyzed under basic conditions to produce soap.

Separatory funnel—A piece of laboratory equipment used in extraction; immiscible solvents are separated by gravity, causing the denser layer to sink to the bottom, where it can be removed by turning the stopcock at the bottom.

Shielding—The phenomenon of atoms pushing electron density toward surrounding atoms; in NMR spectroscopy, pulls a group further upfield on the spectrum.

Sigma (σ) bond—The bonding molecular orbital formed by head-to-head or tail-to-tail overlap of atomic orbitals; all single bonds are sigma bonds.

Simple distillation—Distillation without any special features; can be used to separate liquids that boil below 150°C and that have at least a 25°C difference in boiling points.

Size-exclusion chromatography—A special type of column chromatography in which the beads in the column contain tiny pores of varying sizes, slowing down small compounds that enter the beads.

sp—A hybrid orbital with 50% *s*-character and 50% *p*-character.

***sp*^{2}**—A hybrid orbital with 33% *s*-character and 67% *p*-character.

***sp*^{3}**—A hybrid orbital with 25% *s*-character and 75% *p*-character.

Specific rotation ([α])—A standardized measure of a compound's ability to rotate plane-polarized light.

Spectroscopy—Laboratory technique that relies on measurement of the energy differences between the possible states of a molecular system by determining the frequencies of electromagnetic radiation (light) absorbed by the molecules or response to a magnetic field.

Spin quantum number (m_s)—Describes the intrinsic spin of the two electrons in an orbital by arbitrarily assigning one of the electrons a spin of $+\frac{1}{2}$ and the other a spin of $-\frac{1}{2}$.

Spotting—In thin-layer chromatography, placing the sample directly onto the adsorbent as a small, well-defined spot.

Staggered conformation—When a molecule has no overlapping substituents along the line of sight between two carbons, as in a Newman projection.

Stationary phase—A solid medium onto which a sample is placed for chromatography; also called the adsorbent.

Stereogenic—Describes a chiral center in a molecule.

Stereoisomers—Isomers that have the same chemical formula and the same atomic connectivity, but differ in how atoms are arranged in space; any isomer that is not a structural isomer is a stereoisomer.

Steric hindrance—The prevention of a reaction at a particular location in a molecule by substituent groups around the reactive site.

Steric protection—The prevention of the formation of alternative products using a protecting group.

Strecker synthesis—A method of synthesizing amino acids that uses condensation between an aldehyde and hydrogen cyanide, followed by hydrolysis.

Structural isomers—Molecules that have the same molecular formulas but different connectivity; also called constitutional isomers.

Substituent—Any functional group that is not part of the parent chain.

Tautomer—An isomer that differs from another by the placement of a proton and a double bond.

Tetramethylsilane (TMS)—The calibration standard that marks 0 ppm when plotting an NMR spectrum.

Thin-layer chromatography (TLC)—A type of chromatography that uses silica gel or alumina on a card as the medium for the stationary phase.

Torsional strain—Increased energy that results when molecules assume eclipsed or *gauche* staggered conformations.

Tosylate—A compound containing the functional group $-SO_3C_6H_4CH_3$, derived from toluenesulfonic acid.

Totally eclipsed conformation—A type of conformation in which the two largest groups are 0° apart; the most energetically unfavorable conformation.

Trans—A molecule in which the two substituents are on opposite sides of an immovable bond.

Transesterification—The process that transforms one ester to another when an alcohol acts as a nucleophile and displaces the alkoxy group on an ester.

Triacylglycerols—Esters of long-chain carboxylic acids (fatty acids) and glycerol (1,2,3-propanetriol); used as a storage form of energy.

Triplet—Three peaks with an area ratio of 1:2:1 in an NMR spectrum that are centered around the true chemical shift of a group of protons; results from splitting by two equivalent hydrogens.

Ubiquinone—A biologically active quinone that is a vital electron carrier in the electron transport chain; also called coenzyme Q.

Ultraviolet (UV) spectroscopy—A technique that measures absorbance of ultraviolet light of various wavelengths passing through a sample.

Upfield—Movement to the right in an NMR spectrum.

Vacuum distillation—A modified form of distillation used to separate two liquids with boiling points over 150°C; lowers the pressure to decrease the temperature at which a liquid will boil.

Vicinal diol—A dialcohol with hydroxyl groups on adjacent carbons.

Wash—The reverse of extraction, in which a small amount of solvent is poured over the compound of interest to dissolve and remove impurities.

Wavenumber—An analog of frequency used for infrared spectra instead of wavelength.

Zwitterion—A compound that contains charges but is overall neutral.

D

Decarboxylation, 189–190, 192, 194, 239, 297
Dehydration reactions, 168, 171
Deoxyribonucleic acid (DNA)
  backbone, 235, 239, 281
  DNA polymerase, 235, 300
  phosphodiester bonds, 235, 239
  synthesis, 234
Deoxyribonucleic acid (DNA): phosphodiester bond, 235*f*
Deprotection, 122, 128, 297
Deprotonation, 99, 163, 169, 170, 183, 297
Deprotonation: alpha carbon, 162*f*
Deshielding, 255, 261, 297
Developing chamber, 278, 297
Dialcohols: protection of a ketone by ketal formation, 123*f*
Diastereomers, 38, 39, 42–43, 44, 51, 296, 297
Diasteromers: 2^n possible stereoisomers, 42*f*
1,1-Dibromo-2,2-dichloroethane, 256*f*
1,1-Dibromo-2-chloroethane, 256*f*
1,3-Dicarbonyl compounds: general structure, 185*f*
Dicarboxylic acids
  beta-dicarboxylic acids, acidity of alpha hydrogen in, 184*f*
  IUPAC and common names, 183*f*
Dichloromethyl methyl ether: proton NMR, 255*f*
Dichromate salt: oxidation of a secondary alcohol to a ketone, 121*f*
Diethyl ether, 272
Diol: oxidation reactions, 94
Dipolar ions, 228–229, 238
Distillation, 274–277, 285, 297, 301, 302
  fractional, 276
  vacuum, 275
Doublets, 256, 261, 262, 297
Downfield, 254, 255, 256, 261, 297

E

(*E*) and (*Z*) nomenclature, 44
Eclipsed conformations, 35, 50, 302
Electron acceptors, 84, 105, 124, 129, 299
Electron donors, 84, 91, 105, 299
Electronic effects, 209–210
Electron transitions, 252
Electrophiles, 89–90, 105, 297
Electrophilicity: comparisons, 89*f*
Eluents, 278, 281, 297
Elution, 281
Enamination, 165
Enamines, 145, 150, 165, 170
Enantiomers, 38–43, 50, 296, 297, 300
Enantiomers: 1-bromo-1-chloroethane, 39*f*
Enol and enolate forms: ketone, 97*f*
Enolate chemistry, 163–166, 170
Enolates: kinetic and thermodynamic, 165*f*
Enolization, 163*f*. *See also* Tautomerization
Enols, 127, 163, 165, 170
Epoxide: oxidation reactions, 94*f*
Equatorial position, 37, 50, 297

Equatorial positions:
cyclohexane, 37*f*
Esterification, 187. *See also* Fischer esterification; Transesterification
Fischer esterification, 205*f*
reaction of a carboxylic acid with an alcohol, 188*f*
Esterifying groups, 14, 204, 213, 216, 217
Esters. *See also* Lactones; Triacylglycerols
formation, 187–188, 203
naming, 15*f*, 205*f*
nomenclature, 14–15, 204–205
nucleophilic substitution reaction, 212*f*
oxidation reactions, 94*f*
pK_a value, 85*t*
reactivity, 90, 208, 209, 210, 216
reduction, 94, 107
Ethanal. *See* Acetaldehyde
Ethanol, 9, 19, 117, 204, 274
Ethers: absorption frequencies, 251*t*
Ethyl alcohol, 9, 19, 118
Extraction, 271–273, 285, 297

F

Fatty acids, 9, 190, 194, 205, 216, 302
Figure 1.12. Naming Amides, 15
Figure 2.9. Hands as Examples of Chiral Structures, 38
Figure 7.7. Aldol Condensation, Step 2: Dehydration of the Aldol, 167
Figure 9.16. Nucleophilic Acyl Substitution: Transesterification, 213
Figure 9.17. Nucleophilic Acyl Substitution: Amide to Carboxylic Acid, 214
Figure 10.2. L- and D-Amino Acids, 228
Filtration, 273, 285
Fingerprint region, 250, 251, 260, 297
Fischer esterification, 205, 216, 297
Fischer projections, 47, 47–48, 51, 228, 297
Fischer projections: manipulations, 48*f*
Flash column chromatography, 280, 297
Flowchart: isomer relationships, 32*f*
Formaldehyde, 11, 19, 140
Fractional distillation, 275–276, 276*f*, 285, 297–298
Functional groups
common: pK_a values, 85*t*
lowest-priority: placing in the back, 46*f*
major, 17*t*

G

Gabriel (malonic-ester) synthesis, 232–234, 237, 239, 298
Gabriel synthesis, 233*f*
Gas chromatography, 282*f*
Gas chromatography (GC), 277, 278, 282, 286, 298
Gauche conformations, 35, 50, 298, 301
Geminal diols, 10, 19, 121, 143, 149, 298
Glycine, 228, 229, 238, 295
Gravity filtration, 273, 285

H

Hemiacetal formation, 144
Hemiacetals, 144, 149, 298
Hemiketals, 144, 149, 298
Heteroatoms, 5, 93
Heterolysis, 90, 106, 298
Hexane (C_6H_{14}): structural isomers, 33*f*
Highest occupied molecular orbital (HOMO), 252, 260, 262, 298
High-performance liquid chromatography (HPLC), 278, 282–283, 286, 298
Histidine, 229, 238, 281
Hybridized molecular orbitals
sp^2 hybridized, 69*f*
sp^3 hybridized, 68*f*
sp hybridized, 70*f*
Hydration, 143, 149
Hydration reaction, 143*f*
Hydride reagents, 147, 150, 298
Hydrocarbon chains, 14, 18, 190–191
Hydrocarbons. *See also* Alkanes
nomenclature, 4, 6–9, 17
Hydrogen bonding
alcohols, 117, 118–120, 127, 128, 141, 149
amides, 204
carboxylic acids, 181, 183
Hydrogen bonding, intermolecular, in alcohols, 119
Hydrogen cyanide, 145, 150
Hydrogen: pK_a value, 85*t*
Hydrogens, adjacent, area ratios for, 257
Hydrolysis
amides, 213, 217
cleavage of peptide bonds, 229
in Gabriel synthesis, 233, 298
lactams and lactones, 210, 217
Hydronium ions: pK_a value, 85*t*
Hydroquinones: examples of, 125
Hydroxyl-containing compounds: pK_a values, 119*f*
Hydroxyquinones, 124–125, 127, 129, 130, 298

I

Imine formation, 145*f*
Imines
formation, 145, 151, 240
oxidation state, 93, 106
tautomerization, 145, 165
Immiscible solvents, 271, 274, 298
Induction, 71, 74, 106, 161, 209, 216, 298
Infrared (IR) spectroscopy, 249–251, 260, 298
Infrared (IR) spectroscopy, molecular vibrations measured by, 250*f*
Infrared (IR) spectrum: aliphatic alcohol, 251*f*
Ion-exchange chromatography, 281, 286, 298
Isobutyric acid, 272*f*
Isomer relationships: flowchart, 32*f*
isomers. *See also* Configurational isomers
Isomers
cis–trans, 43, 51, 66, 296
conformational, 34–38, 50, 296
optical, 38, 299
stereoisomers, 34–38, 50–51, 301
structural, 31–33, 50, 301
Isopropol alcohol, 117
IUPAC names
alcohols, 118
complete: example, 7*f*
dicarboxylic acids, 183

J

Jones oxidation, 121*f*, 298

K

Ketal formation, 123*f*, 144*f*
Ketals, 122, 128, 144, 298
Keto-enol tautomerization, 163–164
ketones. *See also* Aldehydes and ketones
Ketones
absorption frequencies, 251*t*
carbonyl groups in, 11, 12, 19, 141
enol and enolate forms, 97*f*
naming, 12*f*, 141*f*
nomenclature, 11–12, 140–141
oxidation reactions, 94*f*
pK_a value, 85*t*
protection of, by conversion to an acetal, 98*f*
protection of, by ketal formation using a dialcohol, 123*f*
reduction, 147*f*
Strecker synthesis, 231*f*
Kinetic enolate, 164–165, 170
Kinetic enolates, 165*f*

L

Lactams, 187, 193, 204, 205, 210, 216, 217, 299
examples, 187*f*
examples of, 204*f*
β-lactam-containing antibiotic, 210*f*
Lactones, 188, 193, 205, 210, 216, 299
Lactones: examples of, 188*f*, 205*f*
Leaving groups, 90, 106, 299
Lewis acid–base reactions, 84*f*
Lewis acids and bases, 83–84, 86, 89, 105, 299
Light, plane-polarized, 40*f*
Lithium aluminum hydride, 100, 107, 108, 122, 147, 189, 192, 193
Long-chain carboxylic acids, 190, 194, 205, 216, 302
Lowest unoccupied molecular orbital (LUMO), 252, 260, 299
Lysine, 103, 229, 238

M

Magnetic quantum number, 64, 73, 299
Magnetic resonance imaging (MRI), 254*f*, 255*f*
Magnetic states (NMR spectroscopy)
  α-state, 253, 256, 261, 295
  β-state, 253, 256, 261, 296
measure of strength. See Acid dissociation constant
  as thermodynamic property, 89
Menaquinone, 124, 129
Meso compounds, 43, 43–44, 50, 299
Mesylate anion: structure, 122*f*
Mesylates, 91, 120, 122, 128, 299
Methanal. *See* Formaldehyde
Methanol, 117
Micelles, 190–191, 194
Michael addition, 163–164, 164, 170, 299
Mobile phase, 277, 278, 286, 299
Molecular orbitals, 65–70, 73. *See also* Highest occupied molecular orbital; Lowest unoccupied molecular orbital
  pi (π) bonds, 66*f*
  sp^2 hybridized, 69*f*
  sp^3 hybridized, 68*f*
  sp hybridized, 70*f*
  visualization, 65*f*
Molecular vibrations: measured by IR spectroscopy, 250
Multiplets, 254, 257, 261, 299

N

Negatively charged (acidic) amino acids, 229, 238
Neutral pH, 229*f*
Newman projection: butane, 34*f*
Newman projections, 34, 50, 299, 301
Nitrile groups, 231
Nodes, 64, 299
Nomenclature
  alcohols, 18–19, 117–118
  aldehydes and ketones, 11–13, 19, 139–140, 149
  alkanes, 5, 8–9, 18
  alkenes, 9, 17, 18
  alkynes, 9
  amides, 15, 20
  anhydrides, 15–16, 20, 188, 206
  carboxylic acids and derivatives, 14–16, 19, 182–183
  esters, 14–15, 20, 188, 193, 204–205
  functional groups, 17, 20
  hydrocarbons, 3, 6–9, 18
Nonaromatic alcohols, 120
Nonbonded strain, 36, 37, 50, 100, 299, 300
Nonpolar nonaromatic amino acids, 229, 238
Nonpolar solvents, 89, 271, 279, 286
Nuclear magnetic resonance (NMR) spectroscopy, 253–258, 259, 260–261, 299
Nuclear magnetic resonance: proton NMR, 255*f*
Nucleophiles, 87–89, 105, 299
Nucleophiles: examples of, 87*f*
Nucleophilic acyl substitution, 186*f*, 186–189, 187*f*, 192, 193, 212, 213*f*, 299*f*
Nucleophilic addition, 186, 189, 231
Nucleophilic addition reaction mechanism, 143
Nucleophilic substitution
  alcohols, 122, 127, 128
  aldehydes and ketones, 144
  carboxylic acid derivatives, 217
nucleophilic substitution reactions, 187

O

Optical activity, 39, 40–41, 43, 50
Optical isomers, 38, 299
Organic phase, 272, 285
Oxidation, 93, 299
Oxidation reactions, 93–94. *See also* Jones oxidation
  aldehyde, 147*f*
  common oxidizing agents and, 94*f*
  Jones oxidation, 121*f*
  phenol to quinone, 124*f*
  primary alcohol to aldehyde, 121
  primary alcohol to carboxylic acid, 186*f*
  secondary alcohol to ketone, 121*f*
Oxidation–reduction (redox) reactions, 92–95, 106, 147
Oxidation state, 92–93, 106, 299
Oxidizing agents, 93–94, 107, 121, 128, 149, 299
Ozone: structure, 71*f*

P

Paper chromatography, 278, 286, 299
Partitioning, 277, 286, 299
Penicillin, 210*f*
Peptide bonds, 86, 103, 229–230, 238, 300
  formation and cleavage, 229*f*
  resonance in, 230*f*
Peptides, 227–230, 238
Phenols, 118, 120, 124–126, 127, 128, 129
  aromatic alcohols, 118*f*
  oxidation of, to quinone, 124*f*
Phosphate groups, 236, 239, 299
Phosphodiester bond: DNA, 235*f*
Phosphodiester bonds, 235, 239, 300
Phosphoric acid, 234, 236, 239, 298
Phosphorus-containing compounds, 234–236, 239
Phylloquinone, 124, 129
Phylloquinone (Vitamin K_1), 124
Pi (π) bonds, 66, 66–67, 73, 300
pK_a value
  Table 4.1. pKa Values for Common Functional Groups, 85
pK_a Values. *See* Acid dissociation constant
Plane-polarized light, 38, 40*f*, 41, 42, 50, 297, 299, 301
Polar amino acids, 229, 238
Polar aprotic solvents, 88*f*
Polarity, 149, 188, 192, 277–278, 300
Polarizer, 40*f*
Polar solvents, 89, 271, 279, 286
Polypeptides, 229, 238, 300
Positively charged (basic) amino acids, 229, 238
Preparative thin-layer chromatography, 279, 300
Principal quantum number, 64, 73, 300
Proline, 229, 238
Propanal. *See* Propionaldehyde
Propionaldehyde, 11, 19, 140
Proteins, 114, 227, 229, 230, 238, 281
Protonation, 99, 300
Proton chemical shift ranges, 257*t*
Proton NMR
  1,1-dibromo-2-chloroethane, 256*f*
  1,1-dibromo-2,2-dichloroethane, 256*f*
  dichloromethyl methyl ether, 255*f*
Proton NMR (^{1}H-NMR), 254–258, 261
Pyridinium chlorochromate, 93, 102, 107, 121, 128, 141, 149
Pyridinium chlorochromate (PCC): oxidation of a primary alcohol to an aldehyde, 121*f*
Pyrophosphate, 235, 236, 239, 300
Pyrophosphate anion, 235*f*
Pyruvate dehydrogenase, 190

Q

Quantum numbers, 63–64, 73
Quinone, oxidation of phenol to, 124
Quinones, 124–126, 127, 129, 298, 300, 302

R

(*R*) and (*S*) nomenclature, 45–47, 47, 51
(*R*)/(*S*) designation, drawing a circle to determine, 47
Racemic mixtures, 41, 43, 50, 91, 106, 232, 234, 300
Reactivity principles, 208–210, 216–217
Recrystallization, 273, 285
Reducing agents, 94–96, 99, 107, 189, 193, 209
Reducing agents, common, reduction reactions and, 95*f*
Reduction. *See also* Oxidation–reduction (redox) reactions
  aldehydes and ketones, 94, 108, 147, 149
  amides, 94, 107
  carboxylic acids, 107, 189, 193
  esters, 107
Reduction reactions
  carboxylic acid to primary alcohol, 189*f*
  common: reducing agents andReduction reactions, 95*f*
  ketones, 147*f*

Relative configuration, 44–47, 51, 300
Residue, 273, 285
Resonance, 70–71, 74, 120, 230, 238, 300
  amides, 187*f*
  peptide bonds, 230*f*
Resonance forms: carbonate, 70*f*
Retardation factor, 279, 286, 288, 300
Retro-aldol reaction, 168*f*
Retro-aldol reactions, 168, 171, 300
Reverse-phase chromatography, 279, 286, 300
Ring strain, 36, 210, 217, 300
Rotary evaporators, 273

S

Saponification, 190–191, 192, 194, 205, 216, 300
Separations and purifications, 271–286. *See also* Chromatography; Distillation; Extraction; Filtration; Recrystallization
Separatory funnel, 272*f*
Separatory funnels, 272*f*–273, 285, 301
Shielding, 255, 301
Sigma (σ) bonds, 66–67, 73, 301
Simple distillation, 274, 285, 301
Size-exclusion chromatography, 281, 286, 301
S_N1 reactions, 90–91, 97, 106
S_N2 reactions, 90, 91, 97, 106, 233
Soap micelle, 191*f*
Soaps, 181, 194, 216
Sodium borohydride, 108, 147, 189, 193
Solvent effects, 88–89
Specific rotation, 41, 42, 301
Spectroscopy, 249–261, 301
Spin quantum number, 64, 73, 301
Spin-spin coupling, 256, 261
Splitting patterns, 256
Spotting, 278, 301
Staggered conformations, 35, 50, 301
Stationary phase, 277–282, 285–286, 301
Stereoisomers, 34–38, 50–51, 301
Stereoselectivity, 100, 101, 107, 109
Steric hindrance, 88, 97, 162, 208–209, 216, 301
Steric protection, 97, 301
Steric strain. *See* Nonbonded strain
Straight-chain conformational isomers: stability, 35*f*
Straight-chain conformations, 34–35
Strecker synthesis, 231, 231–232, 232, 234, 237, 239, 301
Structural (constitutional) isomers: C_6H_{14}, 33*f*
Structural isomers, 31–33, 50, 301
Substituents, common alternative alkyl substituents, 6*f*
  normal alkyl substituents, 5*f*
Substituents, multiple, rings with: nomenclature, 38*f*
Substituents: naming steps, 4–5

T

Table 11.3. Proton Chemical Shift Ranges, 258
Tautomerization, 145, 163*f*, 163–164, 165, 190
Tautomers, 163, 165, 170, 301

Preface

And now it starts: your long, yet fruitful journey toward wearing a white coat. Proudly wearing that white coat, though, is hopefully only part of your motivation. You are reading this book because you want to be a healer.

If you're serious about going to medical school, then you are likely already familiar with the importance of the MCAT in medical school admissions. While the holistic review process puts additional weight on your experiences, extracurricular activities, and personal attributes, the fact remains: along with your GPA, your MCAT score remains one of the two most important components of your application portfolio—at least early in the admissions process. Each additional point you score on the MCAT pushes you in front of thousands of other students and makes you an even more attractive applicant. But the MCAT is not simply an obstacle to overcome; it is an opportunity to show schools that you will be a strong student and a future leader in medicine.

We at Kaplan take our jobs very seriously and aim to help students see success not only on the MCAT, but as future physicians. We work with our Learning Science experts to ensure that we're using the most up-to-date teaching techniques in our resources. Multiple members of our team hold advanced degrees in medicine or associated biomedical sciences, and are committed to the highest level of medical education. Kaplan has been working with the MCAT for over 50 years and our commitment to premed students is unflagging; in fact, Stanley Kaplan created this company when he had difficulty being accepted to medical school due to unfair quota systems that existed at the time.

We stand now at the beginning of a new era in medical education. As citizens of this 21st-century world of healthcare, we are charged with creating a patient-oriented, culturally competent, cost-conscious, universally available, technically advanced and research-focused healthcare system, run by compassionate providers. Suffice it to say, this is no easy task. Problem-based learning, integrated curricula, and classes in interpersonal skills are some of the responses to this demand for an excellent workforce—a workforce of which you'll soon be a part.

We're thrilled that you've chosen us to help you on this journey. Please reach out to us to share your challenges, concerns, and successes. Together, we will shape the future of medicine in the United States and abroad; we look forward to helping you become the doctor you deserve to be.

Good luck!

About *Scientific American* . . . viii

About the MCAT . . . ix

How This Book Was Created . . . xx

Using This Book . . . xxi

Chapter 1: Kinematics and Dynamics ☆☆ 1

1.1 Units . . . 4

1.2 Vectors and Scalars . . . 5

1.3 Displacement and Velocity . . . 12

1.4 Forces and Acceleration . . . 14

1.5 Newton's Laws . . . 20

1.6 Motion with Constant Acceleration . . . 21

1.7 Mechanical Equilibrium . . . 28

Chapter 2: Work and Energy ☆☆ 47

2.1 Energy . . . 50

2.2 Work . . . 56

2.3 Mechanical Advantage . . . 61

Chapter 3: Thermodynamics ☆☆ 79

3.1 Zeroth Law of Thermodynamics . . . 82

3.2 Systems . . . 86

3.3 First Law of Thermodynamics . . . 87

3.4 Second Law of Thermodynamics and Entropy . . . 95

Chapter 4: Fluids ☆☆☆☆ 111

4.1 Characteristics of Fluids and Solids . . . 113

4.2 Hydrostatics . . . 118

4.3 Fluid Dynamics . . . 124

4.4 Fluids in Physiology . . . 133

Chapter 5: Electrostatics and Magnetism ★★★ **147**

5.1 Charges 150
5.2 Coulomb's Law 152
5.3 Electrical Potential Energy 156
5.4 Electrical Potential 158
5.5 Special Cases in Electrostatics 159
5.6 Magnetism 165

Chapter 6: Circuits ★★ **187**

6.1 Current 190
6.2 Resistance 193
6.3 Capacitance and Capacitors 202
6.4 Meters 208

Chapter 7: Waves and Sound ★★ **221**

7.1 General Wave Characteristics 224
7.2 Sound 231

Chapter 8: Light and Optics ★★★★ **257**

8.1 Electromagnetic Spectrum 260
8.2 Geometrical Optics 262
8.3 Diffraction 280
8.4 Polarization 285

Chapter 9: Atomic and Nuclear Phenomena ★★ **299**

9.1 The Photoelectric Effect 301
9.2 Absorption and Emission of Light 305
9.3 Nuclear Binding Energy and Mass Defect 308
9.4 Nuclear Reactions 310

Chapter 10: Mathematics ★★★ **331**

10.1 Arithmetic and Significant Figures 334
10.2 Exponents and Logarithms 338
10.3 Trigonometry 343
10.4 Problem-Solving 345

Chapter 11: Reasoning About the Design and Execution of Research ★★★★ **363**

11.1 The Scientific Method 366

11.2 Basic Science Research 368

11.3 Human Subjects Research 371

11.4 Ethics 376

11.5 Research in the Real World 379

Chapter 12: Data-Based and Statistical Reasoning ★★★★ **393**

12.1 Measures of Central Tendency 396

12.2 Distributions 399

12.3 Measures of Distribution 402

12.4 Probability 406

12.5 Statistical Testing 408

12.6 Charts, Graphs, and Tables 410

12.7 Applying Data 418

Glossary **433**

Index **441**

About *Scientific American*

Founded in 1845, *Scientific American* is the award-winning authoritative source for the science discoveries and technology innovations that matter. The longest continuously published magazine in the United States, it is translated into 14 languages and reaches a global audience of more than 6 million. Other titles include *Scientific American Mind* and *Spektrum der Wissenschaft* in Germany. In its history, 152 Nobel Prize scientists have contributed 246 articles to *Scientific American*, including Albert Einstein, Francis Crick, Stanley Prusiner, and Richard Axel.

Scientific American is at the heart of Nature Publishing Group's consumer media division, meeting the needs of the general public. For more information, please visit www.scientificamerican.com.

About the MCAT

ANATOMY OF THE MCAT

Here is a general overview of the structure of Test Day:

Section	Number of Questions	Time Allotted
Examinee Agreement		8 minutes
Tutorial (optional)		10 minutes
Chemical and Physical Foundations of Biological Systems	59	95 minutes
Break (optional)		10 minutes
Critical Analysis and Reasoning Skills (CARS)	53	90 minutes
Lunch Break (optional)		30 minutes
Biological and Biochemical Foundations of Living Systems	59	95 minutes
Break (optional)		10 minutes
Psychological, Social, and Biological Foundations of Behavior	59	95 minutes
Void Question		5 minutes
Satisfaction Survey (optional)		5 minutes

The structure of the four sections of the MCAT is further detailed below.

Chemical and Physical Foundations of Biological Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 5% • General Chemistry: 30% • Organic Chemistry: 15% • Physics: 25%
Critical Analysis and Reasoning Skills (CARS)	
Time	90 minutes
Format	• 53 questions • 9 passages • All questions are passage-based. There are no discrete (stand-alone) questions. • Score between 118 and 132

What It Tests	Disciplines: • Humanities: 50% • Social Sciences: 50% Skills: • *Foundations of Comprehension*: 30% • *Reasoning Within the Text*: 30% • *Reasoning Beyond the Text*: 40%
Biological and Biochemical Foundations of Living Systems	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biochemistry: 25% • Biology: 65% • General Chemistry: 5% • Organic Chemistry: 5%
Psychological, Social, and Biological Foundations of Behavior	
Time	95 minutes
Format	• 59 questions • 10 passages • 44 questions are passage-based, and 15 are discrete (stand-alone) questions. • Score between 118 and 132
What It Tests	• Biology: 5% • Psychology: 65% • Sociology: 30%
Total	
Testing Time	375 minutes (6 hours, 15 minutes)
Total Seat Time	453 minutes (7 hours, 33 minutes)
Questions	230
Score	472 to 528

SCIENTIFIC INQUIRY AND REASONING SKILLS (SIRS)

The AAMC has defined four *Scientific Inquiry and Reasoning Skills* (SIRS) that will be tested in the three science sections of the MCAT:

1. *Knowledge of Scientific Concepts and Principles* (35% of questions)
2. *Scientific Reasoning and Problem-Solving* (45% of questions)
3. *Reasoning About the Design and Execution of Research* (10% of questions)
4. *Data-Based and Statistical Reasoning* (10% of questions)

Let's see how each one breaks down into more specific Test Day behaviors. Note that the bullet points of specific objectives for each of the SIRS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Skill 1: *Knowledge of Scientific Concepts and Principles*

This is probably the least surprising of the four SIRS; the testing of science knowledge is, after all, one of the signature qualities of the MCAT. Skill 1 questions will require you to do the following:

- Recognize correct scientific principles
- Identify the relationships among closely-related concepts
- Identify the relationships between different representations of concepts (verbal, symbolic, graphic)
- Identify examples of observations that illustrate scientific principles
- Use mathematical equations to solve problems

At Kaplan, we simply call these Science Knowledge or Skill 1 questions. Another way to think of Skill 1 questions is as "one-step" problems. The single step is either to realize which scientific concept the question stem is suggesting or to take the concept stated in the question stem and identify which answer choice is an accurate application of it. Skill 1 questions are particularly prominent among discrete questions (those not associated with a passage). These questions are an opportunity to gain quick points on Test Day—if you know the science concept attached to the question, then that's it! On Test Day, 35% of the questions in each science section will be Skill 1 questions.

Here are some sample Skill 1 question stems:

- How would a proponent of the James–Lange theory of emotion interpret the findings of the study cited the passage?
- Which of the following most accurately describes the function of FSH in the human female menstrual cycle?
- If the products of Reaction 1 and Reaction 2 were combined in solution, the resulting reaction would form:
- Ionic bonds are maintained by which of the following forces?

Skill 2: *Scientific Reasoning and Problem-Solving*

The MCAT science sections do, of course, move beyond testing straightforward science knowledge; Skill 2 questions are the most common way in which it does so. At Kaplan, we also call these Critical Thinking questions. Skill 2 questions will require you to do the following:

- Reason about scientific principles, theories, and models
- Analyze and evaluate scientific explanations and predictions
- Evaluate arguments about causes and consequences
- Bring together theory, observations, and evidence to draw conclusions
- Recognize scientific findings that challenge or invalidate a scientific theory or model
- Determine and use scientific formulas to solve problems

Just as Skill 1 questions can be thought of as "one-step" problems, many Skill 2 questions are "two-step" problems, and more difficult Skill 2 questions may require three or more steps. These questions can require a wide spectrum of reasoning skills, including integration of multiple facts from a passage, combination of multiple science content areas, and prediction of an experiment's results. Skill 2 questions also tend to ask about science content without actually mentioning it by name. For example, a question might describe the results of one experiment and ask you to predict the results of a second experiment without actually telling you what underlying scientific principles are at work—part of the question's difficulty will be figuring out which principles to apply in order to get the correct answer. On Test Day, 45% of the questions in each science section will be Skill 2 questions.

Here are some sample Skill 2 question stems:

- Which of the following experimental conditions would most likely yield results similar to those in Figure 2?
- All of the following conclusions are supported by the information in the passage EXCEPT:
- The most likely cause of the anomalous results found by the experimenter is:
- An impact to a man's chest quickly reduces the volume of one of his lungs to 70% of its initial value while not allowing any air to escape from the man's mouth. By what percentage is the force of outward air pressure increased on a 2 cm^2 portion of the inner surface of the compressed lung?

Skill 3: *Reasoning About the Design and Execution of Research*

The MCAT is interested in your ability to critically appraise and analyze research, as this is an important day-to-day task of a physician. We call these questions Skill 3 or Experimental and Research Design questions for short. Skill 3 questions will require you to do the following:

- Identify the role of theory, past findings, and observations in scientific questioning
- Identify testable research questions and hypotheses
- Distinguish between samples and populations and distinguish results that support generalizations about populations
- Identify independent and dependent variables
- Reason about the features of research studies that suggest associations between variables or causal relationships between them (such as temporality and random assignment)
- Identify conclusions that are supported by research results
- Determine the implications of results for real-world situations
- Reason about ethical issues in scientific research

Over the years, the AAMC has received input from medical schools to require more practical research skills of MCAT test-takers, and Skill 3 questions are the response to these demands. This skill is unique in that the outside knowledge you need to answer Skill 3 questions is not taught in any one undergraduate course; instead, the research design principles needed to answer these questions are learned gradually throughout your science classes and especially through any laboratory work you have completed. It should be noted that Skill 3 comprises 10% of the questions in each science section on Test Day.

Here are some sample Skill 3 question stems:

- What is the dependent variable in the study described in the passage?
- The major flaw in the method used to measure disease susceptibility in Experiment 1 is:
- Which of the following procedures is most important for the experimenters to follow in order for their study to maintain a proper, randomized sample of research subjects?
- A researcher would like to test the hypothesis that individuals who move to an urban area during adulthood are more likely to own a car than are those who have lived in an urban area since birth. Which of the following studies would best test this hypothesis?

Skill 4: *Data-Based and Statistical Reasoning*

Lastly, the science sections of the MCAT test your ability to analyze the visual and numerical results of experiments and studies. We call these Data and Statistical Analysis questions. Skill 4 questions will require you to do the following:

- Use, analyze, and interpret data in figures, graphs, and tables
- Evaluate whether representations make sense for particular scientific observations and data

- Use measures of central tendency (mean, median, and mode) and measures of dispersion (range, interquartile range, and standard deviation) to describe data
- Reason about random and systematic error
- Reason about statistical significance and uncertainty (interpreting statistical significance levels and interpreting a confidence interval)
- Use data to explain relationships between variables or make predictions
- Use data to answer research questions and draw conclusions

Skill 4 is included in the MCAT because physicians and researchers spend much of their time examining the results of their own studies and the studies of others, and it's very important for them to make legitimate conclusions and sound judgments based on that data. The MCAT tests Skill 4 on all three science sections with graphical representations of data (charts and bar graphs) as well as numerical ones (tables, lists, and results summarized in sentence or paragraph form). On Test Day, 10% of the questions in each science section will be Skill 4 questions.

Here are some sample Skill 4 question stems:

- According to the information in the passage, there is an inverse correlation between:
- What conclusion is best supported by the findings displayed in Figure 2?
- A medical test for a rare type of heavy metal poisoning returns a positive result for 98% of affected individuals and 13% of unaffected individuals. Which of the following types of error is most prevalent in this test?
- If a fourth trial of Experiment 1 was run and yielded a result of 54% compliance, which of the following would be true?

SIRS Summary

Discussing the SIRS tested on the MCAT is a daunting prospect given that the very nature of the skills tends to make the conversation rather abstract. Nevertheless, with enough practice, you'll be able to identify each of the four skills quickly, and you'll also be able to apply the proper strategies to solve those problems on Test Day. If you need a quick reference to remind you of the four SIRS, these guidelines may help:

Skill 1 (**Science Knowledge**) questions ask:

- Do you remember this science content?

Skill 2 (**Critical Thinking**) questions ask:

- Do you remember this science content? And if you do, could you please apply it to this novel situation?
- Could you answer this question that cleverly combines multiple content areas at the same time?

Skill 3 (**Experimental and Research Design**) questions ask:

- Let's forget about the science content for a while. Could you give some insight into the experimental or research methods involved in this situation?

Skill 4 (**Data and Statistical Analysis**) questions ask:

- Let's forget about the science content for a while. Could you accurately read some graphs and tables for a moment? Could you make some conclusions or extrapolations based on the information presented?

CRITICAL ANALYSIS AND REASONING SKILLS (CARS)

The *Critical Analysis and Reasoning Skills* (CARS) section of the MCAT tests three discrete families of textual reasoning skills; each of these families requires a higher level of reasoning than the last. Those three skills are as follows:

1. *Foundations of Comprehension* (30% of questions)
2. *Reasoning Within the Text* (30% of questions)
3. *Reasoning Beyond the Text* (40% of questions)

These three skills are tested through nine humanities- and social sciences-themed passages, with approximately 5 to 7 questions per passage. Let's take a more in-depth look into these three skills. Again, the bullet points of specific objectives for each of the CARS are taken directly from the *Official Guide to the MCAT Exam*; the descriptions of what these behaviors mean and sample question stems, however, are written by Kaplan.

Foundations of Comprehension

Questions in this skill will ask for basic facts and simple inferences about the passage; the questions themselves will be similar to those seen on reading comprehension sections of other standardized exams like the SAT® and ACT®. *Foundations of Comprehension* questions will require you to do the following:

- Understand the basic components of the text
- Infer meaning from rhetorical devices, word choice, and text structure

This admittedly covers a wide range of potential question types including Main Idea, Detail, Function, and Definition-in-Context questions, but finding the correct answer to all *Foundations of Comprehension* questions will follow from a basic understanding of the passage and the point of view of its author (and occasionally that of other voices in the passage).

Here are some sample *Foundations of Comprehension* question stems:

- **Main Idea**—The author's primary purpose in this passage is:
- **Detail**—Based on the information in the second paragraph, which of the following is the most accurate summary of the opinion held by Schubert's critics?
- **(Scattered) Detail**—According to the passage, which of the following is FALSE about literary reviews in the 1920s?
- **Function**—The author's discussion of the effect of socioeconomic status on social mobility primarily serves which of the following functions?
- **Definition-in-Context**—The word "obscure" (paragraph 3), when used in reference to the historian's actions, most nearly means:

Reasoning Within the Text

While *Foundations of Comprehension* questions will usually depend on interpreting a single piece of information in the passage or understanding the passage as a whole, *Reasoning Within the Text* questions will typically require you to infer unstated parts of arguments or bring together two disparate pieces of the passage. *Reasoning Within the Text* questions will require you to:

- Integrate different components of the text to increase comprehension

In other words, questions in this skill often ask either *How do these two details relate to one another?* or *What else must be true that the author didn't say?* The CARS section will also ask you to judge certain parts of the passage or even judge the author. These questions, which fall under the *Reasoning Within the Text* skill, can ask you to identify authorial bias, evaluate the credibility of cited sources, determine the logical soundness of an argument, or search for relevant evidence in the passage to support a given conclusion. In all, this category includes Inference and Strengthen–Weaken (Within the Passage) questions, as well as a smattering of related—but rare—question types.

Here are some sample *Reasoning Within the Text* question stems:

- **Inference (Implication)**—Which of the following phrases, as used in the passage, is most suggestive that the author has a personal bias toward narrative records of history?
- **Inference (Assumption)**—In putting together her argument in the passage, the author most likely assumes:
- **Strengthen–Weaken (Within the Passage)**—Which of the following facts is used in the passage as the most prominent piece of evidence in favor of the author's conclusions?
- **Strengthen–Weaken (Within the Passage)**—Based on the role it plays in the author's argument, *The Possessed* can be considered:

Reasoning Beyond the Text

The distinguishing factor of *Reasoning Beyond the Text* questions is in the title of the skill: the word *Beyond*. Questions that test this skill, which make up a larger share of the CARS section than questions from either of the other two skills, will always introduce a completely new situation that was not present in the passage itself; these questions will ask you to determine how one influences the other. *Reasoning Beyond the Text* questions will require you to:

- Apply or extrapolate ideas from the passage to new contexts
- Assess the impact of introducing new factors, information, or conditions to ideas from the passage

The *Reasoning Beyond the Text* skill is further divided into Apply and Strengthen–Weaken (Beyond the Passage) questions, and a few other rarely appearing question types.

Here are some sample *Reasoning Beyond the Text* question stems:

- **Apply**—If a document were located that demonstrated Berlioz intended to include a chorus of at least 700 in his *Grande Messe des Mortes*, how would the author likely respond?
- **Apply**—Which of the following is the best example of a "virtuous rebellion," as it is defined in the passage?
- **Strengthen–Weaken (Beyond the Text)**—Suppose Jane Austen had written in a letter to her sister, "My strongest characters were those forced by circumstance to confront basic questions about the society in which they lived." What relevance would this have to the passage?
- **Strengthen–Weaken (Beyond the Text)**—Which of the following sentences, if added to the end of the passage, would most WEAKEN the author's conclusions in the last paragraph?

CARS Summary

Through the *Foundations of Comprehension* skill, the CARS section tests many of the reading skills you have been building on since grade school, albeit in the context of very challenging doctorate-level passages. But through the two other skills (*Reasoning Within the Text* and *Reasoning Beyond the Text*), the MCAT demands that you understand the deep structure of passages and the arguments within them at a very advanced level. And, of course, all of this is tested under very tight timing restrictions: only 102 seconds per question—and that doesn't even include the time spent reading the passages.

Here's a quick reference guide to the three CARS skills:

Foundations of Comprehension questions ask:

- Did you understand the passage and its main ideas?
- What does the passage have to say about this particular detail?

Reasoning Within the Text questions ask:

- What must be true that the author did not say?
- What's the logical relationship between these two ideas from the passage?
- How well argued is the author's thesis?

Reasoning Beyond the Text questions ask:

- How does this principle from the passage apply to this new situation?
- How does this new piece of information influence the arguments in the passage?

SCORING

Each of the four sections of the MCAT is scored between 118 and 132, with the median at 125. This means the total score ranges from 472 to 528, with the median at 500. Why such peculiar numbers? The AAMC stresses that this scale emphasizes the importance of the central portion of the score distribution, where most students score (around 125 per section, or 500 total), rather than putting undue focus on the high end of the scale.

Note that there is no wrong answer penalty on the MCAT, so you should select an answer for every question—even if it is only a guess.

The AAMC has released the official correlation between scaled score and percentile, as shown here. It should be noted that the percentile scale is adjusted and renormalized over time and thus should not be overinterpreted.

Total Score	Percentile	Total Score	Percentile
528	100	499	47
527	100	498	43
526	100	497	40
525	100	496	37
524	100	495	34
523	100	494	31
522	99	493	28
521	99	492	25
520	98	491	22
519	98	490	20
518	97	489	18
517	96	488	15
516	95	487	13

Total Score	Percentile	Total Score	Percentile
515	93	486	11
514	91	485	10
513	89	484	8
512	87	483	7
511	85	482	6
510	83	481	5
509	80	480	4

502	57	473	0
501	54	472	0
500	51		

Source: AAMC. 2015. *Summary of Total and Section Scores from the MCAT Exam Based on Results for Tests Administered in April and May 2015.* Accessed February 2016. https://students-residents.aamc.org/search/?q=percentilenewmcat.pdf.

Further information on score reporting is included at the end of the next section (see *After Your Test*).

MCAT POLICIES AND PROCEDURES

We strongly encourage you to download the latest copy of *MCAT® Essentials*, available on the AAMC's website, to ensure that you have the latest information about registration and Test Day policies and procedures; this document is updated annually. A brief summary of some of the most important rules is provided here.

MCAT Registration

The only way to register for the MCAT is online. You can access AAMC's registration system at: www.aamc.org/mcat.

You will be able to access the site approximately six months before Test Day. The AAMC designates three registration "Zones"—Gold, Silver, and Bronze. Registering during the Gold Zone (from the opening of registration until approximately one month before Test Day) provides the most flexibility and lowest test fees. The Silver Zone runs until approximately two to three weeks before Test Day and has less flexibility and higher fees; the Bronze Zone runs until approximately one to two weeks before Test Day and has the least flexibility and highest fees.

Fees and the Fee Assistance Program (FAP)

Payment for test registration must be made by MasterCard or VISA. As described earlier, the fees for registering for the MCAT—as well as rescheduling the exam or changing your testing center—increase as one approaches Test Day. In addition, it is not uncommon for test centers to fill up well in advance of the registration deadline. For these reasons, we recommend identifying your preferred Test Day as soon as possible and registering. There are ancillary benefits to having a set Test Day, as well: when you know the date you're working toward, you'll study harder and are less likely to keep pushing back the exam. The AAMC offers a Fee Assistance Program (FAP) for students with financial hardship to help reduce the cost of taking the MCAT, as well as for the American Medical College Application Service (AMCAS®) application. Further information on the FAP can be found at: www.aamc.org/students/applying/fap.

Testing Security

On Test Day, you will be required to present a government-issued ID. When registering, take care to spell your name precisely the same as it appears on this ID; failure to provide this ID at the test center or differences in spelling between your registration and ID will be considered a "no-show," and you will not receive a refund for the exam.

You will also be required to provide an electronic thumbprint and electronic signature verification to take the exam. Some testing centers may use a metal detection wand to ensure that no prohibited items are brought into the testing room. Prohibited items include all electronic devices, including watches and timers, calculators, cell phones, and any and all forms of recording equipment; food, drinks (including water), and cigarettes or other smoking paraphernalia; hats and scarves (except for religious purposes); and books, notes, or other study materials. If you require a medical device, such as an insulin pump or pacemaker, you must apply for accommodated testing. During breaks, you are allowed to access food and drink, but not electronic devices, including cell phones.

Testing centers are under video surveillance and the AAMC does not take potential violations of testing security lightly. The bottom line: *know the rules and don't break them*.

Accommodations

Students with disabilities or medical conditions can apply for accommodated testing. Documentation of the disability or condition is required, and requests may take two months—or more—to be approved. For this reason, it is recommended that you begin the process of applying for accommodated testing as early as possible. More information on applying for accommodated testing can be found at: www.aamc.org/students/applying/mcat/accommodations

After Your Test

When your MCAT is all over, no matter how you feel you did, be good to yourself when you leave the test center. Celebrate! Take a nap. Watch a movie. Ride your bike. Plan a trip. Call up all of your neglected friends or stalk them on Facebook. Totally consume a cheesesteak and drink dirty martinis at night (assuming you're over 21). Whatever you do, make sure that it has absolutely nothing to do with thinking too hard—you deserve some rest and relaxation.

Perhaps most importantly, do not discuss specific details about the test with anyone. For one, it is important to let go of the stress of Test Day, and reliving your exam only inhibits you from being able to do so. But more significantly, the Examinee Agreement you sign at the beginning of your exam specifically prohibits you from discussing or disclosing exam content. The AAMC is known to seek out individuals who violate this agreement and retains the right to prosecute these individuals at their discretion. This means that you should not, under any circumstances, discuss the exam in person or over the phone with other individuals—including us at Kaplan—or post information or questions about exam content to Facebook, Student Doctor Network, or other online social media. You are permitted to comment on your "general exam experience," including how you felt about the exam overall or an individual section, but this is a fine line. In summary: *if you're not certain whether you can discuss an aspect of the test or not, just don't do it!* Do not let a silly Facebook post stop you from becoming the doctor you deserve to be.

Scores are released approximately one month after Test Day. The release is staggered during the afternoon and evening, starting at 5 p.m. Eastern. This means that not all examinees receive their scores at exactly the same time. Your score report will include a scaled score for each section between 118 and 132, as well as your total combined score between 472 and 528. These scores are given as confidence intervals. For each section, the confidence interval is approximately the given score ±1; for the total score, it is approximately the given score ±2. You will also be given the corresponding percentile rank for each of these section scores and the total score.

AAMC CONTACT INFORMATION

How This Book Was Created

The *Kaplan MCAT Review* project began shortly after the release of the *Preview Guide for the MCAT 2015 Exam*, 2nd edition. Through thorough analysis by our staff psychometricians, we were able to analyze the relative yield of the different topics on the MCAT, and we began constructing tables of contents for the books of the *Kaplan MCAT Review* series. A dedicated staff of 30 writers, 7 editors, and 32 proofreaders worked over 5,000 combined hours to produce these books. The format of the books was heavily influenced by weekly meetings with Kaplan's learning-science team.

These books were submitted for publication in February 2016. For any updates after this date, please visit www.kaplanmcat.com/pages/retail-book-corrections-and-updates.

If you have any questions about the content presented here, email KaplanMCATfeedback@kaplan.com. For other questions not related to content, email booksupport@kaplan.com.

Each book has been vetted through at least eight rounds of review. To that end, the information presented is these books is true and accurate to the best of our knowledge. Still, your feedback helps us improve our prep materials. Please notify us of any inaccuracies or errors in the books by sending an email to KaplanMCATfeedback@kaplan.com.

Using This Book

Kaplan MCAT Physics and Math Review, along with the other seven books in your student kit, is the cornerstone of your prep for the MCAT. This book offers the content review, strategies, and practice that make Kaplan the #1 choice for MCAT prep.

This book is designed to help you review the physics and math topics covered on the MCAT. Please understand that content review—no matter how thorough—is not sufficient preparation for the MCAT! The MCAT tests not only your science knowledge but also your critical reading, reasoning, and problem-solving skills. Do not assume that simply memorizing the contents of this book will earn you high scores on Test Day; to maximize your scores, you must also improve your reading and test-taking skills through MCAT-style questions and practice tests.

MCAT CONCEPT CHECKS

At the end of each section, you'll find a few open-ended questions that you can use to assess your mastery of the material. These MCAT Concept Checks were introduced after multiple conversations with Kaplan's learning-science team. Research has demonstrated repeatedly that introspection and self-analysis improve mastery, retention, and recall of material. Complete these MCAT Concept Checks to ensure that you've got the key points from each section before moving on!

PRACTICE QUESTIONS

At the end of each chapter, you'll find 15 MCAT-style practice questions. These are designed to help you assess your understanding of the chapter you just read. Most of these questions focus on the first of the *Scientific Inquiry and Reasoning Skills* (*Knowledge of Scientific Concepts and Principles*), although there are occasional questions that fall into the second or fourth SIRS (*Scientific Reasoning and Problem-Solving*, and *Data-Based and Statistical Reasoning*, respectively). This book also contains a full chapter each for two of the SIRS: Chapter 11 (*Reasoning about the Design and Execution of Research*) and Chapter 12 (*Data-Based and Statistical Reasoning*).

SIDEBARS

The following is a guide to the five types of sidebars you'll find in *Kaplan MCAT Physics and Math Review*:

- **Bridge:** These sidebars create connections between science topics that appear in multiple chapters throughout the *Kaplan MCAT Review* series.
- **Key Concept:** These sidebars draw attention to the most important takeaways in a given topic, and they sometimes offer synopses or overviews of complex information. If you understand nothing else, make sure you grasp the Key Concepts for any given subject.
- **MCAT Expertise:** These sidebars point out how information may be tested on the MCAT or offer key strategy points and test-taking tips that you should apply on Test Day.
- **Mnemonic:** These sidebars present memory devices to help recall certain facts.
- **Real World:** These sidebars illustrate how a concept in the text relates to the practice of medicine or the world at large. While this is not information you need to know for Test Day, many of the topics in Real World sidebars are excellent examples of how a concept may appear in a passage or discrete (stand-alone) question on the MCAT.

WHAT THIS BOOK COVERS

The information presented in the *Kaplan MCAT Review* series covers everything listed on the official MCAT content lists. Every topic in these lists is covered in the same level of detail as is common to the undergraduate and postbaccalaureate classes that are considered prerequisites for the MCAT. Note that your premedical classes may include topics not discussed in these books, or they may go into more depth than these books do. Additional exposure to science content is never a bad thing, but recognize that all of the content knowledge you are expected to have walking in on Test Day is covered in these books.

New to the Third Edition of the *Kaplan MCAT Review* series are **Star Ratings**. You'll see these stars throughout the book, and they are meant as a guide to the number and density of test-worthy facts in each chapter and sub-chapter.

★★★★ Four-star chapters and topics are packed with testable facts. Make sure you have all of these down before Test Day. Even if you find these topics difficult to grasp, you should put in the extra effort to fully understand them.

★★★ Three-star chapters and topics contain content that is tested an above-average amount. If you plan to score above average–and you probably do!–then you should master all or nearly all of these before Test Day.

★★ Two-star sections will demand varied focus, depending on your personal studying needs. These topics have been proven to be MCAT-worthy, but if you have limited study time or already feel confident with these topics, you can move more quickly through this material.

★ One-star chapters and topics are unlikely to be directly tested, but many of these topics provide foundations for, and connections between, higher-yield material.

These Star Ratings were created based on material released by the AAMC. In other words, according to the testmaker and all our experience with their resources, more stars means more questions on Test Day.

This book also contains a thorough glossary and index for easy navigation of the text.

In the end, this is your book, so write in the margins, draw diagrams, highlight the key points—do whatever is necessary to help you get that higher score. We look forward to working with you as you achieve your dreams and become the doctor you deserve to be!

Concept Summary 35

Introduction

A professor once said: *Biology is chemistry. Chemistry is physics. Physics is life.* Not surprisingly, this was the claim of a physics professor.

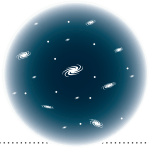
Walking into MCAT preparation, many students think of physics as the least applicable science to medicine, reflecting on calculus-heavy premedical classes. But even in the medical field, physics is all around us. When we treat patients at a rehab hospital, we often talk about motion, forces, and bone strength. An ophthalmologist may draw diagrams to help students better understand myopia and hyperopia. When we talk about mitochondria functioning as the batteries of the cell, we mean that fairly literally.

This first chapter reviews the three systems of units encountered on the MCAT: MKS (meter–kilogram–second), CGS (centimeter–gram–second), and SI (International System of Units). We'll take a few moments to review the geometry of physics questions, especially vector mathematics. Next, we'll move into true physics content as we consider kinematics—the equations that deal with the motion of objects—and Newtonian mechanics and dynamics—the study of forces and their effects.

Real World

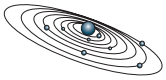
Natural phenomena occur on many scales, as shown in Figure 1.1. We often assume that the fine details have little bearing on the larger scale of the universe, but the rapid inflation of the universe allows the infinitesimally small to affect the astronomically big.

10^{26} meters: Observable universe



10^{21} meters: Milky Way galaxy

10^{13} meters: Solar system



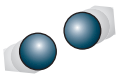
10^{7} meters: Earth

10^{-2} meters: Insect

10^{-10} meters: Atom

10^{-15} meters: Atomic nucleus

10^{-18} meters: Smallest distance probed by particle accelerators



10^{-18} to 10^{-35} meters: Typical size of fundamental strings and of extra dimensions

10^{-35} meters: Minimum meaningful length in nature

?

Figure 1.1. Size of Natural Phenomena

1.1 Units

Before we begin our discussion of motion, we must define a consistent vocabulary for our discussion of physics throughout this book. Physics relies on the language of mathematics to convey important descriptions and explanations of the world around us. Yet those numbers would themselves be meaningless—or vague at best—without the labels of units.

FUNDAMENTAL MEASUREMENTS

Over the years, various systems of units have been developed for specific purposes. Some of these systems are commonly used in everyday life but rarely in science. The **British** or **Imperial system** (foot–pound–second or **FPS**) is used commonly in the United States but virtually nowhere else—not even in Britain. Basic units for length, weight, and time are the **foot** (**ft**), the **pound** (**lb**), and the **second** (**s**), respectively. Because weight, and not mass, is used, the British system later derived the **slug** as a unit of mass. The MCAT rarely—if ever—utilizes FPS in passages or questions.

The most common system of units is the metric system, which is the basis for the SI units used on the MCAT. Depending on the context of a passage or question, the **metric system** may be given in meters, kilograms, and seconds (**MKS**) or centimeters, grams, and seconds (**CGS**). **SI units** include the MKS system as well as four other base units, as shown in Table 1.1.

Quantity	Unit	Symbol
Length	meter	m
Mass (*not* weight)	kilogram	kg
Time	second	s
Current	ampère (coulomb/second)	A
Amount of Substance	mole	mol
Temperature	kelvin	K
Luminous Intensity	candela	cd

Table 1.1. SI Units

In each measurement system, there are base units and derived units. **Base units** are the standard units around which the system itself is designed. **Derived units**, as the name implies, are created by associating base units with each other. For example, the newton—a unit of force—is derived from kilograms, meters, and seconds: $1\ \text{N} = 1\frac{\text{kg} \cdot \text{m}}{\text{s}^2}$. Table 1.2 contains examples of important derived units from each of the systems described above. Prefixes for metric units and conversions between metric and Imperial units are discussed in Chapter 10 of *MCAT Physics and Math Review*.

Quantity	FPS	CGS	MKS (SI)
Mass	slug $\left(\frac{lb \cdot s^2}{ft}\right)$ or blob $\left(\frac{lb \cdot s^2}{in}\right)$		
Force		dyne $\left(\frac{g \cdot cm}{s^2}\right)$	newton $\left(\frac{kg \cdot m}{s^2}\right)$
Work and Energy	foot–pound (ft · lb)	erg $\left(\frac{g \cdot cm^2}{s^2}\right)$	joule $\left(\frac{kg \cdot m^2}{s^2}\right)$
Power	foot–pound per second	erg per second	watt $\left(\frac{kg \cdot m^2}{s^3}\right)$

Table 1.2. Derived Units in Various Systems of Measurement

At the molecular, atomic, or subatomic level, different units may be given that are easier to work with at such a small scale. For example, length may be given in **ångströms** (1 Å = 10^{-10} m) or nanometers (1 nm = 10^{-9} m). Energy on the atomic scale can be expressed in **electron–volts** (1 eV = 1.6×10^{-19} J), which represent the amount of energy gained by an electron accelerating through a potential difference of one volt.

MCAT Expertise

While it is good to be aware of the various systems of measurement, the only system that you are required to memorize for the MCAT is the SI system.

MCAT Concept Check 1.1:

Before you move on, assess your understanding of the material with this question.

1. If the newton is the product of kilograms and meters/second^2, what units comprise the pound?

_____

2. Order the following units from smallest to largest: centimeter, angstrom, inch, mile, foot.

_____ < _____ < _____ < _____ < _____

1.2 Vectors and Scalars ★

Vectors are numbers that have magnitude and direction. Vector quantities include displacement, velocity, acceleration, and force. **Scalars** are numbers that have magnitude only and no direction. Scalar quantities include distance, speed, energy, pressure, and mass. The difference between a vector and scalar quantity can be quite pronounced when there is a nonlinear path involved. For example, in the course of a year, the Earth travels a distance of roughly 940 million kilometers.

However, because this is a circular path, the displacement of the Earth in one year is zero kilometers. This difference between distance and displacement can be further illustrated with vector representations.

Vectors may be represented by arrows; the direction of the arrow indicates the direction of the vector. The length of the arrow is usually proportional to the magnitude of the vector quantity. Common notations for a vector quantity are either an arrow or boldface. For example, the straight-line path from *here* to *there* might be represented by a vector identified as $\vec{\mathbf{A}}$ or **A**. The magnitude of the displacement between the two positions can be represented as $|\vec{\mathbf{A}}|$, |**A**|, or *A*. Scalar quantities are generally represented with italic type: the distance between two points could be represented by *d*.

In this book (and all books of the *Kaplan MCAT Review series*), we will consistently use **boldface** to represent a vector quantity and *italic* to represent the magnitude of a vector or a scalar quantity.

VECTOR ADDITION

Key Concept

When adding vectors, always add tip-to-tail!

The sum or difference of two or more vectors is called the **resultant** of the vectors. One way to find the sum or resultant of two vectors **A** and **B** is to place the tail of **B** at the tip of **A** without changing either the length or the direction of either arrow. In this **tip-to-tail method**, the lengths of the arrows must be proportional to the magnitudes of the vectors. The vector sum **A** + **B** is the vector joining the tail of **A** to the tip of **B** and pointing toward the tip of **B**. Vector addition is demonstrated in Figure 1.2 below.

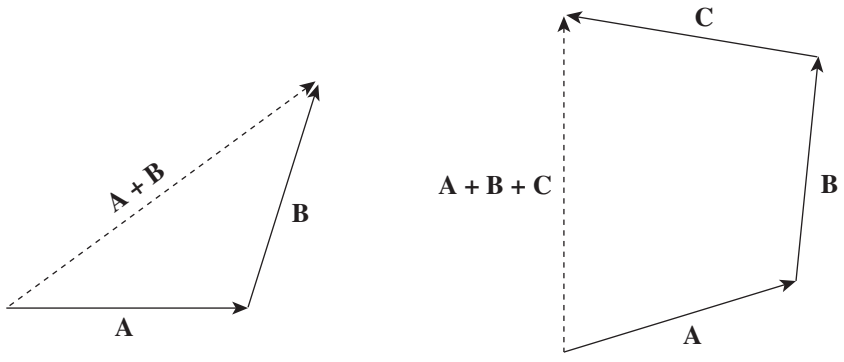


Figure 1.2. The Tip-to-Tail Method of Vector Addition
(a) Vectors **A** and **B** with resultant **A** + **B**;
(b) Vectors **A**, **B**, and **C** with resultant **A** + **B** + **C**

Another method for finding the resultant of several vectors involves breaking each vector into perpendicular **components**. In most cases, these components are horizontal and vertical (***x***- and ***y***-components, respectively); however, in some instances—such as inclined planes—it may make more sense to define the components as parallel and perpendicular ($\parallel$ and $\perp$, respectively) to some other surface.

Given any vector **V**, we can find the *x*- and *y*-components (**X** and **Y**) by drawing a right triangle with **V** as the hypotenuse, as shown in Figure 1.3.

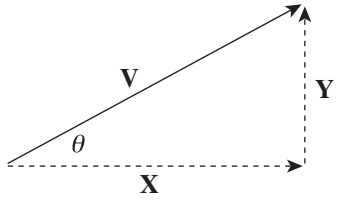

Figure 1.3. Splitting a Vector into Components

If θ is the angle between **V** and the *x*-component, then $\cos\theta = \frac{\mathbf{X}}{\mathbf{V}}$ and $\sin\theta = \frac{\mathbf{Y}}{\mathbf{V}}$. In other words:

$$\mathbf{X} = \mathbf{V}\cos\theta$$
$$\mathbf{Y} = \mathbf{V}\sin\theta$$

Equation 1.1

Example: Find the *x*- and *y*-components of the following vector

$$\mathbf{V} = 10\ \frac{\text{m}}{\text{s}}$$
$$\theta = 30°$$

Solution:

$$\mathbf{X} = \mathbf{V}\cos\theta = 10\cos 30° = \frac{10\sqrt{3}}{2} = 5\sqrt{3}\ \frac{\text{m}}{\text{s}}$$
$$\mathbf{Y} = \mathbf{V}\sin\theta = 10\sin 30° = \frac{10}{2} = 5\ \frac{\text{m}}{\text{s}}$$

Conversely, if we know **X** and **Y**, we can find **V**, as shown in Figure 1.4 below.

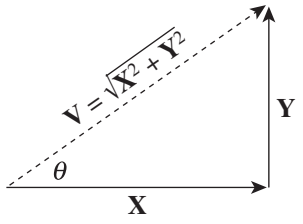

Figure 1.4. Using the Pythagorean Theorem to Determine the Magnitude of the Resultant Vector

Calculating the magnitude of **V** requires use of the **Pythagorean theorem:**

$$\mathbf{X}^2 + \mathbf{Y}^2 = \mathbf{V}^2 \quad \text{or} \quad \mathbf{V} = \sqrt{\mathbf{X}^2 + \mathbf{Y}^2}$$

Equation 1.2

The angle of the resultant vector can also be calculated by knowing inverse trigonometric functions, discussed in Chapter 10 of *MCAT Physics and Math Review*:

$$\theta = \tan^{-1}\frac{\mathbf{Y}}{\mathbf{X}}$$

Equation 1.3

Example: What is the magnitude and direction of the vector with the following components?

$$\mathbf{X} = 3\ \frac{\text{m}}{\text{s}}$$
$$\mathbf{Y} = 4\ \frac{\text{m}}{\text{s}}$$

Solution:

$$\mathbf{V} = \sqrt{3^2 + 4^2} = \sqrt{25} = 5\ \frac{\text{m}}{\text{s}}$$

$\theta = \tan^{-1}\frac{\mathbf{Y}}{\mathbf{X}} = \tan^{-1}\frac{4}{3} = 53°$ (Note: This inverse tangent calculation is beyond the scope of the MCAT.)

The *x*-component of a resultant vector is simply the sum of the *x*-components of the vectors being added. Similarly, the *y*-component of a resultant vector is simply the sum of the *y*-components of the vectors being added. This is illustrated in Figure 1.5.

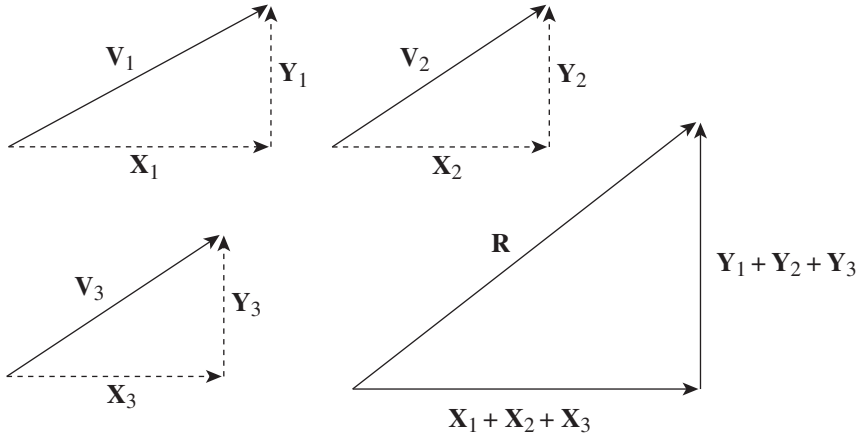

Figure 1.5. Finding the Resultant (R) of $\mathbf{V_1} + \mathbf{V_2} + \mathbf{V_3}$

To find the resultant (**R**) using the components method, follow these steps:

1. Resolve the vectors to be added into their *x*- and *y*-components.
2. Add the *x*-components to get the *x*-component of the resultant ($\mathbf{R}_x$). Add the *y*-components to get the *y*-component of the resultant ($\mathbf{R}_y$).
3. Find the magnitude of the resultant by using the Pythagorean theorem. If $\mathbf{R}_x$ and $\mathbf{R}_y$ are the components of the resultant, then $R = \sqrt{R_x^2 + R_y^2}$
4. Find the direction (θ) of the resultant by using the relationship $\theta = \tan^{-1}\frac{R_y}{R_x}$.

VECTOR SUBTRACTION

Subtracting one vector from another can be accomplished by adding a vector with equal magnitude—but opposite direction—to the first vector. This can be expressed mathematically as $\mathbf{A} - \mathbf{B} = \mathbf{A} + (-\mathbf{B})$, where $-\mathbf{B}$ represents a vector with the same magnitude as **B**, but pointing in the opposite direction. Vector subtraction may also be performed on the component vectors first and then combined to create a final vector. As with vector addition, the *x*-component of the resultant vector is the difference of the *x*-components of the vectors being subtracted. Similarly, the *y*-component of the resultant vector is the difference of the *y*-components of the vectors being subtracted.

Key Concept

Notice that when you subtract vectors, you are simply flipping the direction of the vector being subtracted and then following the same rules as normal: adding tip-to-tail.

MULTIPLYING VECTORS BY SCALARS

When a vector is multiplied by a scalar, its magnitude will change. Its direction will be either parallel or antiparallel to its original direction. If a vector **A** is multiplied by the scalar value *n*, a new vector, **B**, is created such that $\mathbf{B} = n\mathbf{A}$. To find the magnitude of the new vector, **B**, simply multiply the magnitude of **A** by $|n|$, the absolute value of *n*. To determine the direction of the vector **B**, we must look at the sign on *n*. If *n* is a positive number, then **B** and **A** are in the same direction. However, if *n* is a negative number, then **B** and **A** point in opposite directions. For example, if vector **A** is multiplied by the scalar +3, then the new vector **B** is three times as long as **A**, and points in the same direction. If vector **A** is multiplied by the scalar –3, then **B** would still be three times as long as **A** but would now point in the opposite direction.

MULTIPLYING VECTORS BY OTHER VECTORS

In some circumstances, we want to be able to use two vector quantities to generate a third vector or a scalar by multiplication. To generate a scalar quantity like work, we multiply the magnitudes of the two vectors of interest (force and displacement) and the cosine of the angle between the two vectors. In vector calculus, this is called the **dot product** ($\mathbf{A} \cdot \mathbf{B}$):

$$\mathbf{A} \cdot \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}| \cos\theta$$

Equation 1.4

In contrast, when generating a third vector like torque, we need to determine both its magnitude and direction. To do so, we multiply the magnitudes of the two vectors of interest (force and lever arm) and the sine of the angle between the two vectors. Once we have the magnitude, we use the **right-hand rule** to determine its direction. In vector calculus, this is called the **cross product** ($\mathbf{A} \times \mathbf{B}$):

$$\mathbf{A} \times \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}| \sin\theta$$

Equation 1.5

The resultant of a cross product will always be perpendicular to the plane created by the two vectors. Because the MCAT is a two-dimensional test, this usually means that the vector of interest will be going into or out of the page (or screen).

There are multiple versions of the right-hand rule that can be used to determine the direction of a cross product resultant vector. Shown in Figure 1.6 is one method considering a resultant **C** where $\mathbf{C} = \mathbf{A} \times \mathbf{B}$:

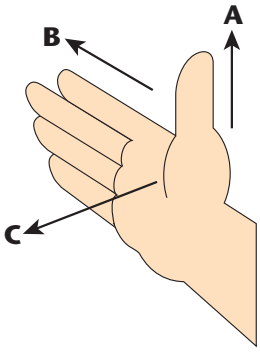

Figure 1.6. Applying the Right-Hand Rule

1. Start by pointing your thumb in the direction of vector **A**.
2. Extend your fingers in the direction of vector **B**. You may need to rotate your wrist to get the correct configuration of thumb and fingers.
3. Your palm establishes the plane between the two vectors. The direction your palm points is the direction of the resultant **C**.

Note that you may have learned a version of the right-hand rule that is different from what is described here. For example, some students learn to point the right index finger in the direction of **A** and the right middle finger in the direction of **B**; when one holds the thumb perpendicular to these two fingers, it points in the direction of **C**. It makes no difference which version of the right-hand rule you use, as long as you are comfortable with it and are skilled in its proper use.

MCAT Expertise

There are several different methods for determining the direction of a cross product resultant vector. Choose whichever method you prefer and stick with it—it's more important to be skilled in using one method than to be only somewhat familiar with multiple methods.

Example: What are the magnitudes and directions of the resultant vectors from the following cross products: $\mathbf{C} = \mathbf{A} \times \mathbf{B}$ and $\mathbf{D} = \mathbf{B} \times \mathbf{A}$?

A: $\mathbf{X} = -3$ N, $\mathbf{Y} = 0$

B: $\mathbf{X} = 0$, $\mathbf{Y} = +4$ m

Solution: The magnitude of the resultant vector is simply the product of the magnitudes of the factor vectors and the sine of the angle between them. In this case, because one is oriented in the *x*-direction and the other is in the *y*-direction, the angle between them is 90°.

$$|\mathbf{A}| \times |\mathbf{B}| \times \sin 90° = 3 \text{ N} \times 4 \text{ m} \times 1 = 12 \text{ N·m}$$

The magnitude is therefore 12 N·m.

Now, to determine the direction of **C**, start by pointing your right thumb toward the left (negative *x*-direction). Your fingers will point toward the top of the page (positive *y*-direction). Your palm is therefore pointing into the page.

Now, to determine the direction of **D**, start by pointing your right thumb toward the top of the page (positive *y*-direction). Your fingers will point toward the left (negative *x*-direction). Your palm is therefore pointing out of the page.

Therefore, **C** is 12 N·m [⊗ (into the page)] and **D** is 12 N·m [⊙ (out of the page)].

Key Concept

For cross products and the right-hand rule, order matters! Unlike scalar multiplication, which is commutative ($3 \times 4 = 4 \times 3$), vector multiplication is not commutative ($\mathbf{A} \times \mathbf{B} \neq \mathbf{B} \times \mathbf{A}$)!

MCAT Concept Check 1.2:

Before you move on, assess your understanding of the material with these questions.

1. When calculating the sum of vectors **A** and **B** (**A** + **B**) we put the tail of **B** at the tip of **A**. What would be the effect of reversing this order (**B** + **A**)?

_____

2. When calculating the difference of vectors **A** and **B** (**A** – **B**) we invert **B** and put the tail of this new vector at the tip of **A**. What would be the effect of reversing this order (**B** – **A**)?

_____

3. How is a scalar calculated from the product of two vectors? How is a vector calculated?
   - Scalar:

     _____
   - Vector:

     _____

4. True or False: If $\mathbf{C} = \mathbf{A} \times \mathbf{B}$, where **A** is directed toward the right side of the page and **B** is directed to the top of the page, then **C** is directed midway between **A** and **B** at a 45° angle.

_____

1.3 Displacement and Velocity

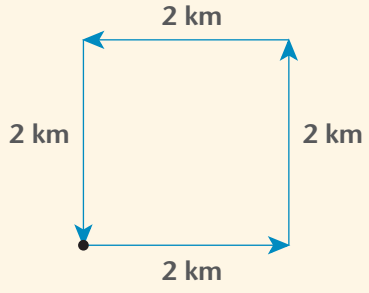
Now that we've covered the basic geometry that serves as the foundation of physics, we can examine the related physical quantities. The basic quantities that relate to kinematics are displacement, velocity, and acceleration.

DISPLACEMENT

An object in motion may experience a change in its position in space, known as **displacement** (**x** or **d**). This is a vector quantity and, as such, has both magnitude and direction. The displacement vector connects (in a straight line) the object's initial position and its final position. Understand that displacement does not account for the actual pathway taken between the initial and the final positions—only the net change in position from initial to final. **Distance** (*d*) traveled, on the other hand, considers the pathway taken and is a scalar quantity.

Example: What is the displacement of a man who walks 2 km east, then 2 km north, then 2 km west, and then 2 km south?

Solution: While his total distance traveled is 8 km, his displacement is a vector quantity that represents the change in position. In this case, his displacement is zero because the man ends up the same place he started, as shown below.



VELOCITY

As was mentioned earlier, **velocity** (**v**) is a vector. Its magnitude is measured as the rate of change of displacement in a given unit of time, and its SI units are meters per second. The direction of the velocity vector is necessarily the same as the direction of the displacement vector. **Speed** (*v*) is the rate of actual distance traveled in a given unit of time.

The distinction is subtle, so let's examine this a little more carefully. The **instantaneous speed** of an object will always be equal to the magnitude of the object's **instantaneous velocity**, which is a measure of the average velocity as the change in time (Δt) approaches zero:

$$\mathbf{v} = \lim_{\Delta t \to 0} \frac{\Delta \mathbf{x}}{\Delta t}$$

Equation 1.6

where **v** is the instantaneous velocity, $\Delta \mathbf{x}$ is the change in position, and Δt is the change in time. As a measure of speed, instantaneous speed is a scalar number. Average speed will not necessarily always be equal to the magnitude of the average velocity. This is because average velocity is the ratio of the displacement vector over the change in time (and is a vector), whereas average speed (which is scalar) is the ratio of the total distance traveled over the change in time. Average speed accounts for actual distance traveled, whereas average velocity does not:

$$\overline{\mathbf{v}} = \frac{\Delta \mathbf{x}}{\Delta t}$$

Equation 1.7

where $\overline{\mathbf{v}}$ is the average velocity, $\Delta \mathbf{x}$ is the change in position, and Δt is the change in time.

Consider the example given earlier regarding the Earth's orbit. In one year, the Earth travels roughly 940 million kilometers, but its displacement is zero:

$$d = 9.4 \times 10^8 \text{ km}$$
$$\mathbf{x} = 0 \text{ km}$$

The average speed is a measure of distance traveled in a given period of time; the average velocity is a measure of the displacement of an object over a given period of time. While the average speed of the Earth over a year is about 30 kilometers per second, its average velocity is again zero:

$$v = \frac{9.4 \times 10^8 \text{ km}}{3.16 \times 10^7 \text{ s}} = 29.8 \frac{\text{km}}{\text{s}}$$
$$\overline{\mathbf{v}} = \frac{0 \text{ km}}{3.16 \times 10^7 \text{ s}} = 0 \frac{\text{km}}{\text{s}}$$

MCAT Concept Check 1.3:
Before you move on, assess your understanding of the material with these questions.

1. What is the relationship between instantaneous velocity and instantaneous speed? Between average velocity and average speed?

_____

_____

_____

2. True or False: Total distance traveled can never be less than the total displacement.

3. Provide a definition for displacement or velocity in terms of the other variable.

_____

_____

1.4 Forces and Acceleration ★★

Every change in velocity is motivated by a push or a pull—a **force**. In this section, we'll examine how forces interact with one another, as well as how acceleration results from those forces.

FORCES

Force (**F**) is a vector quantity that is experienced as pushing or pulling on objects. Forces can exist between objects that are not even touching. While it is common for forces to be exerted by one object pushing on another, there are even more instances in which forces exist between objects nowhere near each other, such as gravity or electrostatic forces between point charges. The SI unit for force is the **newton** (**N**), which is equivalent to one $\frac{kg \cdot m}{s^2}$.

Gravity

When Newton observed apples falling out of trees, he was struck by the fact that they always fell perpendicularly to the ground, rather than sideways or even away from the ground. Furthermore, Newton began to wonder about the farthest reaches of gravity. If the apple feels this attractive pull toward the Earth, then what about the Moon? Indeed, what Newton came to understand he called universal gravitation.

MCAT Expertise

Acceleration due to gravity, g, decreases with height above the Earth and increases the closer one gets to the Earth's center of mass. Near the Earth's surface, use $g = 10 \frac{m}{s^2}$.

Gravity is an attractive force that is felt by all forms of matter. We usually think of gravity as acting on us to keep us from floating off of the Earth's surface, or for holding the planets of our solar system in orbit. However, all objects exert gravitational forces on each other; there is a small (but measurable) force of gravity between you and this *MCAT Physics and Math Review* book, the chair you're sitting on, and all the objects around you. Gravitational forces usually do not have much significance on the small scale because other forces tend to be much larger in magnitude. Only on the planetary level do gravitational forces really take on a significant value.

The magnitude of the **gravitational force** between two objects is

$$F_g = \frac{Gm_1m_2}{r^2}$$

Equation 1.8

where G is the universal gravitational constant $\left(6.67\times10^{-11}\,\frac{\text{N}\cdot\text{m}^2}{\text{kg}^2}\right)$, m_1 and m_2 are the masses of the two objects, and r is the distance between their centers of mass. This equation is commonly tested in the context of proportionalities. For instance, the magnitude of the gravitational force is inversely related to the square of the distance (that is, if r is halved, then F_g will quadruple). The magnitude of the gravitational force is also directly related to the masses of the objects (that is, if m_1 is tripled, then F_g will triple).

Example: Find the gravitational force between an electron and a proton that are 10^{-11} m apart. (Note: Mass of a proton = 1.67×10^{-27} kg; mass of an electron = 9.11×10^{-31} kg)

Solution: Use Newton's law of gravitation:

$$F_g = \frac{Gm_1m_2}{r^2} = \frac{\left(6.67\times10^{-11}\,\frac{\text{N}\cdot\text{m}^2}{\text{kg}^2}\right)(1.67\times10^{-27}\text{ kg})(9.11\times10^{-31}\text{ kg})}{(10^{-11}\text{ m})^2}$$

$$F_g \approx \frac{\left(\frac{20}{3}\times10^{-11}\right)\left(\frac{5}{3}\times10^{-27}\right)(9\times10^{-31})}{10^{-22}} = \frac{10^{-67}}{10^{-22}}$$

$$= 10^{-45}\text{ N (actual} = 1.02\times10^{-45}\text{ N)}$$

Friction

Friction is a type of force that opposes the movement of objects. Unlike other kinds of forces, such as gravity or electromagnetic force, which can cause objects either to speed up or slow down, friction forces always oppose an object's motion and cause it to slow down or become stationary. There are two types of friction: static and kinetic.

Real World

Newton's third law states that the force of gravity on m_1 from m_2 is equal and opposite to the force of gravity on m_2 from m_1. This means that the force of gravity on you from the Earth is equal and opposite to the force of gravity from you on the Earth. Because the forces are equal but the masses are very different, the accelerations must also be very different, from **F** = *m***a** (discussed later in this chapter). Because your mass is very small compared to the Earth, you experience a large acceleration from it. In contrast, because the Earth is massive, it experiences a tiny acceleration from the same magnitude of force.

Static friction ($\mathbf{f}_s$) exists between a stationary object and the surface upon which it rests. The equation that describes the magnitude of static friction is

$$0 \leq f_s \leq \mu_s N$$

Equation 1.9

where μ_s is the coefficient of static friction and N is the magnitude of the normal force. The **coefficient of static friction** is a unitless quantity that is dependent on the two materials in contact. The **normal force** is the component of the force between two objects in contact that is perpendicular to the plane of contact between the object and the surface upon which it rests.

Note the less-than-or-equal-to signs in the equation. These signify that there is a range of possible values for static friction. The minimum, of course, is zero. This would be the case if an object were resting on a surface with no applied forces. The maximum value of static friction can be calculated from the right side of the previous equation. One should not assume that objects that are stationary are experiencing a maximal static force of friction.

Consider trying to push a heavy piece of luggage. When a 25 N force is applied, the bag does not move. When a 50 N force is applied, the bag still does not move. When a 100 N force is applied, the bag slides a meter or so and slows to a rest. This setup implies that the maximal value of static friction is somewhere between 50 and 100 N; any applied force less than this threshold will not be sufficient to move the bag as there will be an equal but opposite force of static friction opposing the bag's motion.

Key Concept

Contact points are the places where friction occurs between two rough surfaces sliding past each other. If the normal load—the force that squeezes the two together—rises, the total area of contact increases. That increase, more than the surface's roughness, governs the degree of friction. This is illustrated in Figure 1.7 below.

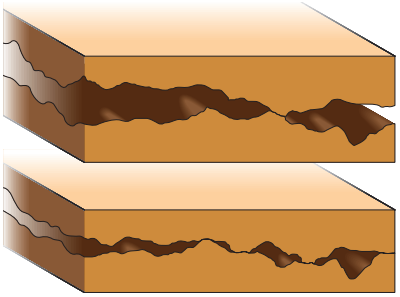


Figure 1.7. Increases in Contact Area Increase Frictional Forces

Kinetic friction ($\mathbf{f}_k$) exists between a sliding object and the surface over which the object slides. Sometimes, students misidentify the presence of kinetic friction. A wheel, for example, that is rolling along a road does not experience kinetic friction because the tire is not actually sliding against the pavement. The tire maintains an instantaneous point of static contact with the road and, therefore, experiences static friction. Only when the tire begins to slide on, say, an icy patch will kinetic friction come into play. To be sure, any time two surfaces slide against each other, kinetic friction will be present and its magnitude can be measured according to this equation:

$$f_k = \mu_k N$$

Equation 1.10

where μ_k is the coefficient of kinetic friction and N is the normal force. There are two important distinctions between this equation for kinetic friction and the previous

equation for static friction. First, the kinetic friction equation has an equals sign. This means that kinetic friction will have a constant value for any given combination of a coefficient of kinetic friction and normal force. It does not matter how much surface area is in contact or even the velocity of the sliding object. Second, the two equations have a different coefficient of friction. The value of μ_s is always larger than the value of μ_k. Therefore, the maximum value for static friction will always be greater than the constant value for kinetic friction: objects will "stick" until they start moving, and then will slide more easily over one another.

As previously mentioned in the discussion of static friction, pay close attention to the conditions set in an MCAT passage or question. Does it say that friction can be assumed to be negligible, or does it provide the coefficient of friction values, which will most likely need to be used in a calculation of friction? Friction will be incorporated into our examination of translational equilibrium later in this chapter.

Key Concept

The coefficient of static friction will always be larger than the coefficient of kinetic friction. It always requires more force to get an object to start sliding than it takes to keep an object sliding.

MASS AND WEIGHT

Mass and weight are not the same. **Mass** (m) is a measure of a body's inertia—the amount of matter in the object. Mass is a scalar quantity, and, as such, has magnitude only. The SI unit for mass is the kilogram, which is independent of gravity. One kilogram of material on Earth will have the same mass as one kilogram of material on the Moon. **Weight** ($\mathbf{F}_g$), on the other hand, is a measure of gravitational force (usually that of the Earth) on an object's mass. Because weight is a force, it is a vector quantity with the units of newtons (N).

While mass and weight are not synonymous, they are related by the equation:

$$\mathbf{F}_g = m\mathbf{g}$$

Equation 1.11

where $\mathbf{F}_g$ is the weight of the object, m is its mass, and $\mathbf{g}$ is acceleration due to gravity, 9.8 $\frac{\text{m}}{\text{s}^2}$ (usually rounded to 10 $\frac{\text{m}}{\text{s}^2}$).

The weight of an object can be thought of as being applied at a single point in that object called the **center of mass** or **gravity**. The MCAT will not directly test your ability to determine center of mass; however, such a calculation may be an important step in a problem with the larger focus of Newtonian mechanics.

To illustrate this concept and calculation, consider a tennis racquet that has been thrown into the air. Each part of the racquet moves in its own pathway, so it's not possible to represent the motion of the whole racquet as a single particle. However, one point within the racquet moves in a simple parabolic path, very similar to the flight of a ball. It is this point within the racquet that is known as the center of mass. This is clearly shown in Figure 1.8.

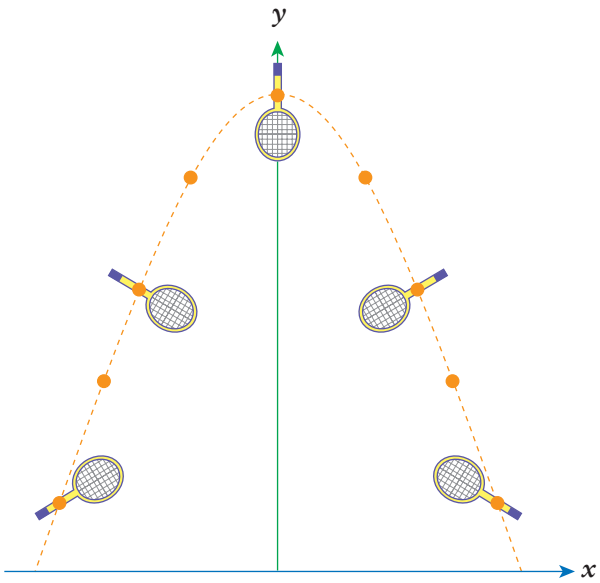

Figure 1.8. Center of Mass of a Tennis Racquet
The center of mass of a racquet thrown into the air travels along a parabolic pathway.

For a system in which particles are distributed in all three dimensions, the center of mass is defined by the three coordinates:

$$x = \frac{m_1x_1 + m_2x_2 + m_3x_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$
$$y = \frac{m_1y_1 + m_2y_2 + m_3y_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$
$$z = \frac{m_1z_1 + m_2z_2 + m_3z_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$

Equation 1.12

where m_1, m_2, and m_3 are the three sample masses, and the x-, y- and z-values are coordinates. The center of gravity is related and corresponds to the single point at which one can conceptualize gravity acting on an object. Only for a homogeneous body (with symmetrical shape and uniform density) should one expect the center of gravity be located at its geometric center. For example, we can approximate the center of gravity for a metal ball as the geometric center of the sphere. The same cannot be said, however, for a human body, television, or any asymmetrical, non-uniform object.

Key Concept

The center of mass of a uniform object is at the geometric center of the object.

ACCELERATION

Acceleration (**a**) is the rate of change of velocity that an object experiences as a result of some applied force. Acceleration, like velocity, is a vector quantity and is measured in SI units of meters per second squared. Acceleration in the direction

opposite the initial velocity may be called **deceleration**. **Average acceleration** is defined as

$$\bar{\mathbf{a}} = \frac{\Delta \mathbf{v}}{\Delta t}$$

Equation 1.13

where $\bar{\mathbf{a}}$ is the average acceleration, $\Delta \mathbf{v}$ is the change in velocity, and Δt is the change in time.

Instantaneous acceleration is defined as the average acceleration as Δt approaches zero.

$$\mathbf{a} = \lim_{\Delta t \to 0} \frac{\Delta \mathbf{v}}{\Delta t}$$

Equation 1.14

On a graph of velocity *vs.* time, the tangent to the graph at any time t, which corresponds to the slope of the graph at that time, indicates the instantaneous acceleration. If the slope is positive, the acceleration is positive and is in the direction of the velocity. If the slope is negative, the acceleration is negative (deceleration) and is in the direction opposite of the velocity.

MCAT Concept Check 1.4:

Before you move on, assess your understanding of the material with these questions.

1. When calculating frictional forces, how is directionality assigned?

   _____

   _____

2. When no force is being applied, the velocity must be:

   _____

3. True or False: The Earth creates a larger force on you than you create on the Earth.
4. Name two forces in addition to mechanical manipulation (pushing or pulling forces created by contact with an object):

   - _____
   - _____

1.5 Newton's Laws

Now that we have a clear understanding of force, mass, and acceleration, let's examine how they relate to each other. While it is unlikely that Newton "discovered" gravity by having an apple on his head, he did record that he was indeed inspired by watching apples fall from trees. His observations about objects in motion and at rest are the basis for the branch of physics that we now know as mechanics. Newton's laws, which are expressed as equations, concisely describe the effects forces have on objects that have mass.

FIRST LAW

$$\mathbf{F}_{net} = m\mathbf{a} = 0$$

Equation 1.15

where $\mathbf{F}_{net}$ is the net force, m is the mass, and $\mathbf{a}$ is the acceleration.

A body either at rest or in motion with constant velocity will remain that way unless a net force acts upon it. This is also known as the law of **inertia**. Newton's first law ought to be thought of as a special case of his second law, which is described next.

SECOND LAW

$$\mathbf{F}_{net} = m\mathbf{a}$$

Equation 1.16

where $\mathbf{F}_{net}$ is the net force, m is the mass, and $\mathbf{a}$ is the acceleration.

What Newton's second law states is actually a corollary of the first: *An object of mass m will accelerate when the vector sum of the forces results in some nonzero resultant force vector*. No acceleration will occur when the vector sum of the forces results in a cancellation of those forces. Note that the net force and acceleration vectors necessarily point in the same direction.

THIRD LAW

$$\mathbf{F}_{AB} = -\mathbf{F}_{BA}$$

Equation 1.17

This law is also known as the law of action and reaction: *To every action, there is always an opposed but equal reaction*. More formally, the law states that for every force exerted by object A on object B, there is an equal but opposite force exerted

by object B on object A. For example, when you hit your hand against your desk, your hand exerts a force on the desk. Simultaneously, the desk exerts a force of equal magnitude in the opposite direction on your hand. Physical contact is not necessary for Newton's third law; the mutual gravitational pull between the Earth and the Moon traverses hundreds of thousands of kilometers of space.

MCAT Concept Check 1.5:
Before you move on, assess your understanding of the material with this question.

1. In your own words, provide a description of Newton's laws of motion:

1. _____
_____

2. _____
_____

3. _____
_____

1.6 Motion with Constant Acceleration ★

Objects can undergo only two types of motion—that which is constant (with no acceleration) or that which is changing (with acceleration). If an object's motion is changing, as indicated by a change in velocity, then the object is experiencing acceleration, and that acceleration may be constant or itself changing. A moving object that experiences constant acceleration presents a relatively simple case for analysis. The MCAT tends to restrict kinematics problems to those that involve motion with constant acceleration.

LINEAR MOTION

In **linear motion**, the object's velocity and acceleration are along the line of motion, so the pathway of the moving object continues along a straight line. Linear motion does not need to be limited to vertical or horizontal paths; the inclined surface of a ramp will provide a path for linear motion at some angle. On the MCAT, the most common presentations of linear motion problems involve objects, such as balls, being dropped to the ground from some starting height.

Falling objects exhibit linear motion with constant acceleration. This one-dimensional motion can be fully described by the following equations:

$$\mathbf{v} = \mathbf{v}_0 + \mathbf{a}t$$
$$\mathbf{x} = \mathbf{v}_0 t + \frac{\mathbf{a}t^2}{2}$$
$$\mathbf{v}^2 = \mathbf{v}_0^2 + 2\mathbf{a}\mathbf{x}$$
$$\mathbf{x} = \overline{\mathbf{v}}t$$

Equations 1.18 to 1.21

where $\mathbf{x}$, $\mathbf{v}$, and $\mathbf{a}$ are the displacement, velocity, and acceleration vectors, respectively; $\mathbf{v}_0$ is the initial velocity; $\overline{\mathbf{v}}$ is the average velocity; and t is time. When the motion is vertical, we often use $\mathbf{y}$ instead of $\mathbf{x}$ for displacement.

MCAT Expertise

When dealing with free fall problems, you can choose to make *down* either positive or negative. However, for the sake of simplicity, get in the habit of always making *up* positive and *down* negative.

To demonstrate the typical setup of a kinematics problem on the MCAT, we will consider an object falling through the air. For now, we will assume air resistance to be negligible, meaning that the only force acting on the object would be the gravitational force causing it to fall. Consequently, the object would fall with constant acceleration—the **acceleration due to gravity** $\left(\mathbf{g} = 9.8\ \frac{\text{m}}{\text{s}^2}\right)$—and would not reach **terminal velocity**. This is called **free fall**. Under these conditions, which are typical for Test Day, we could analyze the fall, using the relevant kinematics equations.

Example: A ball is thrown vertically up into the air from a window ledge 30 meters above the ground with an initial velocity of 10 $\frac{\text{m}}{\text{s}}$.

A. Find the velocity and position of the ball after two seconds.
B. Find the distance and time at which the ball reaches its maximum height above the window ledge.

Solution:

A. Remember that velocity and acceleration are vector quantities. For this question, let's call the ball's initial position, $\mathbf{y}_0$, zero. If we consider *up* to be positive, then the initial velocity, $\mathbf{v}_0$, is +10 $\frac{\text{m}}{\text{s}}$, and the acceleration, $\mathbf{g}$, is –9.8 $\frac{\text{m}}{\text{s}^2}$. Note that $\mathbf{g}$ is negative because it's oriented downward. Velocity after two seconds can be found using Equation 1.18:

$$\begin{aligned}\mathbf{v} &= \mathbf{v}_0 + \mathbf{a}t \\ &= \left(+10\ \frac{\text{m}}{\text{s}}\right) + \left(-9.8\ \frac{\text{m}}{\text{s}^2}\right)(2\ \text{s}) \\ &= -9.6\ \frac{\text{m}}{\text{s}}\end{aligned}$$

After two seconds, the position of the ball is found using Equation 1.19:

$$\begin{aligned}\mathbf{y} &= \mathbf{v}_0 t + \frac{\mathbf{a}t^2}{2} \\ &= \left(10\,\frac{\text{m}}{\text{s}}\right)(2\text{ s}) + \frac{\left(-9.8\,\frac{\text{m}}{\text{s}^2}\right)(2\text{ s})^2}{2} \\ &= 20 - 19.6 = 0.4\text{ m (above the ledge)}\end{aligned}$$

B. When the ball is at its maximum height, the velocity, which has been decreasing on the way up, is now zero. We can find the maximum height the ball reaches using Equation 1.20:

$$\begin{aligned}\mathbf{v}^2 &= \mathbf{v}_0^2 + 2\mathbf{a}\mathbf{y} \\ 0^2 &= \left(10\,\frac{\text{m}}{\text{s}}\right)^2 + 2\left(-9.8\,\frac{\text{m}}{\text{s}^2}\right)(\mathbf{y}) \\ 19.6\mathbf{y} &= 100 \\ \mathbf{y} &\approx 5\text{ m (actual = 5.1 m)}\end{aligned}$$

The time at which the ball reaches its maximum height can be found from Equation 1.18:

$$\begin{aligned}\mathbf{v} &= \mathbf{v}_0 + \mathbf{a}t \\ 0 &= \left(+10\,\frac{\text{m}}{\text{s}}\right) + \left(-9.8\,\frac{\text{m}}{\text{s}^2}\right)(t) \\ t &\approx 1\text{ s (actual = 1.02 s)}\end{aligned}$$

Let's now consider what happens when air resistance is *not* negligible. **Air resistance**, like friction, opposes the motion of an object. Its value increases as the speed of the object increases. Therefore, an object in free fall will experience a growing **drag force** as the magnitude of its velocity increases. Eventually, this drag force will be equal in magnitude to the weight of the object, and the object will fall with constant velocity according to Newton's first law. This velocity is called the **terminal velocity**.

PROJECTILE MOTION

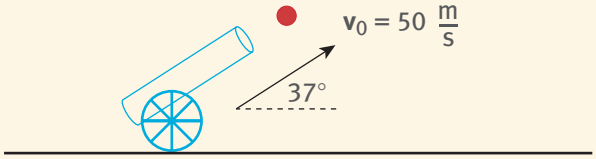
Projectile motion is motion that follows a path along two dimensions. The velocities and accelerations in the two directions (usually horizontal and vertical) are independent of each other and must, accordingly, be analyzed separately. Objects in projectile motion on Earth, such as cannonballs, baseballs, or bullets, experience the force and acceleration of gravity only in the vertical direction (along the *y*-axis). This means that $\mathbf{v}_y$ will change at the rate of $\mathbf{g}$ but $\mathbf{v}_x$ will remain constant. In fact, on the MCAT, you will generally be able to assume that the horizontal velocity, $\mathbf{v}_x$, will be

MCAT Expertise

The amount of time that an object takes to get to its maximum height is the same time it takes for the object to fall back down to the starting height (assuming air resistance is negligible); this fact makes solving these problems much easier. Because you can solve for the time to reach maximum height by setting your final velocity to zero, you can then multiply your answer by two, getting the total time in flight—as long as the object ends at the same height at which it started. Because the only force acting on the object after it is launched is gravity, the velocity it has in the *x*-direction will remain constant throughout its time in flight. By multiplying the time by the velocity in the *x*-direction, one can find the horizontal distance traveled.

constant because we usually assume that air resistance is negligible and, therefore, no measurable force is acting along the *x*-axis.

Example: A projectile is fired from ground level with an initial velocity of 50 $\frac{m}{s}$ and an initial angle of elevation of 37°, as shown below. Assuming $\mathbf{g} = 10\ \frac{m}{s^2}$, find the following: (Note: sin 37° = 0.6; cos 37° = 0.8)



A. The projectile's total time in flight
B. The total horizontal distance traveled

Solution:

A. Let **y** equal the vertical displacement, and *up* be the positive direction. If we are going to use the vertical displacement and acceleration due to gravity (which is also in the *y*-direction), we must use the *y*-component of velocity in this part of the problem:

$$\mathbf{v}_{0_y} = \mathbf{v}_0 \sin 37° = \left(50\ \frac{m}{s}\right)(0.6) = 30\ \frac{m}{s}$$

Now we can plug in:

$$\mathbf{y} = \mathbf{v}_{0_y}\, t + \frac{\mathbf{a}_y t^2}{2}$$

$$0 = \left(30\ \frac{m}{s}\right)(t) + \frac{\left(-10\ \frac{m}{s^2}\right)(t)^2}{2}$$

$$5t^2 = 30\, t$$

$$t = 0 \quad \text{or} \quad 6\ s$$

The height of the ball is zero at 0 seconds (its initial position) and 6 seconds (when it hits the ground again).

B. Now that we know the time, we can find the horizontal distance traveled. Here, we will need to consider only the *x*-component of the velocity:

$$\mathbf{v}_{0_x} = \mathbf{v}_0 \cos 37° = \left(50\ \frac{m}{s}\right)(0.8) = 40\ \frac{m}{s}$$

Now we can plug in:

$$\mathbf{x} = \mathbf{v}_x\, t + \frac{\mathbf{a}_x t^2}{2} = \left(40\ \frac{m}{s}\right)(6\ s) + 0 = 240\ m$$

INCLINED PLANES

Inclined planes are another example of motion in two dimensions. When working with an inclined plane question, it is often best to divide force vectors into components that are parallel and perpendicular to the plane. Most often, gravity must be split into components for these calculations. These components can be defined as:

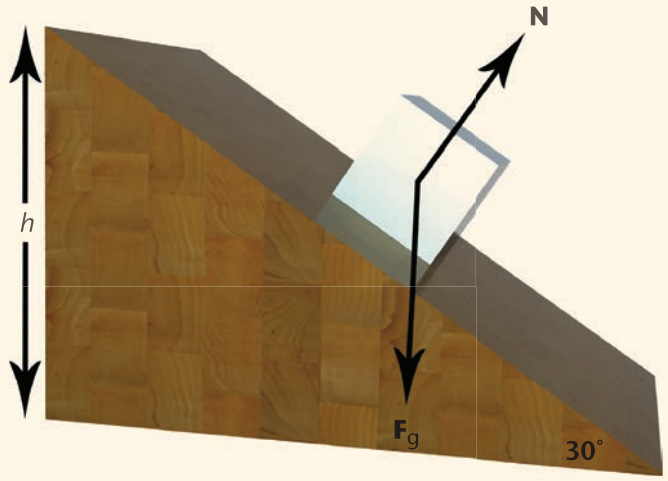
$$\mathbf{F}_{g,\parallel} = mg\sin\theta$$
$$\mathbf{F}_{g,\perp} = mg\cos\theta$$

Equation 1.22

where $\mathbf{F}_{g,\parallel}$ is the component of gravity parallel to the plane (oriented down the plane), $\mathbf{F}_{g,\perp}$ is the component of gravity perpendicular to the plane (oriented into the plane), m is the mass, g is acceleration due to gravity, and θ is the angle of the incline. Otherwise, the same kinematics equations can be used in these problems.

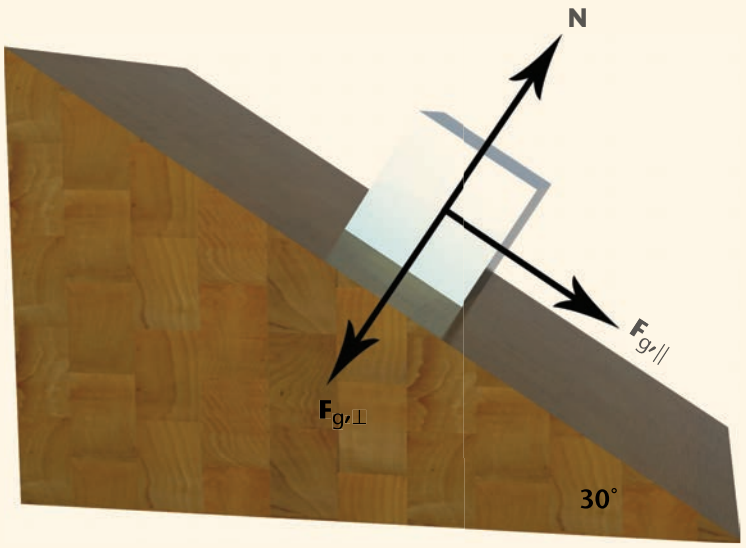
Example: A 5 kg block slides down a frictionless incline at 30°. Find the normal force and acceleration of the block. (Note: sin 30° = 0.5, sin 60° = 0.866)

Solution: The block in this example has two forces acting on it: the normal force, which is perpendicular to the surface, and gravity, which points straight down:



Because gravity is not in the same coordinate system as the normal force, one of the two forces must be split into components. In this case, because we are concerned with magnitude of the normal force (which is perpendicular to the plane) and the acceleration (which is

parallel to the plane), we should split the force of gravity into parallel and perpendicular components:



Because there is no acceleration in the perpendicular dimension, the magnitude of the normal force must be equal to that of the perpendicular component of gravity:

$$|\mathbf{N}| = |\mathbf{F}_{g,\perp}| = mg\cos\theta = (5\text{ kg})\left(9.8\frac{\text{m}}{\text{s}^2}\right)\cos 30° \approx 50(0.866)$$
$$= 43.3\text{ N (actual} = 42.4\text{ N)}$$

The acceleration can then be determined in the parallel direction. Because the only force in this dimension is the parallel component of the force of gravity, it is the net force:

$$\mathbf{F}_{\text{net},\parallel} = \mathbf{F}_{g,\parallel} = ma_{\parallel}$$
$$mg\sin\theta = ma_{\parallel}$$
$$g\sin\theta = a_{\parallel} = \left(9.8\frac{\text{m}}{\text{s}^2}\right)(0.5) = 4.9\frac{\text{m}}{\text{s}^2}$$

CIRCULAR MOTION

Circular motion occurs when forces cause an object to move in a circular pathway. Upon completion of one cycle, the displacement of the object is zero. Although the MCAT focuses on uniform circular motion, in which case the speed of the object is constant, recognize that there is also nonuniform circular motion.

In **uniform circular motion**, the instantaneous velocity vector is always tangent to the circular path, as shown in Figure 1.9. What this means is that the object moving in the circular path has a tendency (inertia) to break out of its circular pathway and move in a linear direction along the tangent. It is kept from doing so by a **centripetal force**, which always points radially inward. In all circular motion, we can resolve the forces into radial and tangential components. In uniform circular motion, the tangential force is zero because there is no change in the speed of the object.

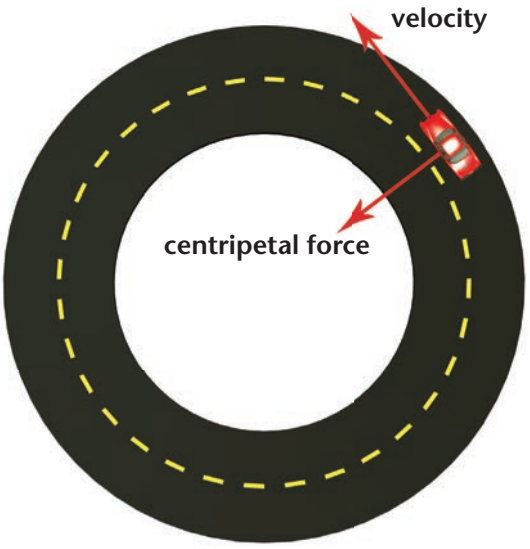


Figure 1.9. Uniform Circular Motion

As a force, the centripetal force generates **centripetal acceleration**. Remember from the discussion of Newton's laws that both force and acceleration are vectors and the acceleration is always in the same direction as the net force. Thus, it is this acceleration generated by the centripetal force that keeps an object in its circular pathway. When the centripetal force is no longer acting on the object, it will simply exit the circular pathway and assume a path tangential to the circle at that point. The equation that describes circular motion is

$$F_c = \frac{mv^2}{r}$$

Equation 1.23

where F_c is the magnitude of the centripetal force, m is the mass, v is the speed, and r is the radius of the circular path. Note that the centripetal force can be caused by tension, gravity, electrostatic forces, or other forces.

MCAT Concept Check 1.6:
Before you move on, assess your understanding of the material with these questions.

1. How do the forces acting in free fall and projectile motion differ?

_____

_____

2. At what angle of launch is a projectile going to have the greatest horizontal displacement? What angle will result in the greatest vertical displacement, assuming a level surface?
   - Greatest horizontal displacement: _____
   - Greatest vertical displacement: _____

3. What is the equation for centripetal acceleration?

_____

1.7 Mechanical Equilibrium ★★

So far we've been paying attention to kinematics and the special cases of linear and projectile motion. However, many times the MCAT will require us to eliminate acceleration, or otherwise maintain a system in equilibrium. To accomplish this, we must be familiar with analyzing forces, especially with free body diagrams, as well as with the special conditions for translational and rotational equilibrium. The study of forces and torques is called **dynamics**.

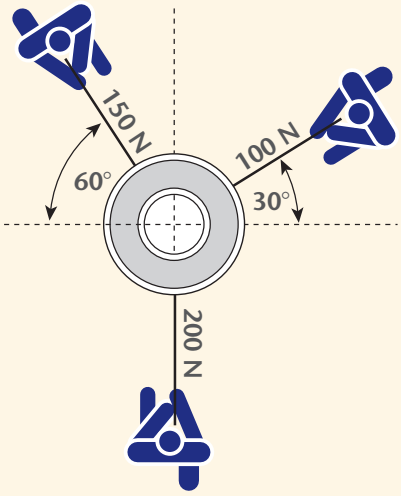
FREE BODY DIAGRAMS

While we all have an intuitive sense of forces (and their effects) in everyday life, students often struggle to represent them diagrammatically. Drawing **free body diagrams** takes some practice but will be a valuable tool on the MCAT. On Test Day, make sure to draw a free body diagram for any problem in which you must perform calculations on forces.

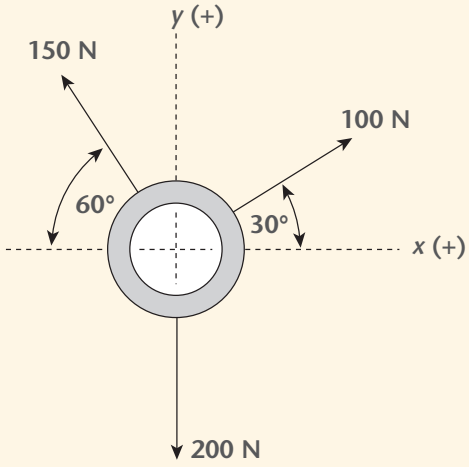
MCAT Expertise

When dealing with dynamics questions, always draw a quick picture of what is happening in the problem; this will keep everything in its proper relative position and help prevent you from making simple mistakes.

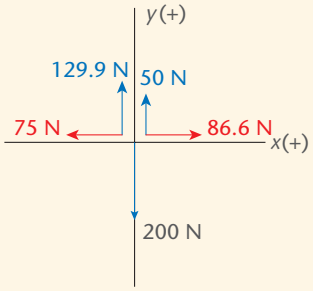
Example: Three people are pulling on ropes tied to a tire with forces of 100 N, 150 N, and 200 N as shown below. Find the magnitude and direction of the resultant force. (Note: sin 30° = 0.5, sin 60° = 0.866)



Solution: First, draw a free body diagram that shows the forces acting on the tire. Its purpose is to identify and visualize the acting forces.

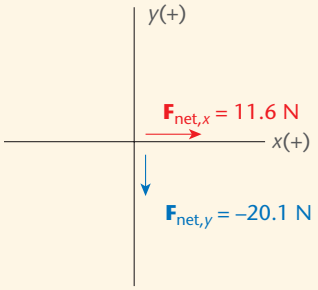


The resultant force is simply the sum of the forces. To find the resultant force vector, we need the sum of the force components, shown below.



$$F_{net,x} = \sum F_x = 100\cos 30^\circ - 150\cos 60^\circ = 86.6 - 75 = 11.6 \text{ N}$$
$$F_{net,y} = \sum F_y = 100\sin 30^\circ + 150\sin 60^\circ - 200 = 50 + 129.9 - 200 = -20.1 \text{ N}$$

The net component vectors are shown graphically below.



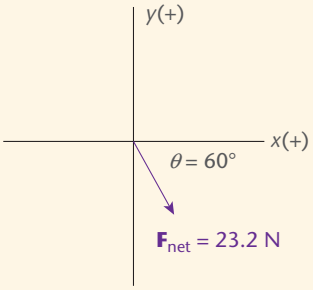
The magnitude can then be determined using the Pythagorean theorem:

$$F_{net}^2 = F_x^2 + F_y^2$$
$$F_{net} = \sqrt{(11.6)^2 + (-20.1)^2} \approx \sqrt{144 + 400} \approx 23 \text{ N (actual = 23.2 N)}$$

The direction can be determined using the tangent function:

$$\tan\theta = \frac{-20.1}{11.6} \approx -1.66$$
$$\theta \approx \tan^{-1}(-1.66) \approx -60^\circ$$

Note that this calculation of an inverse tangent is beyond the scope of Test Day math. The resultant vector is shown below.



TRANSLATIONAL EQUILIBRIUM

Translational motion occurs when forces cause an object to move without any rotation. The simplest pathways may be linear, such as when a child slides down a snowy hill on a sled, or parabolic, as in the case of a cannonball shot out of a cannon. Any problem regarding translational motion in the *Chemical and Physical Foundations of Biological Systems* section can be solved using free body diagrams and Newton's three laws.

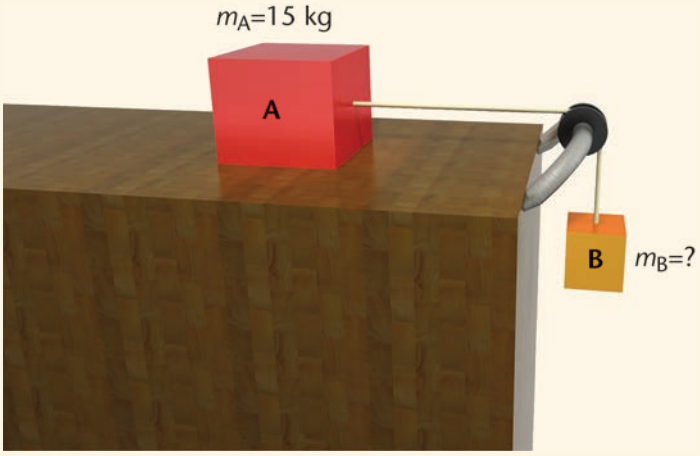
Equilibrium Conditions

Translational equilibrium exists only when the vector sum of all of the forces acting on an object is zero. This is called the **first condition of equilibrium**, and it is merely a reiteration of Newton's first law. Remember that when the resultant force upon an object is zero, the object will not accelerate; that may mean that the object is stationary, but it could just as well mean that the object is moving with a constant nonzero velocity. Thus, an object experiencing translational equilibrium will have a constant velocity: both a constant speed (which could be a zero or nonzero value) and a constant direction.

Key Concept

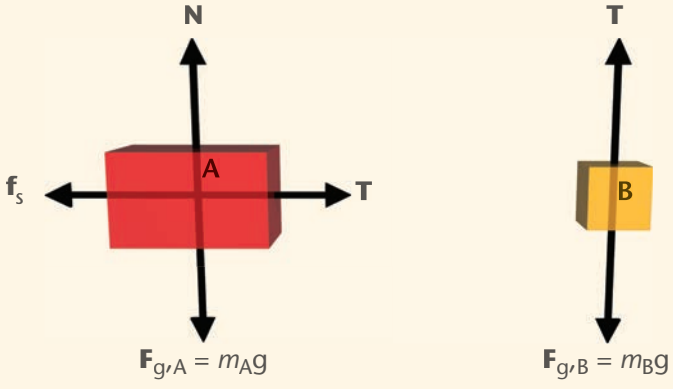
If there is no acceleration, then there is no net force on the object. This means that any object with a constant velocity has no net force acting on it. However, just because the net force equals zero does not mean the velocity equals zero.

Example: Two blocks are in static equilibrium, as shown below:



If block A has a mass of 15 kg and the coefficient of static friction between block A and the surface is 0.2, what is the maximum mass of block B?

Solution: Start by making a free body diagram of each block:



Both blocks have a net force of zero because they are in equilibrium. Therefore, the magnitude of **T** is equal to that of $\mathbf{F}_{g,B}$. Asking for the maximum mass of block B means that the force of static friction is maximized ($f_s = \mu_s N$); further, because block A is in equilibrium, $\mathbf{f}_s$ is equal in magnitude to **T** and $\mathbf{F}_{g,A}$ is equal in magnitude to **N**. Therefore:

$$f_s = T \quad \text{and} \quad T = F_{g,B}$$
$$f_s = F_{g,B}$$
$$\mu_s N = m_B g$$
$$\mu_s m_A g = m_B g$$
$$\mu_s m_A = m_B$$
$$(0.2)(15\text{ kg}) = m_B = 3.0\text{ kg}$$

ROTATIONAL EQUILIBRIUM

Rotational motion occurs when forces are applied against an object in such a way as to cause the object to rotate around a fixed pivot point, also known as the **fulcrum**. Application of force at some distance from the fulcrum generates **torque** ($\boldsymbol{\tau}$) or the **moment of force**. The distance between the applied force and the fulcrum is termed the **lever arm**. It is the torque that generates rotational motion, not the mere application of the force itself. This is because torque depends not only on the magnitude of the force but also on the length of the lever arm and the angle at which the force is applied. The equation for torque is a cross product:

$$\boldsymbol{\tau} = \mathbf{r} \times \mathbf{F} = rF \sin\theta$$

Equation 1.24

where r is the length of the lever arm, F is the magnitude of the force, and θ is the angle between the lever arm and force vectors.

Key Concept

Remember that sin 90° = 1. This means that torque is greatest when the force applied is 90 degrees (perpendicular) to the lever arm. Knowing that sin 0° = 0 tells us that there is no torque when the force applied is parallel to the lever arm.

Equilibrium Conditions

Rotational equilibrium exists only when the vector sum of all the torques acting on an object is zero. This is called the **second condition of equilibrium**. Torques that generate clockwise rotation are considered negative, while torques that generate counterclockwise rotation are positive. Thus, in rotational equilibrium, it must be that all of the positive torques exactly cancel out all of the negative torques. Similar to the behavior defined by translational equilibrium, there are two possibilities of motion in the case of rotational equilibrium.

Either the object is not rotating at all (that is, it is stationary), or it is rotating with a constant angular velocity. The MCAT almost always takes rotational equilibrium to mean that the object is not rotating at all.

Example: A seesaw with a mass of 5 kg has one block of mass 10 kg two meters to the left of the fulcrum and another block 0.5 m to the right of the fulcrum, as shown below.

If the seesaw is in equilibrium, find the mass of block 2 and the force exerted by the fulcrum.

Solution: If the seesaw is balanced, this implies rotational equilibrium. Therefore, the positive (counterclockwise) torque exerted by block 1 is equal in magnitude to the negative (clockwise) torque exerted by block 2. Use the fulcrum as the pivot point; because the fulcrum is centered under the seesaw, both the normal force and the weight of the seesaw will be eliminated from the equation because their lever arms are 0.

$$\tau_1 = \tau_2$$
$$r_1 F_{g_1} \sin\theta_1 = r_2 F_{g_2} \sin\theta_2$$
$$r_1(m_1 g)\sin 90^\circ = r_2(m_2 g)\sin 90^\circ$$
$$r_1 m_1 = r_2 m_2 \rightarrow m_2 = \frac{r_1 m_1}{r_2} = \frac{(2\text{ m})(10\text{ kg})}{0.5\text{ m}} = 40\text{ kg}$$

To find the normal force exerted by the fulcrum, consider that the seesaw is not only in rotational equilibrium but also translational equilibrium. Therefore, the combined weight of the seesaw and blocks (pointing down) is equal in magnitude to the normal force (pointing up):

$$N = F_{g,\text{ seesaw + blocks}}$$
$$= (m_{\text{seesaw}} + m_1 + m_2)g$$
$$\approx (5\text{ kg} + 10\text{ kg} + 40\text{ kg})\left(10\ \frac{\text{m}}{\text{s}^2}\right) = 550\text{ N (actual} = 539\text{ N)}$$

MCAT Concept Check 1.7:
Before you move on, assess your understanding of the material with these questions.

1. Can a moving object be in equilibrium? Why or why not?

_____

_____

2. If you have an object three times as heavy as you can lift, how could a lever be used to lift the object? Where would the fulcrum need to be placed?

_____

_____

Conclusion

In this chapter, we've equipped you with the math—the language of physics—necessary to understand our first important topic for the MCAT *Chemical and Physical Foundations of Biological Systems* section: kinematics and Newtonian mechanics. This study of objects in motion allows us to describe an object's position, displacement, distance traveled, velocity, speed, and acceleration with respect to time. We now understand how to use the four key kinematics equations when objects experience constant acceleration, a relatively simple scenario presented on Test Day.

We also learned that different kinds of forces act on objects to cause them to move in certain ways. Application of forces may cause objects to accelerate or decelerate according to Newton's second law. If the vector sum of all the forces acting on an object is equal to zero, the forces cancel out, and the object experiences no acceleration, a condition known as translational equilibrium. This is expressed in Newton's first law. Even when objects aren't touching, they can still exert forces between them, as described by Newton's third law. We considered linear motion, projectile motion, inclined planes, and circular motion. We also considered the special conditions of translational and rotational equilibrium.

We hope that you will come to appreciate the relevance that these concepts and principles have for your performance not only on the MCAT but also in medical school, residency training, and your career as a physician. Your careful consideration of the discussion topics in this chapter and your practice with the kinds of problems demonstrated here will earn you many points on Test Day.

CONCEPT SUMMARY

Units

- The MCAT will test the **SI units** that are related to the metric system. The SI units include meter, kilogram, second, ampère, mole, kelvin, and candela.

Vectors and Scalars

- **Vectors** are physical quantities that have both magnitude and direction. Vector quantities include displacement, velocity, acceleration, and force, among others.
- **Scalars** are quantities without direction. Scalar quantities may be the magnitude of vectors, like speed, or may be dimensionless, like coefficients of friction.
- Vector addition may be accomplished using the tip-to-tail method or by breaking a vector into its components and using the Pythagorean theorem.
- Vector subtraction is accomplished by changing the direction of the subtracted vector and then following the procedures for vector addition.
- Multiplying a vector by a scalar changes the magnitude and may reverse the direction.
- Multiplying two vectors using the **dot product** results in a scalar quantity. The dot product is the product of the vectors' magnitudes and the cosine of the angle between them.
- Multiplying two vectors using the **cross product** results in a vector quantity. The cross product is the product of the vectors' magnitudes and the sine of the angle between them. The right-hand rule is used to determine the resultant vector's direction.

Displacement and Velocity

- **Displacement** is the vector representation of a change in position. It is path independent and is equivalent to the straight line distance between the start and end locations.
- **Distance** is a scalar quantity that reflects the path traveled.
- **Velocity** is the vector representation of the change in displacement with respect to time.
  - **Average velocity** is the total displacement divided by the total time.
  - **Average speed** is the total distance traveled divided by the total time.
  - **Instantaneous velocity** is limit of the change in displacement over time as the change in time approaches zero.
  - **Instantaneous speed** is the magnitude of the instantaneous velocity vector.

Forces and Acceleration

- A **force** is any push or pull that has the potential to result in an acceleration.
- **Gravity** is the attractive force between two objects as a result of their masses.
- **Friction** is a force that opposes motion as a function of electrostatic interactions at the surface between two objects.
  - **Static friction** exists between two objects that are not in motion relative to each other.
  - **Kinetic friction** exists between two objects that are in motion relative to each other.
  - Whereas static friction can take on many values depending on the magnitude of an applied force, kinetic friction is a constant value.
  - The **coefficient of friction** depends on the two materials in contact. The coefficient of static friction is always higher than the coefficient of kinetic friction.
- Mass and weight are not synonymous.
  - **Mass** is a measure of the inertia of an object—its amount of material.
  - **Weight** is the force experienced by a given mass due to the gravitational attraction to the Earth.
- **Acceleration** is the vector representation of the change in velocity over time. Average or instantaneous acceleration may both be considered, similar to velocity.

Newton's Laws

- **Newton's first law**, or the **law of inertia**, states that an object will remain at rest or move with a constant velocity if there is no net force on the object.
- **Newton's second law** states that any acceleration is the result of the sum of the forces acting on the object and its mass.
- **Newton's third law** states that any two objects interacting with one another experience equal and opposite forces as a result of their interaction.

Motion with Constant Acceleration

- **Linear motion** includes **free fall** and motion in which the velocity and acceleration vectors are parallel or antiparallel.
- **Projectile motion** contains both an x- and y-component. Assuming negligible air resistance, the only force acting on the object is gravity.
- **Inclined planes** are another example of two-dimensional movement. It is often easiest to consider the dimensions as being parallel and perpendicular to the surface of the plane.

- **Circular motion** is best thought of as having radial and tangential dimensions. In **uniform circular motion**, the only force is the **centripetal force**, pointing radially inward. The instantaneous velocity vector always points tangentially.

Mechanical Equilibrium

- **Free body diagrams** are representations of the forces acting on an object. They are useful for equilibrium and dynamics problems.
- **Translational equilibrium** occurs in the absence of any net forces acting on an object. An object in translational equilibrium has a constant velocity, and may or may not also be in rotational equilibrium.
- **Rotational equilibrium** occurs in the absence of any net **torques** acting on an object. Rotational motion may consider any pivot point, but the center of mass is most common. An object in rotational equilibrium has a constant angular velocity; on the MCAT, the angular velocity is usually zero.

ANSWERS TO CONCEPT CHECKS

1.1

1. Force will obey the same relationship with mass and acceleration, regardless of the unit system. Force is always the product of mass and acceleration, so one pound (lb) must be equal to one $\frac{\text{slug} \cdot \text{ft}}{\text{s}^2}$.
2. ångström < centimeter < inch < foot < mile

1.2

1. Vector addition, unlike vector multiplication, is a commutative function. The resultant of $\mathbf{A} + \mathbf{B}$ is the same as $\mathbf{B} + \mathbf{A}$, so there would be no difference between the two resultants.
2. Vector subtraction, like vector multiplication, is not a commutative function. The resultant of $\mathbf{A} - \mathbf{B}$ has the same magnitude as $\mathbf{B} - \mathbf{A}$, but is oriented in the opposite direction.
3. A scalar is calculated from two vectors by using the dot product: $\mathbf{A} \cdot \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}| \cos\theta$. A vector is calculated by using the cross product: $\mathbf{A} \times \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}| \sin\theta$.
4. False. This would be true of an addition problem in which both vectors have equal magnitude, but it is never true for vector multiplication. To find the direction of **C**, we must use the right-hand rule. If the thumb points in the direction of **A**, and the fingers point in the direction of **B**, then our palm, **C**, points out of the page.

1.3

1. Instantaneous speed is the magnitude of the instantaneous velocity vector. Average speed and average velocity may be unrelated because speed does not depend on displacement, but is rather the total distance traveled divided by time.
2. True. Displacement considers the most direct route between two points. Distance will always be equal or larger in magnitude than displacement.
3. Velocity is the rate of the change of the displacement of an object. Displacement is a function of velocity acting over a period of time.

1.4

1. The direction of the frictional force always opposes movement. Once the instantaneous velocity vector is known (or net force, in the case of static friction), the frictional force must be in the opposite direction.
2. If there is no net force acting on an object, then that object is not experiencing an acceleration and it has a constant velocity.

3. False. Forces are always reciprocal in nature. When the Earth creates a force on a person, the person also exerts a force of the same magnitude on the Earth (in the opposite direction). The difference in masses gives the Earth an apparent acceleration of zero.
4. Gravity and frictional forces were discussed in this chapter. Electrostatic, magnetic, elastic, weak nuclear, and strong nuclear forces are other examples of forces.

1.5

1. Any answer which is similar to the following is acceptable:
   1. In the absence of any forces—or when the net force is zero—there will be no change in velocity.
   2. Acceleration results from the sum of the force vectors.
   3. For any two interacting objects, all forces acting on one object have an equal and opposing force acting on the other object.

1.6

1. The only force acting in both free fall and projectile motion is gravity.
2. The product of sine and cosine is maximized when the angle is 45°. Because horizontal displacement relies on both measurements, the maximum horizontal displacement will also be achieved at this angle. Vertical displacement will always be zero as the object returns to the starting point. Objects launched vertically will experience the greatest vertical *distance*.
3. If the equation for centripetal force is $F_c = \frac{mv^2}{r}$ and force is simply mass times acceleration (from Newton's second law), then $a_c = \frac{v^2}{r}$.

1.7

1. A moving object can be in either translational or rotational equilibrium (or both). Translational equilibrium only requires the net force on an object be zero—its velocity is constant. The corresponding condition in rotational equilibrium is that net torque equals zero—its angular velocity is constant.
2. One could place the fulcrum one quarter of the way across the lever, closer to the object. The ratio of the lever arms would then be 3:1, which means that only one-third of the original force is necessary. (Alternatively, the fulcrum could be placed at the end with the object one-third of the way across the lever. This would again result in a 3:1 ratio of lever arms, meaning that only one-third of the original force is necessary.)

EQUATIONS TO REMEMBER

(1.1) **Component vectors:** $\mathbf{X} = \mathrm{V}\cos\theta$

$\mathbf{Y} = \mathrm{V}\sin\theta$

(1.2) **Pythagorean theorem:** $\mathbf{X}^2 + \mathbf{Y}^2 = \mathbf{V}^2$ or $\mathbf{V} = \sqrt{\mathbf{X}^2 + \mathbf{Y}^2}$

(1.3) **Determination of direction from component vectors:** $\theta = \tan^{-1}\dfrac{\mathbf{Y}}{\mathbf{X}}$

(1.4) **Dot product:** $\mathbf{A} \cdot \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}|\cos\theta$

(1.5) **Cross product:** $\mathbf{A} \times \mathbf{B} = |\mathbf{A}|\,|\mathbf{B}|\sin\theta$

(1.6) **Instantaneous velocity:** $\mathbf{v} = \lim\limits_{\Delta t \to 0} \dfrac{\Delta \mathbf{x}}{\Delta t}$

(1.7) **Average velocity:** $\overline{\mathbf{v}} = \dfrac{\Delta \mathbf{x}}{\Delta t}$

(1.8) **Universal gravitation equation:** $F_g = \dfrac{Gm_1m_2}{r^2}$

(1.9) **Static friction:** $0 \le f_s \le \mu_s N$

(1.10) **Kinetic friction:** $f_k = \mu_k N$

(1.11) **Force of gravity (weight on Earth):** $\mathbf{F}_g = m\mathbf{g}$

(1.12) **Center of mass:**

$$x = \frac{m_1x_1 + m_2x_2 + m_3x_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$

$$y = \frac{m_1y_1 + m_2y_2 + m_3y_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$

$$z = \frac{m_1z_1 + m_2z_2 + m_3z_3 + \cdots}{m_1 + m_2 + m_3 + \cdots}$$

(1.13) **Average acceleration:** $\overline{\mathbf{a}} = \dfrac{\Delta \mathbf{v}}{\Delta t}$

(1.14) **Instantaneous acceleration:** $\mathbf{a} = \lim\limits_{\Delta t \to 0} \dfrac{\Delta \mathbf{v}}{\Delta t}$

(1.15) **Newton's first law:** $\mathbf{F}_{net} = m\mathbf{a} = 0$

(1.16) **Newton's second law:** $\mathbf{F}_{net} = m\mathbf{a}$

(1.17) **Newton's third law:** $\mathbf{F}_{AB} = -\mathbf{F}_{BA}$

(1.18) **Kinematics (no displacement):** $\mathbf{v} = \mathbf{v}_0 + \mathbf{a}t$

(1.19) **Kinematics (no final velocity):** $\mathbf{x} = \mathbf{v}_0 t + \dfrac{\mathbf{a}t^2}{2}$

(1.20) **Kinematics (no time):** $\mathbf{v}^2 = \mathbf{v}_0^2 + 2\mathbf{ax}$

(1.21) **Kinematics (no acceleration):** $\mathbf{x} = \overline{\mathbf{v}}t$

(1.22) **Components of gravity on an inclined plane:** $\mathbf{F}_{g,\parallel} = mg\sin\theta$

$\mathbf{F}_{g,\perp} = mg\cos\theta$

(1.23) **Centripetal force:** $F_c = \frac{mv^2}{r}$

(1.24) **Torque:** $\boldsymbol{\tau} = \mathbf{r} \times \mathbf{F} = rF \sin\theta$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. A man walks 30 m east and then 40 m north. What is the difference between his traveled distance and his displacement?

A. 0 m
B. 20 m
C. 50 m
D. 70 m

2. A 1000 kg rocket ship, travelling at 100 $\frac{m}{s}$, is acted upon by an average force of 20 kN applied in the direction of its motion for 8 s. What is the change in velocity of the rocket?

A. 160 $\frac{m}{s}$
B. 260 $\frac{m}{s}$
C. 160,000 $\frac{m}{s}$
D. 260,000 $\frac{m}{s}$

3. A car is traveling at 40 $\frac{km}{hr}$ and the driver puts on the brakes, bringing the car to rest in a time of 6 s. What is the magnitude of the average acceleration of the car?

A. 240 $\frac{km}{hr^2}$
B. 12,000 $\frac{km}{hr^2}$
C. 24,000 $\frac{km}{hr^2}$
D. 30,000 $\frac{km}{hr^2}$

4. An elevator is designed to carry a maximum weight of 9800 N (including its own weight), and to move upward at a speed of 5 $\frac{m}{s}$ after an initial period of acceleration. What is the relationship between the maximum tension in the elevator cable and the maximum weight of the elevator while the elevator is accelerating upward?

A. The tension is greater than 9800 N.
B. The tension is less than 9800 N.
C. The tension equals 9800 N.
D. It cannot be determined from the information given.

5. At a place where g = 9.8 $\frac{m}{s^2}$, an object is thrown vertically downward with a speed of 5 $\frac{m}{s}$ while a different object is thrown vertically upward with a speed of 10 $\frac{m}{s}$. Which object undergoes a greater change in speed in a time of 2 s?

A. The first object has a greater change in speed.
B. The second object has a greater change in speed.
C. Both objects undergo the same change in speed.
D. It cannot be determined from the information given.

6. A firefighter jumps horizontally from a burning building with an initial speed of 1.5 $\frac{m}{s}$. At what time is the angle between his velocity and acceleration vectors the greatest?

A. The instant he jumps
B. When he reaches terminal velocity
C. Halfway through his fall
D. Right before he lands on the ground

7. A 10 kg wagon rests on a frictionless inclined plane. The plane makes an angle of 30° with the horizontal. Approximately how large is the force required to keep the wagon from sliding down the plane?

A. 10 N
B. 49 N
C. 85 N
D. 98 N

8. Which of the following expressions correctly illustrates the SI base units for each of the variables in the formula below?

$$m\Delta\mathbf{v} = \mathbf{F}\Delta t$$

A. lb × mph = ft × lb × s
B. $\text{kg} \times \frac{\text{m}}{\text{s}} = \text{N} \times \text{s}$
C. $\text{kg} \times \frac{\text{m}}{\text{s}} = \frac{\text{kg} \cdot \text{m}}{\text{s}^2} \times \text{s}$
D. $\text{g} \times \frac{\text{m}}{\text{s}} = \frac{\text{g} \cdot \text{m}}{\text{s}^2} \times \text{s}$

9. A 20 kg wagon is released from rest from the top of a 15 m long lane, which is angled at 30° with the horizontal. Assuming that there is friction between the ramp and the wagon, how is this frictional force affected if the angle of the incline is increased?

A. The frictional force increases.
B. The frictional force decreases.
C. The frictional force remains the same.
D. It cannot be determined from the information given.

10. Which of the following quantities is NOT a vector?

A. Velocity
B. Force
C. Displacement
D. Distance

11. A 30 kg girl sits on a seesaw at a distance of 2 m from the fulcrum. Where must her father sit to balance the seesaw if he has a mass of 90 kg?

A. 67 cm from the girl
B. 67 cm from the fulcrum
C. 133 cm from the girl
D. 267 cm from the fulcrum

12. A BASE jumper runs off a cliff with a speed of 3 $\frac{m}{s}$. Which of the following is closest to his speed after 0.5 seconds?

A. 3 $\frac{m}{s}$
B. 6 $\frac{m}{s}$
C. 8 $\frac{m}{s}$
D. 10 $\frac{m}{s}$

13. A rock (m = 2 kg) is shot up vertically at the same time that a ball (m = 0.5 kg) is projected horizontally. If both start from the same height:

A. the rock and ball will reach the ground at the same time.
B. the rock will reach the ground first.
C. the ball will reach the ground first.
D. the rock and ball will collide in the air before reaching the ground.

14. Centrifugal force is an apparent outward force during circular motion. It has been described as a reaction force according to Newton's third law. Which of the following statements is most likely to be correct regarding centrifugal force?

A. Centrifugal force exists only for uniform circular motion, not nonuniform circular motion.
B. Centrifugal force exists only when tension or a normal force provides centripetal acceleration.
C. Centrifugal force always acts antiparallel to the centripetal force vector.
D. Centrifugal force is result of repulsive electrostatic interactions.

15. Which of the following statements is true of movement on a plane with friction?

I. Acceleration is a function of applied force only.
II. More force is needed to accelerate a stationary object than an identical moving object.
III. The force of friction is independent of the mass of objects.

A. I only
B. II only
C. I and II only
D. I and III only

Explanations to Discrete Practice Questions

1. B

Using the Pythagorean theorem, calculate the magnitude of the man's displacement:

$$x = \sqrt{30^2 + 40^2} = 50 \text{ m}$$

His total distance traveled is equal to 30 + 40 = 70 m. Therefore, the difference between these two is 20 m.

2. A

The average force on the rocket equals its mass times the average acceleration; the average acceleration equals the change in velocity divided by the time over which the change occurs. So, the change in velocity equals the average force times the time divided by the mass:

$$\mathbf{F} = m\mathbf{a} \rightarrow \mathbf{a} = \frac{\mathbf{F}}{m}$$

$$\mathbf{a} = \frac{\Delta \mathbf{v}}{\Delta t} \rightarrow \Delta \mathbf{v} = \mathbf{a}\Delta t = \frac{\mathbf{F}\Delta t}{m} = \frac{(20 \times 10^3 \text{ N})(8 \text{ s})}{1000 \text{ kg}} = 160 \frac{\text{m}}{\text{s}}$$

Choice (B) represents the new velocity of the rocket, not its change in velocity. **Choices (C)** and **(D)** neglect dividing by the mass of the rocket.

3. C

The magnitude of the average acceleration is the change in velocity divided by the time. The velocity changes by $-40 \frac{\text{km}}{\text{hr}}$ because the car comes to rest. The time, in hours, is $6 \text{ s} \times \left[\frac{1 \text{ hr}}{3600 \text{ s}}\right] = \frac{1}{600}$ hr. The average acceleration is then

$$\bar{\mathbf{a}} = \frac{\Delta \mathbf{v}}{\Delta t} = \frac{-40 \frac{\text{km}}{\text{hr}}}{\frac{1}{600} \text{ hr}} = -24{,}000 \frac{\text{km}}{\text{hr}^2}$$

This question asked for the magnitude of this acceleration, which is $24{,}000 \frac{\text{km}}{\text{hr}^2}$.

4. A

The forces on the elevator are the tension upward and the weight downward, so the net force on the elevator is the difference between the two. For the elevator to accelerate upwards, the tension in the cable will have to be greater than the maximum weight so that there is a net force directed upwards.

5. A

Each object experiences an acceleration of $9.8 \frac{\text{m}}{\text{s}^2}$, which means that each object's velocity changes by $9.8 \frac{\text{m}}{\text{s}}$ each second. Therefore, both objects experience the same change in velocity over the 2-second period of $19.6 \frac{\text{m}}{\text{s}}$. However, this question asks for the change in speed. The first object starts with a velocity of $-5 \frac{\text{m}}{\text{s}}$ and ends with a velocity of $-24.6 \frac{\text{m}}{\text{s}}$. This represents a change in speed of $|-24.6| - |-5| = 19.6 \frac{\text{m}}{\text{s}}$. The second object starts with a velocity of $+10 \frac{\text{m}}{\text{s}}$ and ends with a velocity of $-9.6 \frac{\text{m}}{\text{s}}$. This represents a change in speed of $|-9.6| - |10| = -0.4 \frac{\text{m}}{\text{s}}$. Therefore, the second object has a much smaller change in speed than the first. This is because the force acting on the object was the opposite direction from the object's motion in the initial conditions.

6. A

The firefighter's acceleration is always directed downward, whereas his velocity starts out horizontal and gradually rotates downwards as his downward velocity increases. Therefore, as time progresses, the angle between his velocity and acceleration decreases, which means that the maximum angle occurs at the instant he jumps.

7. B

The static force of friction acts parallel to the plane and is in the opposite direction from the parallel component of gravity in this setup. Because the wagon is in equilibrium, these two

forces are equal in magnitude. Remember that gravity is often split into components in inclined plane problems. Rather than splitting into *x*- and *y*-components, however, it is more convenient to split the gravity vector into parallel and perpendicular components. The parallel component of gravity is given by the expression $mg \sin \theta$. Plugging in the values from the question, both the parallel component of gravity and static force of friction must be equal to (10 kg) $\left(9.8 \frac{\text{m}}{\text{s}^2}\right)$ (sin 30°) = 49 N.

8. C

In SI units, mass is measured in kilograms (kg), velocity in meters per second $\left(\frac{\text{m}}{\text{s}}\right)$, and time in seconds (s). The newton is a derived unit, and is not considered to be a base unit of the SI system. A newton is equal to a $\frac{\text{kg} \cdot \text{m}}{\text{s}^2}$.

9. B

The force of friction on an object sliding down an incline equals the coefficient of friction times the normal force. The normal force is equal in magnitude to the perpendicular component of gravity, which is given by $mg \cos \theta$. As θ increases, $\cos \theta$ decreases. Therefore, the normal force and frictional force decrease as the angle of the incline increases.

10. D

A vector is characterized by both magnitude and direction. From the given answer choices, all are vectors except for distance. Distance is a scalar because it has only a numerical value and lacks direction.

11. B

In order for the seesaw to be balanced, the torque due to the girl ($\boldsymbol{\tau}_g$) must be exactly counteracted by the torque due to her father ($\boldsymbol{\tau}_f$). In other words, the magnitudes of these torques must be equal ($\tau_g = \tau_f$):

$$r_g F_g \sin \theta_g = r_f F_f \sin \theta_f$$
$$r_g m_g g \sin 90° = r_f m_f g \sin 90°$$
$$(2 \text{ m})(30 \text{ kg}) = r_f (90 \text{ kg})$$
$$0.67 \text{ m} = r_f$$

Because r represents the distance of each person from the fulcrum, the father must sit 67 cm from the fulcrum.

12. B

This is a projectile motion question. The horizontal component of the jumper's velocity will remain 3 $\frac{\text{m}}{\text{s}}$ throughout the jump. The vertical component of his velocity starts at 0 $\frac{\text{m}}{\text{s}}$. After 0.5 seconds, it will be:

$$\mathbf{v}_y = \mathbf{v}_{0_y} + \mathbf{a}t$$
$$\mathbf{v}_y = \left(-9.8 \frac{\text{m}}{\text{s}^2}\right)(0.5 \text{ s}) = -4.9 \frac{\text{m}}{\text{s}}$$

To get the overall velocity, consider the horizontal and vertical velocities using vector analysis and find the resultant. Doing so gives $\sqrt{3^2 + (4.9)^2} \approx \sqrt{34}$. This magnitude (speed) is just a bit under 6, which matches most closely to **choice (B)**.

13. C

We only need to analyze the motion in the vertical dimension to answer this question. If both the rock and ball began with no vertical velocity, they would reach the ground at the same time. However, because the rock begins with an upward component of velocity, it will take time to reach a maximum height before falling back toward the ground. Functionally, the rock's free fall thus starts higher and later than the ball's. The rock will necessarily hit the ground after the ball.

14. C

Because the question stem indicates that centrifugal force is reactionary and gives its direction, we can draw the conclusion that it is a reaction to the centripetal force. According to Newton's third law, these forces must have equal magnitude and opposite directions (antiparallel).

15. B

The presence of friction does not change the impact of Newton's laws. A net force must still be applied to cause motion. This net force is not necessarily equal to an applied force, as friction and gravity also act on the object; thus, statement I is eliminated. Static friction opposes the movement of stationary objects, and is necessarily greater than the force of kinetic friction; thus, statement II is correct. Statement III is false because the normal force is related to mass, and friction is related to the normal force.

Concept Summary 69

Introduction

The Greek myth of Sisyphus is a tale of unending, pointless work. For eternity, Sisyphus was sentenced to roll a large, heavy rock up a steep hill as penance for his crimes. Just as Sisyphus would nearly reach the top of the hill, the rock would roll back again to the bottom. The cycle continued for eternity: Sisyphus would near the top of the hill, and the boulder—enchanted by Zeus—would roll away, forcing Sisyphus to restart his task.

This is a story of work and mechanical energy transfer. Pushing that boulder up the hill, Sisyphus exerted forces that performed work on the rock, resulting in an increase in the rock's gravitational potential energy. When the rock escaped from his grasp and rolled backwards, its energy changed from gravitational potential energy into kinetic energy. While Sisyphus's punishment was futile work, it serves as a strong model of the exchange of mechanical energy between its two forms: potential and kinetic. While a number of other forms of energy exist (thermal energy, sound, light, chemical potential energy, and electrical potential energy, to name a few), mechanical energy specifically focuses on objects in motion.

This chapter reviews the fundamental concepts of energy and work. The work–energy theorem is a powerful expression of the relationship between energy and work which is often a simpler approach to kinematics questions on Test Day. Finally, we'll discuss the topic of mechanical advantage, and we'll examine how a pulley or ramp might be helpful in raising heavy objects. We hope to convince you throughout the Kaplan MCAT program that your preparation for Test Day is in no way a Sisyphean task.

2.1 Energy

Energy refers to a system's ability to do work or—more broadly—to make something happen. This broad definition helps us understand that different forms of energy have the capacity to perform different actions. For example, mechanical energy can cause objects to move or accelerate. An ice cube sitting on the kitchen counter at room temperature will absorb thermal energy through heat transfer and eventually melt into water, undergoing a phase transformation from solid to liquid. Nuclear binding energy can be released during fission reactions to run power plants. Let's turn our attention to the different forms that energy can take. After that, we will discuss the two ways in which energy can be transferred from one system to another.

KINETIC ENERGY

Key Concept

Kinetic energy is incredibly important on the MCAT; any time an object has a speed, think about kinetic energy and link its kinetic energy to the related concepts of work and conservation of mechanical energy.

Kinetic energy is the energy of motion. Objects that have mass and that are moving with some speed will have an associated amount of kinetic energy, calculated as follows:

$$K = \frac{1}{2}mv^2$$

Equation 2.1

where K is kinetic energy, m is the mass in kilograms, and v is speed in meters per second. The SI unit for kinetic energy, as with all forms of energy, is the **joule** (**J**), which is equal to $\frac{\text{kg} \cdot \text{m}^2}{\text{s}^2}$.

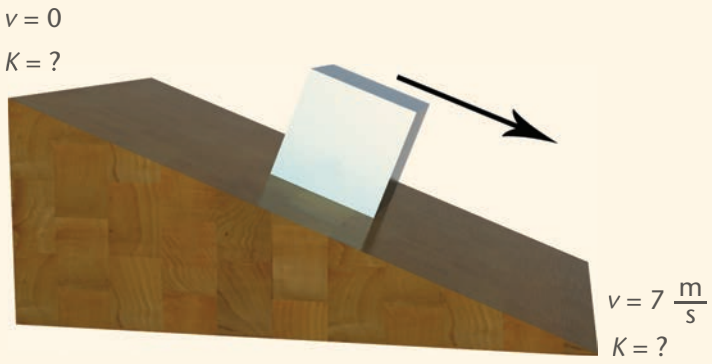
Key Concept

Kinetic energy is related to speed, not velocity. An object has the same kinetic energy regardless of the direction of its velocity vector.

Recall the falling objects in Chapter 1. Such objects have kinetic energy while they fall. The faster they fall, the more kinetic energy they have. Be mindful of the fact that the MCAT is interested in testing students' comprehension of the relationship between kinetic energy and speed. From the equation, we can see that the kinetic energy is a function of the square of the speed. If the speed doubles, the kinetic energy will quadruple, assuming the mass is constant. Also note that kinetic energy is related to speed—not velocity. An object has the same kinetic energy regardless of the direction of its velocity vector.

Falling objects have kinetic energy, but so do objects that are moving in other ways. For example, the kinetic energy of a fluid flowing at some speed can be measured indirectly as the dynamic pressure, which is one of the terms in Bernoulli's equation—discussed in Chapter 4 of *MCAT Physics and Math Review*. Objects that slide down inclined planes gain kinetic energy as their speeds increase down the ramp.

Example: A 15 kg block, initially at rest, slides down a frictionless incline and comes to the bottom with a speed of $7\ \frac{m}{s}$, as shown below. What is the kinetic energy of the object at the top and bottom of the ramp?



Solution: At the top, $v = 0$, so the kinetic energy is

$$K = \frac{1}{2}mv^2 = \frac{1}{2}(15\text{ kg})\left(0\ \frac{m}{s}\right)^2 = 0\text{ J}$$

At the bottom, the kinetic energy is

$$K = \frac{1}{2}mv^2 = \frac{1}{2}(15\text{ kg})\left(7\ \frac{m}{s}\right)^2 \approx 15 \times 25 = 375\text{ J (actual} = 367.5\text{ J)}$$

POTENTIAL ENERGY

Potential energy refers to energy that is associated with a given object's position in space or other intrinsic qualities of the system. Potential energy is often said to have the *potential* to do work, and can take named forms. Energy can be stored as chemical potential energy—this is the energy we absorb from the food we eat when we digest and metabolize it. Electrical potential energy, which is discussed in Chapter 5 of *MCAT Physics and Math Review*, is based on the electrostatic attractions between charged particles. In this chapter, we'll examine the types of potential energy that are dissipated as movement: gravitational potential energy and elastic potential energy.

Gravitational Potential Energy

Gravitational potential energy depends on an object's position with respect to some level identified as the **datum** ("ground" or the zero potential energy position). This zero potential energy position is usually chosen for convenience. For example, you may find it convenient to consider the potential energy of the pencil in your hand with respect to the floor if you are holding the pencil above the floor

MCAT Expertise

The height used in the potential energy equation is relative to whatever the problem states is the ground level. It will often be simply the distance to the ground, but it doesn't need to be. The zero potential energy position may be a ledge, a desktop, or a platform. Just pay attention to the question stem and use the height that is discussed.

or with respect to a desktop if you are holding the pencil over a desk. The equation that we use to calculate gravitational potential energy is

$$U = mgh$$

Equation 2.2

where U is the potential energy, m is the mass in kilograms, g is the acceleration due to gravity, and h is the height of the object above the datum.

Potential energy has a direct relationship with all three of the variables, so changing any one of them by some given factor will result in a change in the potential energy by the same factor. Tripling the height—or tripling the mass of the object—will increase the gravitational potential energy by a factor of three.

Example: An 80 kg diver leaps from a 10 m cliff into the sea, as shown below. Find the diver's potential energy at the top of the cliff and when he is two meters underwater, using sea level as the datum.

Solution: At the top of the cliff:

$$U = mgh = (80\text{ kg})\left(9.8\frac{\text{m}}{\text{s}^2}\right)(10\text{ m}) \approx 8000\text{ J (actual} = 7840\text{ J)}$$

When he is two meters underwater:

$$U = mgh = (80\text{ kg})\left(9.8\frac{\text{m}}{\text{s}^2}\right)(-2\text{ m}) \approx -1600\text{ J (actual} = -1568\text{ J)}$$

Elastic Potential Energy

Springs and other elastic systems act to store energy. Every spring has a characteristic length at which it is considered relaxed, or in equilibrium. When a spring is stretched or compressed from its **equilibrium length**, the spring has **elastic potential energy**, which can be determined by

$$U = \frac{1}{2}kx^2$$

Equation 2.3

Where U is the potential energy, k is the **spring constant** (a measure of the stiffness of the spring), and x is the magnitude of displacement from equilibrium. Note the similarities between this equation and the formula for kinetic energy.

TOTAL MECHANICAL ENERGY

The sum of an object's potential and kinetic energies is its **total mechanical energy**. The equation is

$$E = U + K$$

Equation 2.4

where E is total mechanical energy, U is potential energy, and K is kinetic energy. The **first law of thermodynamics** accounts for the **conservation of mechanical energy**, which posits that energy is never created nor destroyed—it is merely transferred from one form to another. This does not mean that the total mechanical energy will necessarily remain constant, though. You'll notice that the total mechanical energy equation accounts for potential and kinetic energies but not for other forms of energy, such as thermal energy that is transferred as a result of friction (heat). If frictional forces are present, some of the mechanical energy will be transformed into thermal energy and will be "lost"—or, more accurately, dissipated from the system and not accounted for by the equation. Note that there is no violation of the first law of thermodynamics, as a full accounting of all the forms of energy (kinetic, potential, thermal, sound, light, and so on) would reveal no net gain or loss of total energy, but merely the transformation of some energy from one form to another.

CONSERVATION OF MECHANICAL ENERGY

In the absence of nonconservative forces, such as frictional forces, the sum of the kinetic and potential energies will be constant. **Conservative forces** are those that are path independent and that do not dissipate energy. Conservative forces also have potential energies associated with them. On the MCAT, the two most commonly encountered conservative forces are gravitational and electrostatic. Elastic forces can also be approximated to be conservative in many cases, although the MCAT may include spring problems in which frictional forces are *not* ignored (in actuality, springs heat up as they move back and forth due to the friction between the particles of the spring material). There are two equivalent ways to determine whether a force is conservative, as demonstrated in Figure 2.1.

Bridge

The transfer of energy from one form to another is a key feature of bioenergetics and metabolism, discussed in Chapters 9 through 12 of *MCAT Biochemistry Review*. When looking at carbohydrate metabolism, one can see the chemical potential energy in the bonds in glucose being converted into electrical potential energy in the high-energy electrons of NADH and $FADH_2$, which is dissipated along the electron transport chain to generate the proton-motive force (another example of electrical potential energy). This force fuels ATP synthase, trapping the energy in high-energy phosphate bonds in ATP.

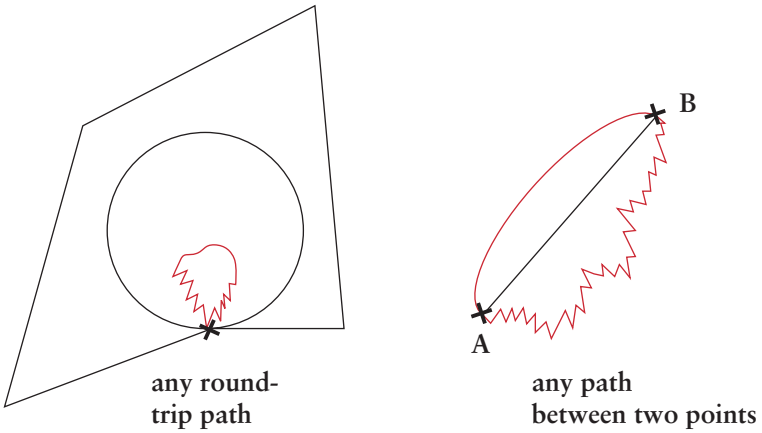


Figure 2.1. Determining if a Force is Conservative
If the change in energy around any round-trip path is zero—or if the change in energy is equal despite taking any path between two points—then the force is conservative.

One method is to consider the change in energy of a system in which the system is brought back to its original setup. In mechanical terms, this means that an object comes back to its starting position. If the net change in energy is zero regardless of the path taken to get back to the initial position, then the forces acting on the object are conservative. Basically, this means that a system that is experiencing only conservative forces will be "given back" an amount of usable energy equal to the amount that had been "taken away" from it in the course of a closed path. For example, an object that falls through a certain displacement in a vacuum will lose some measurable amount of potential energy but will gain exactly that same amount of potential energy when it is lifted back to its original height, regardless of whether the return pathway is the same as that of the initial descent. Furthermore, at all points during the fall through the vacuum, there will be a perfect conversion of potential energy into kinetic energy, with no energy lost to nonconservative forces such as air resistance. Of course, in real life, nonconservative forces are impossible to avoid.

The other method is to consider the change in energy of a system moving from one setup to another. In mechanical terms, this means an object undergoes a particular displacement. If the energy change is equal regardless of the path taken, then the forces acting on the object are again all conservative.

Key Concept

Conservative forces (such as gravity and electrostatic forces) conserve mechanical energy. Nonconservative forces (such as friction and air resistance) dissipate mechanical energy as thermal or chemical energy.

When the work done by nonconservative forces is zero, or when there are no nonconservative forces acting on the system, the total mechanical energy of the system ($U + K$) remains constant. The conservation of mechanical energy can be expressed as

$$\Delta E = \Delta U + \Delta K = 0$$

Equation 2.5

where ΔE, ΔU, and ΔK are the changes in total mechanical energy, potential energy, and kinetic energy, respectively.

When **nonconservative forces**, such as friction, air resistance, or viscous drag (a resistance force created by fluid viscosity) are present, total mechanical energy is not conserved. The equation is

$$W_{\text{nonconservative}} = \Delta E = \Delta U + \Delta K$$

Equation 2.6

where $W_{\text{nonconservative}}$ is the work done by the nonconservative forces only. The work done by the nonconservative forces will be exactly equal to the amount of energy "lost" from the system. In reality, this energy is simply transformed into another form of energy, such as thermal energy, that is not accounted for in the mechanical energy equation. Nonconservative forces, unlike conservative forces, are path dependent. The longer the distance traveled, the larger the amount of energy dissipated.

Example: A baseball of mass 0.25 kg is thrown in the air with an initial speed of $30\,\frac{\text{m}}{\text{s}}$, but because of air resistance, the ball returns to the ground with a speed of $27\,\frac{\text{m}}{\text{s}}$. Find the work done by air resistance.

Solution: Air resistance is a nonconservative force. To solve this problem, the energy equation for a nonconservative system is needed. The work done by air resistance is:

$$W_{\text{nonconservative}} = \Delta E = \Delta U + \Delta K$$

In this case, $\Delta U = 0$ because the initial and final heights are the same. Therefore,

$$\begin{aligned} W_{\text{nonconservative}} &= 0 + \Delta K \\ &= \frac{1}{2}mv_{\text{f}}^2 - \frac{1}{2}mv_{\text{i}}^2 \\ &= \frac{1}{2}(0.25\text{ kg})\left[\left(27\,\frac{\text{m}}{\text{s}}\right)^2 - \left(30\,\frac{\text{m}}{\text{s}}\right)^2\right] \\ &= \frac{1}{8}(729 - 900) \approx \frac{-160}{8} \\ &= -20\text{ J (actual} = -21.4\text{ J)} \end{aligned}$$

The negative sign in the answer indicates that energy is being dissipated from the system.

MCAT Concept Check 2.1:
Before you move on, assess your understanding of the material with these questions.

1. Define kinetic energy and potential energy.
   - Kinetic energy:

     _____

   - Potential energy:

     _____

2. Compare and contrast conservative and nonconservative forces:

	Conservative Forces	Nonconservative Forces
What happens to total mechanical energy of the system?		
Does the path taken matter?		
What are some examples?		

2.2 Work

Key Concept
Work is not energy but a measure of energy transfer. The other form of energy transfer is heat.

Often, the term work is used erroneously to mean another form of energy. After all, the SI unit for work is the joule (J), which is the same SI unit for all forms of energy. Nevertheless, to say that work is just another form of energy is to miss something important: **work** is not actually a form of energy itself, but a process by which energy is transferred from one system to another. In fact, it is one of only two ways in which energy can be transferred. The other transfer of energy is called heat, which we will focus on quite a bit in Chapter 3 of *MCAT Physics and Math Review*.

The transfer of energy by work or heat is the only way by which anything occurs. We are familiar with both processes from everyday life. For example, as discussed in the introduction to this chapter, every time King Sisyphus pushed the rock up the hill, the rock gained kinetic and potential energy. That energy came from Sisyphus's muscles, in which the potential energy contained in the high-energy phosphate bonds of ATP molecules was converted to the mechanical energy of the contracting muscles, which exerted forces against the rock, causing it to accelerate and move up the hill.

On a chemical level, the potential energy in the ATP was harnessed by heat transfer. In fact, at the molecular level, this is no different from work because it involves the movement of molecules, atoms, and electrons, each of which exert forces that do work on other molecules and atoms. Like any transfer of energy, it's not a perfectly efficient process, and some of the energy is lost as thermal energy. Our muscles quite literally warm up when we contract them repeatedly.

FORCE AND DISPLACEMENT

Energy is transferred through the process of work when something exerts forces on or against something else. This is expressed mathematically by the equation

$$W = \mathbf{F} \cdot \mathbf{d} = Fd \cos \theta$$

Equation 2.7

where W is work, F is the magnitude of the applied force, d is the magnitude of the displacement through which the force is applied, and θ is the angle between the applied force vector and the displacement vector. You'll notice that work is a dot product; as such, it is a function of the cosine of the angle between the vectors. This also means that only forces (or components of forces) parallel or antiparallel to the displacement vector will do work (that is, transfer energy). We've already said that the SI unit for work is the joule. While this suggests that work and energy are the same thing, remember they are not: work is the process by which a quantity of energy is moved from one system to another.

PRESSURE AND VOLUME

As described above, work is a process of energy transfer. In mechanics, we think of work as application of force through some distance. We will learn in our discussion of fluids in Chapter 4 of *MCAT Physics and Math Review* that pressure can be thought of as an "energy density." In systems of gases, we therefore approach work as a combination of pressure and volume changes. In Chapter 3 of *MCAT Physics and Math Review*, we'll examine how these changes also relate to heat.

For a gas system contained in a cylinder with a movable **piston**, we can analyze the relationship between pressure, volume, and work. When the gas expands, it pushes up against the piston, exerting a force that causes the piston to move up and the volume of the system to increase. When the gas is compressed, the piston pushes down on the gas, exerting a force that decreases the volume of the system. We say that work has been done when the volume of the system has changed due to an applied pressure. Gas expansion and compression processes can be represented in graphical form with volume on the x-axis and pressure on the y-axis. Such graphs, as shown in Figure 2.2, are termed **P–V graphs**.

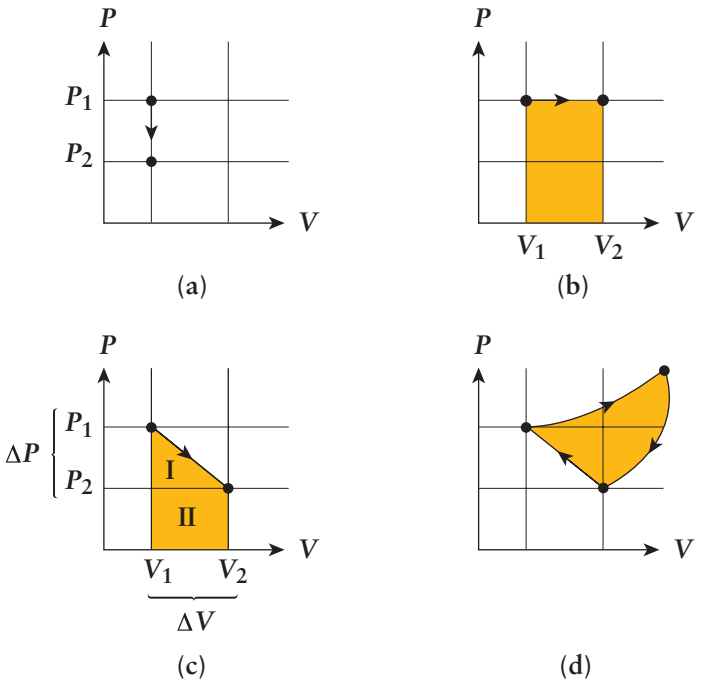

Figure 2.2. Pressure–Volume (P–V) Curves
The work done on or by a system undergoing a thermodynamic process can be determined by finding the area enclosed by the corresponding pressure–volume curve.

Key Concept

When work is done *by* a system (the gas expands), the work is said to be positive. When work is done *on* a system (the gas compresses), the work is said to be negative. The MCAT will not expect you to calculate the integral of a P–V graph using calculus, but you are expected to be able to calculate the area under a straight-line graph if necessary.

When a gas expands, we say that work was done by the gas and the work is positive; when a gas is compressed, we say that work was done on the gas and the work is negative. There are an infinite number of paths between an initial and final state. Different paths require different amounts of work. You can calculate the work done on or by a system by finding the area under the pressure–volume curve. Note that if volume stays constant as pressure changes (that is, $\Delta V = 0$), then no work is done because there is no area to calculate. This is the case in Figure 2.2a above, and is called an **isovolumetric** or **isochoric process**. On the other hand, if pressure remains constant as volume changes (that is, $\Delta P = 0$), then the area under the curve is a rectangle of length P and width ΔV as shown in Figure 2.2b. For processes in which pressure remains constant (**isobaric processes**), the work can be calculated as

$$W = P\Delta V$$

Equation 2.8

Figure 2.2c shows a process in which neither pressure nor volume is held constant. The total area under the graph (Regions I and II) gives the work done.

Region I is a triangle with base ΔV and height ΔP, so the area is

$$A_I = \frac{1}{2}\Delta V \Delta P$$

Region II is a rectangle with base ΔV and height P_2, so its area is

$$A_{II} = P_2 \Delta V$$

The work done is the sum of the areas of regions I and II:

$$W = A_I + A_{II}$$

Figure 2.2d shows a closed cycle in which, after certain interchanges of work and heat, the system returns to its initial state. Because work is positive when the gas expands and negative when the gas is compressed, the work done is the area enclosed by the curve. Calculating the work done in this situation would require calculus, but the MCAT does not test calculus-based physics.

POWER

Power refers to the rate at which energy is transferred from one system to another. It is calculated with the equation

$$P = \frac{W}{t} = \frac{\Delta E}{t}$$

Equation 2.9

where P is power, W is work (which is equal to ΔE, the change in energy) and t is the time over which the work is done. The SI unit for power is the **watt** (**W**), which is equal to $\frac{J}{s}$. In Chapter 6 of *MCAT Physics and Math Review*, we will identify additional ways to calculate power in electric circuits. For now, note that many of the devices we use every day—toaster ovens, light bulbs, phones, cars, and so on—are quantified by the rate at which these appliances transform electrical potential energy into other forms, such as thermal, light, sound, and kinetic energy.

Bridge

Power is calculated in many different situations, especially those involving circuits, resistors, and capacitors. The equation for electric power is $P = IV$, where P is power, I is current, and V is electrical potential difference (voltage). This equation is discussed in Chapter 6 of *MCAT Physics and Math Review*. Power is always a measure of the rate of energy consumption, transfer, or transformation per unit time.

WORK–ENERGY THEOREM

The **work–energy theorem** is a powerful expression of the relationship between work and energy. In its mechanical applications, it offers a direct relationship between the work done by all the forces acting on an object and the change in kinetic energy of that object. The net work done by forces acting on an object will result in an equal change in the object's kinetic energy. In other words,

$$W_{net} = \Delta K = K_f - K_i$$

Equation 2.10

This relationship is important to understand, as it allows one to calculate work without knowing the magnitude of the forces acting on an object or the displacement through which the forces act. If one calculates the change in kinetic energy experienced by an object, then—by definition—the net work done on or by an object is

the same. Pressing the brake pedal in your car puts the work–energy theorem into practice. The brake pads exert frictional forces against the rotors, which are attached to the wheels. These frictional forces do work against the wheels, causing them to decelerate and bringing the car to a halt. The net work done by all these forces is equal to the change in kinetic energy of the car.

In more general iterations, the work–energy theorem can be applied to changes in other forms of energy. In fact, the first law of thermodynamics is essentially a reiteration of the work–energy theorem, in which the change in internal energy (ΔU) is equal to the heat transferred into the system (Q) minus the mechanical work done by the system (W).

Example: A lead ball of mass 0.125 kg is thrown straight up in the air with an initial velocity of 30 $\frac{\text{m}}{\text{s}}$. Assuming no air resistance, find the work done by the force of gravity by the time the ball is at its maximum height.

Solution: The answer could be calculated using kinematics and determining the maximum height of the ball ($W = Fd\cos\theta$), but it is simpler to use the work–energy theorem:

$$\begin{aligned} W_{\text{net}} &= K_{\text{f}} - K_{\text{i}} \\ &= 0 - \frac{1}{2}mv_{\text{i}}^2 \\ &= -\left(\frac{1}{2}\right)\left(\frac{1}{8}\text{ kg}\right)\left(30\ \frac{\text{m}}{\text{s}}\right)^2 = -\frac{900}{16} \approx -\frac{900}{15} \\ &= -60\text{ J (actual } = -56.25\text{ J)} \end{aligned}$$

MCAT Concept Check 2.2:

Before you move on, assess your understanding of the material with these questions.

1. What are the units for work? How are work and energy different?

2. Provide three methods for calculating the work done on or by a system.
   - _____
   - _____
   - _____

2.3 Mechanical Advantage ★

Would it make a difference whether Sisyphus lifted the rock vertically to its final position or rolled it there along an incline? The difference between these two scenarios is mechanical advantage, a measure of the increase in force accomplished by using a tool. Sloping inclines, such as hillsides and ramps, make it easier to lift objects because they distribute the required work over a larger distance, decreasing the required force. For a given quantity of work, any device that allows for work to be accomplished through a smaller applied force is thus said to provide mechanical advantage. In addition to the inclined plane, five other devices are considered the classic **simple machines** designed to provide mechanical advantage: wedge (two merged inclined planes), wheel and axle, lever, pulley, and screw (rotating inclined plane). Of these, the inclined plane, lever, and pulley are most frequently tested on the MCAT.

Mechanical advantage is the ratio of magnitudes of the force exerted on an object by a simple machine (F_{out}) to the force actually applied on the simple machine (F_{in}):

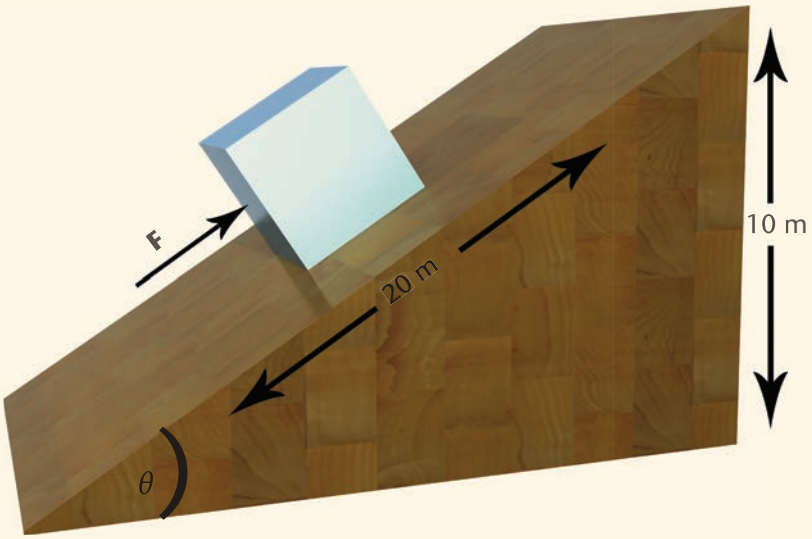
$$\text{Mechanical advantage} = \frac{F_{out}}{F_{in}}$$

Equation 2.11

The mechanical advantage, because it is a ratio, is dimensionless.

Reducing the force needed to accomplish a given amount of work does have a cost associated with it, however: the distance through which the smaller force must be applied in order to do the work must be increased. Inclined planes, levers, and pulleys do not magically change the amount of work necessary to move an object from one place to another. Because displacement is pathway independent, the actual distance traveled from the initial to final position does not matter, assuming all forces are conservative. Therefore, applying a lesser force over a greater distance to achieve the same change in position (displacement) accomplishes the same amount of work. We've already considered the dynamics of inclined planes and levers in Chapter 1 of *MCAT Physics and Math Review*. Here, we look at the work associated with inclined planes.

Example: A block weighing 100 N is pushed up a frictionless incline over a distance of 20 m to a height of 10 m as shown below.

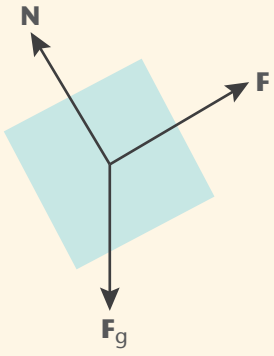


Find:

A. The minimum force required to push the block
B. The work done by the force
C. The force required and the work done by the force if the block were simply lifted vertically 10 m

Solution:

A. To find the minimum force required to push the block, we must draw a free body diagram of the situation:



The minimum force needed is a force that will push the block with no acceleration parallel to the surface of the incline. This means the magnitude of the applied force is equal to that of the parallel component of gravity:

$$F = mg \sin \theta$$

mg represents the weight of the object, which is 100 N. Using trigonometry, sin θ is ratio of the length of the opposite side to the hypotenuse, which is $\frac{10}{20}$. Therefore,

$$F = (100 \text{ N})\left(\frac{10}{20}\right) = 50 \text{ N}$$

B. The work done by **F** is

$$W = Fd \cos \theta$$

In this case, θ represents the angle between the force and displacement vectors, *not* the angle of the inclined plane. Because the force and displacement vectors are parallel, $\theta = 0$ and $\cos \theta = 1$. Therefore,

$$W = (50 \text{ N})(20 \text{ m})(1) = 1000 \text{ J}$$

C. To raise the block vertically, an upward force equal to the object's weight (100 N) would have to be generated. The work done by the lifting force is

$$W = Fd \cos \theta = (100 \text{ N})(10 \text{ m})(1) = 1000 \text{ J}$$

The same amount of work is required in both cases, but twice the force is needed to raise the block vertically compared with pushing it up the incline.

PULLEYS

Pulleys utilize the same paradigm to provide mechanical advantage as the inclined plane: a reduction of necessary force at the cost of increased distance to achieve a given value of work or energy transference. In practical terms, pulleys allow heavy objects to be lifted using a much-reduced force. Simply lifting a heavy object of mass m to a height of h will require an amount of work equal to mgh—its change in gravitational potential energy. If the displacement occurs over a distance equal to the displacement, then the force required to lift the object will equal mg. If, however, the distance through which the displacement is achieved is greater than the displacement (an indirect path), then the applied force will be less than mg. In other words, we've been able to lift this heavy object to the desired height by using a smaller force, but we've had to apply that smaller force through a greater distance in order to lift this heavy object to its final height.

Before examining how pulleys create this mechanical advantage, let's consider first the heavy block in Figure 2.3, suspended from two ropes. Because the block is not accelerating, it is in translational equilibrium, and the force that the block exerts downward (its weight) is cancelled by the sum of the tensions in the two ropes. For a symmetrical system, the tensions in the two ropes are the same and are each equal to half the weight of the block.

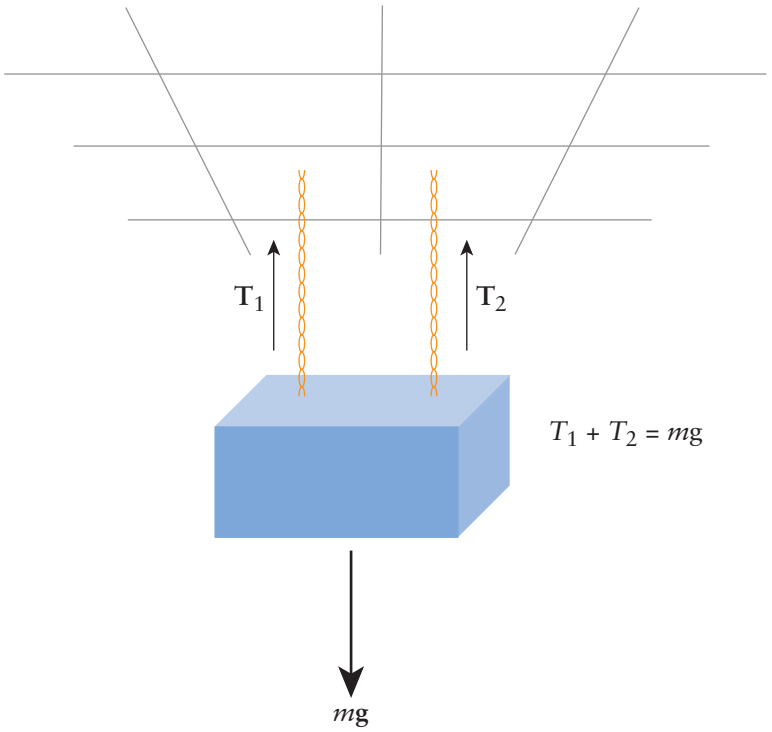


Figure 2.3. Block Suspended by Two Ropes
If the block is in translational equilibrium, the tension in each rope is equal to half the weight of the block.

Now let's imagine the heavy block in Figure 2.4 represents a heavy crate that must be lifted. Assuming that the crate is momentarily being held stationary in midair, we again have a system in translational equilibrium: the weight (the **load**) is balanced by the total tension in the ropes. The tensions in the two vertical ropes are equal to each other; if they were unequal, the pulleys would turn until the tensions were equal on both sides. Therefore, each rope supports one-half of the crate's total weight. By extension, only half the force (**effort**) is required to lift the crate. This decrease in effort is the mechanical advantage provided by the pulley, but as we've already discussed, mechanical advantage comes at the expense of distance. To lift an object to a certain height in the air (the **load distance**), one must pull through a length of rope (the **effort distance**) equal to twice that displacement. If, for example, the crate must be lifted to a shelf 3 meters above the ground, then both sides of the supporting rope must shorten by 3 meters, and the only way to accomplish this is by pulling through 6 meters of rope.

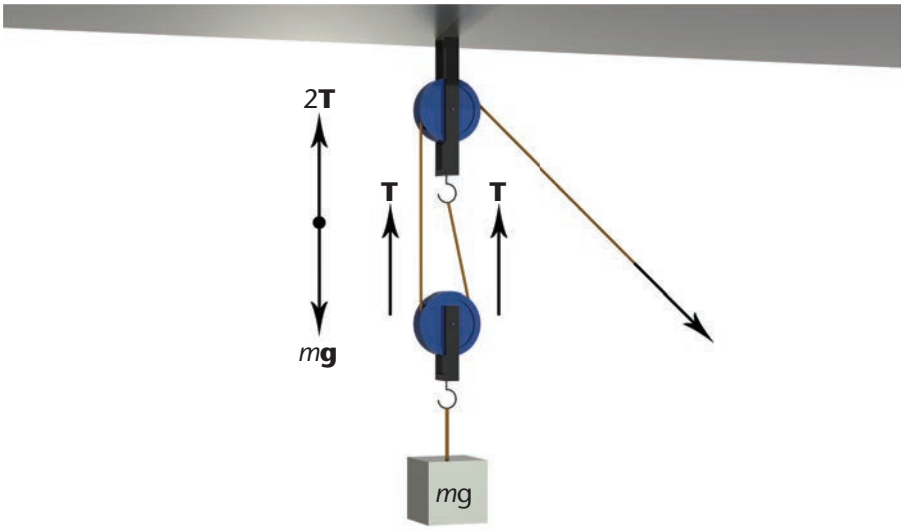

Figure 2.4. Two-Pulley System
The block is suspended from two ropes, each of which bears half of the block's weight.

All simple machines can be approximated as conservative systems if we ignore the (usually) small amount of energy that is lost due to external forces, such as friction. The idealized pulley is massless and frictionless, and under these theoretical conditions, the work put into the system (the exertion of force through a distance of rope) will exactly equal the work that comes out of the system (the displacement of the mass to some height). Real pulleys—and all real machines, for that matter—fail to conform to these idealized conditions and, therefore, do not achieve 100 percent **efficiency** in conserving energy output to input. We can define work input as the product of effort and effort distance; likewise, we can define work output as the product of load and load distance. Comparing the two as a ratio defines the efficiency of the simple machine:

$$\text{Efficiency} = \frac{W_{\text{out}}}{W_{\text{in}}} = \frac{(\text{load})(\text{load distance})}{(\text{effort})(\text{effort distance})}$$

Equation 2.12

Efficiency is often expressed as percentage by multiplying the efficiency ratio by 100 percent. The efficiency of a machine gives a measure of the amount of useful work generated by the machine for a given amount of work put into the system. A corollary of this definition is that the percentage of the work put into the system that becomes unusable is due to nonconservative or external forces.

The pulley system in Figure 2.5 illustrates the fact that adding more pulleys further increases mechanical advantage: for each additional pair of pulleys, we can reduce the effort further still. In this case, the load has been divided among six lengths of

Key Concept

When considering simple machines, load and effort are both forces. The load determines the necessary output force. From the output force and mechanical advantage, we can determine the necessary input force.

rope, so the effort required is now only one-sixth the total load. Remember that we would need to pull through a length of rope that is six times the desired displacement, and that efficiency will decrease due to the added weight of each pulley and the additional friction forces.

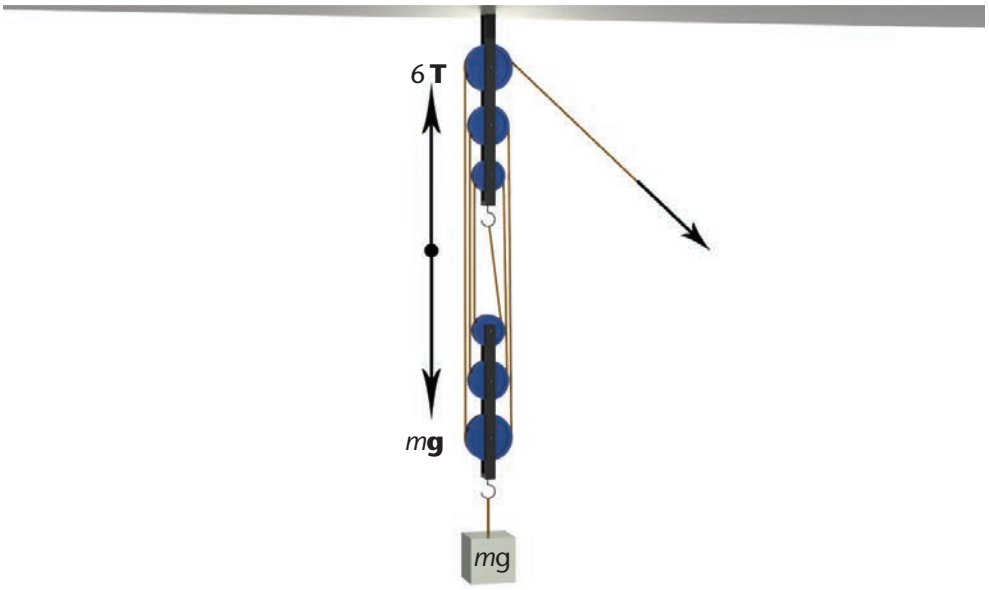

Figure 2.5. System of Six Pulleys
Increasing the number of pulleys decreases the tension in each segment of rope; this leads to an increase in the mechanical advantage of the setup.

Example: The pulley system in Figure 2.5 has an efficiency of 80 percent. A person is lifting a mass of 200 kg with the pulley.

Find:

A. The distance through which the effort must move to raise the load a distance of 4 m
B. The effort required to lift the load
C. The work done by the person lifting the load through a height of 4 m

Solution:

A. For the load to move through a vertical distance of 4 m, all six of the supporting ropes must shorten 4 m also. This may only be accomplished by pulling 6 × 4 = 24 m of rope through the setup. Therefore, the effort must move through a distance of 24 m.
B. To calculate the effort required, the equation for efficiency should be used. The load is the weight of the object being lifted and is equal to the mass of the object times the acceleration due to gravity g. The effort distance, calculated in part A, is 24 m.

$$\text{Efficiency} = \frac{(\text{load})(\text{load distance})}{(\text{effort})(\text{effort distance})}$$

$$0.8 = \frac{\left(200\,\text{kg} \times 9.8\,\frac{\text{m}}{\text{s}^2}\right)(4\,\text{m})}{(\text{effort})(24\,\text{m})}$$

$$\text{effort} \approx \frac{2000 \times 4}{0.8 \times 24} \approx \frac{8000}{20} = 400\,\text{N (actual} = 408\,\text{N)}$$

C. The work done by the person is

$$W_{in} = (\text{effort})(\text{effort distance}) = 408\ \text{N} \times 24$$
$$\approx 9600\ \text{J (actual} = 9800\ \text{J)}$$

MCAT Concept Check 2.3:

Before you move on, assess your understanding of the material with these questions.

1. As the length of an inclined plane increases, what happens to the force required to move an object the same displacement?

_____

_____

2. As the effort decreases in a pulley system, what happens to the effort distance to maintain the same work output?

_____

_____

3. What accounts for the difference between work input and work output in a system that operates at less than 100% efficiency?

_____

_____

4. What does it mean for a device to provide mechanical advantage?

_____

_____

5. Name the six simple machines:
   - _____
   - _____
   - _____
   - _____
   - _____
   - _____

Conclusion

The conceptualization of energy as the capacity to do something or make something happen is a very broad definition. However, such an all-encompassing definition allows us to understand everything from pushing a rock up a hill to melting an ice cube, from stopping a car at an intersection to harnessing the energy of biomolecules in metabolism, to all be forms of energy transfer. Indeed, energy on its own has little significance without considering the *transfer* of energy, either through work or heat. The work–energy theorem is a powerful expression that will guide our approach to many problems in the *Chemical and Physical Foundations of Biological Systems* section. We also covered the application of energy and work with simple machines, such as levers, inclined planes, and pulleys. These devices assist us in accomplishing work by reducing the forces necessary for displacing objects.

Preparing for the MCAT is hard (mental) work, but you are well on your way to achieving success on Test Day. This *MCAT Physics and Math Review* book (and all the materials provided in your Kaplan program) is part of a set of tools—your simple machines, if you will—that will provide you with the mechanical advantage to ease your efforts toward a higher score.

CONCEPT SUMMARY

Energy

- **Energy** is the property of a system that enables it to do something or make something happen, including the capacity to do work. The SI units for all forms of energy are joules (J).
- **Kinetic energy** is energy associated with the movement of objects. It depends on mass and speed squared (not velocity).
- **Potential energy** is energy stored within a system. It exists in gravitational, elastic, electrical, and chemical forms.
  - **Gravitational potential energy** is related to the mass of an object and its height above a zero-point, called a **datum**.
  - **Elastic potential energy** is related to the **spring constant** (a measure of the stiffness of a spring) and the degree of stretch or compression of a spring squared.
  - **Electrical potential energy** exists between charged particles.
  - **Chemical potential energy** is the energy stored in the bonds of compounds.
- The total **mechanical energy** of a system is the sum of its kinetic and potential energies.
- **Conservative forces** are path independent and do not dissipate the mechanical energy of a system.
  - If only conservative forces are acting on an object, the total mechanical energy is conserved.
  - Examples of conservative forces include gravity and electrostatic forces. Elastic forces, such as those created by springs, are nearly conservative.
- **Nonconservative forces** are path dependent and cause dissipation of mechanical energy from a system.
  - While total energy is conserved, some mechanical energy is lost as thermal or chemical energy.
  - Examples of nonconservative forces include friction, air resistance and viscous drag.

Work

- **Work** is a process by which energy is transferred from one system to another.
  - Work may be expressed as the dot product of force and displacement, or the product of force and distance traveled with the cosine of the angle between the two.
  - Work may also be expressed as the area under a **pressure–volume** (**P–V**) **curve**.

- **Power** is the rate at which work is done or energy is transferred. The SI unit for power is the watt (W).
- The **work–energy theorem** states that when net work is done on or by a system, the system's kinetic energy will change by the same amount. In more general applications, the work done on or by a system can be transferred to other forms of energy as well.

Mechanical Advantage

- **Mechanical advantage** is the factor by which a simple machine multiplies the input force to accomplish work.
- The six **simple machines** are the inclined plane, wedge, wheel and axle, lever, pulley, and screw. Simple machines provide the benefit of mechanical advantage.
- Mechanical advantage makes it easier to accomplish a given amount of work because the input force necessary to accomplish the work is reduced; the distance through which the reduced input force must be applied, however, is increased by the same factor (assuming 100% efficiency).
- The **load** is the output force of a simple machine, which acts over a given **load distance** to determine the work output of the simple machine. The **effort** is the input force of a simple machine, which acts over a given **effort distance** to determine the work input of the simple machine.
- **Efficiency** is the ratio of the machine's work output to work input when nonconservative forces are taken into account.

ANSWERS TO CONCEPT CHECKS

2.1

1. Kinetic energy is the energy of motion. It is related to the mass of an object as well as its speed squared.
   Potential energy is energy associated with a given position or intrinsic property of a system; it is stored in gravitational, electrical, elastic, or chemical forms. Gravitational potential energy is directly related to the mass of the object and its height above a reference point.
2.

	Conservative Forces	Nonconservative Forces
What happens to total mechanical energy of the system?	Remains constant	Decreases (energy is dissipated)
Does the path taken matter?	No	Yes; more energy is dissipated with a longer path
What are some examples?	Gravity Electrostatic forces Elastic forces (approximately conservative)	Friction Air resistance Viscous drag

2.2

1. The unit of work is the joule, which is also the unit for energy. Work and energy are related concepts. By performing work, the energy of a system is changed. Work, along with heat, is a form of energy transfer.
2. Three methods for calculating work discussed in this chapter are:
   1. $W = Fd \cos \theta$ (the dot product of the force and displacement vectors)
   2. $W = P\Delta V$ (the area under a pressure–volume curve)
   3. $W_{net} = \Delta K$ (the work–energy theorem)

2.3

1. As the length of an inclined plane increases, the amount of force necessary to perform the same amount of work (moving the object the same displacement) decreases.
2. As the effort (required force) decreases in a pulley system, the effort distance increases to generate the same amount of work.
3. The decrease in work output is due to nonconservative or external forces that generate or dissipate energy.
4. When a device provides mechanical advantage, it decreases the input force required to generate a particular output force. Generally, this is accomplished at the expense of increased distance over which the force must act.
5. The six simple machines are: inclined plane, wedge, wheel and axle, lever, pulley, and screw.

EQUATIONS TO REMEMBER

(2.1) **Kinetic energy:** $K = \frac{1}{2}mv^2$

(2.2) **Gravitational potential energy:** $U = mgh$

(2.3) **Elastic potential energy:** $U = \frac{1}{2}kx^2$

(2.4) **Total mechanical energy:** $E = U + K$

(2.5) **Conservation of mechanical energy:** $\Delta E = \Delta U + \Delta K = 0$

(2.6) **Work done by nonconservative forces:** $W_{\text{nonconservative}} = \Delta E = \Delta U + \Delta K$

(2.7) **Definition of work (mechanical):** $W = \mathbf{F} \cdot \mathbf{d} = Fd\cos\theta$

(2.8) **Definition of work (isobaric gas–piston system):** $W = P\Delta V$

(2.9) **Definition of power:** $P = \frac{W}{t} = \frac{\Delta E}{t}$

(2.10) **Work–Energy theorem:** $W_{\text{net}} = \Delta K = K_{\text{f}} - K_{\text{i}}$

(2.11) **Mechanical advantage:** Mechanical advantage $= \frac{F_{\text{out}}}{F_{\text{in}}}$

(2.12) **Efficiency:** Efficiency $= \frac{W_{\text{out}}}{W_{\text{in}}} = \frac{\text{(load)(load distance)}}{\text{(effort)(effort distance)}}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. A weight lifter lifts a 275 kg barbell from the ground to a height of 2.4 m. How much work has he done in lifting the barbell, and how much work is required to hold the weight at that height?

A. 3234 J and 0 J, respectively
B. 3234 J and 3234 J, respectively
C. 6468 J and 0 J, respectively
D. 6468 J and 6468 J, respectively

2. A tractor pulls a log with a mass of 500 kg along the ground for 100 m. The rope (between the tractor and the log) makes an angle of 30° with the ground and is acted on by a tensile force of 5000 N. How much work does the tractor perform in this scenario? (Note: sin 30° = 0.5, cos 30° = 0.866, tan 30° = 0.577)

A. 250 kJ
B. 289 kJ
C. 433 kJ
D. 500 kJ

3. A 2000 kg experimental car can accelerate from 0 to 30 $\frac{m}{s}$ in 6 s. What is the average power of the engine needed to achieve this acceleration?

A. 150 W
B. 150 kW
C. 900 W
D. 900 kW

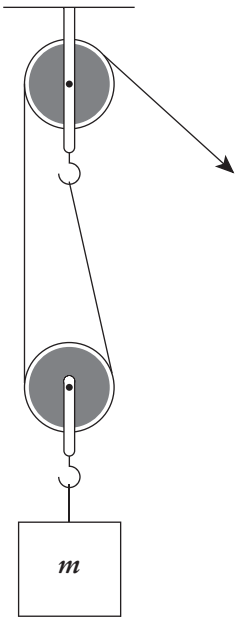
4. A 40 kg block is resting at a height of 5 m off the ground. If the block is released and falls to the ground, which of the following is closest to its total mechanical energy at a height of 2 m, assuming negligible air resistance?

A. 0 J
B. 400 J
C. 800 J
D. 2000 J

5. 5 m^3 of a gas are brought from an initial pressure of 1 kPa to a pressure of 3 kPa through an isochoric process. During this process, the work performed by the gas is:

A. –10 kJ
B. –10 J
C. 0 J
D. +10 kJ

6. In the pulley system shown below, which of the following is closest to the tension force in each rope if the mass of the object is 10 kg and the object is accelerating upwards at 2 $\frac{m}{s^2}$?



A. 50 N
B. 60 N
C. 100 N
D. 120 N

7. Which of the following is a conservative force?

A. Air resistance
B. Friction
C. Gravity
D. Convection

8. During uniform circular motion, which of the following relationships is necessarily true?

A. No work is done.
B. The centripetal force does work.
C. The velocity does work.
D. Potential energy depends on position of the object around the circle.

9. Which of the following best characterizes the work–energy theorem?

A. The work done by any force is proportional only to the magnitude of that force.
B. The total work done on any object is equal to the change in kinetic energy for that object.
C. The work done on an object by any force is proportional to the change in kinetic energy for that object.
D. The work done by an applied force on an object is equal to the change in kinetic energy of that object.

10. A massless spring initially compressed by a displacement of two centimeters is now compressed by four centimeters. How has the potential energy of this system changed?

A. The potential energy has not changed.
B. The potential energy has doubled.
C. The potential energy has increased by two joules.
D. The potential energy has quadrupled.

11. Josh, who has a mass of 80 kg, and Sarah, who has a mass of 50 kg, jump off a 20 m tall building and land on a fire net. The net compresses, and they bounce back up at the same time. Which of the following statements is NOT true?

A. Sarah will bounce higher than Josh.
B. For Josh, the change in speed from the start of the jump to contacting the net is 20 $\frac{m}{s}$.
C. Josh will experience a greater force upon impact than Sarah.
D. The energy in this event is converted from potential to kinetic to elastic to kinetic.

12. A parachutist jumps from a plane. Beginning at the point when she reaches terminal velocity (constant velocity during freefall), which of the following is/are true?

I. The jumper is in translational equilibrium.

II. The jumper is not being acted upon by any forces.

III. There is an equal amount of work being done by gravity and air resistance.

A. I only
B. I and III only
C. II and III only
D. I, II, and III

13. Mechanical advantage and efficiency are both ratios. Which of the following is true regarding the quantities used in these ratios?

A. Mechanical advantage compares values of work; efficiency compares values of power.
B. Mechanical advantage compares values of forces; efficiency compares values of work.
C. Mechanical advantage compares values of power; efficiency compares values of energy.
D. Mechanical advantage compares values of work; efficiency compares values of forces.

14. If the gravitational potential energy of an object has doubled in the absence of nonconservative forces, which of the following must be true, assuming the total mechanical energy of the object is constant?

A. The object has been lifted to twice its initial height.
B. The kinetic energy of the object has been halved.
C. The kinetic energy has decreased by the same quantity as the potential energy has increased.
D. The mass of the object has doubled.

15. A consumer is comparing two new cars. Car A exerts 250 horsepower, while Car B exerts 300 horsepower. The consumer is most concerned about the peak velocity that the car can reach. Which of the following statements would best inform the consumer's decision? (Note: 1 horsepower = 745.7 W)

A. Car A and Car B both have unlimited velocities, ignoring nonconservative forces.
B. Car A will reach its peak velocity more quickly than Car B.
C. Car A will dissipate less energy to the surroundings than Car B.
D. Car A will have a lower peak velocity than Car B.

Explanations to Discrete Practice Questions

1. C

Because the weight of the barbell (force acting downward) is $mg = 275 \text{ kg} \times 10 \frac{\text{m}}{\text{s}^2}$, or about 2750 N, it follows that the weightlifter must exert an equal and opposite force of 2750 N on the barbell. The work done in lifting the barbell is therefore $W = Fd \cos \theta = (2750 \text{ N})(2.4 \text{ m})(\cos 0) \approx 7000$ J. Using the same equation, it follows that the work done to hold the barbell in place is $W = Fd \cos \theta = (2750 \text{ N})(0 \text{ m})(\cos \theta) = 0$ J. Because the barbell is held in place and there is no displacement, the work done is zero. This is closest to **choice (C)**.

2. C

The work done by the tractor can be calculated from the equation $W = Fd \cos \theta = (5000 \text{ N})(100 \text{ m})(\cos 30°) = (5000)(100)(0.866) \approx 5000 \times 80 = 400{,}000 \text{ J} = 400 \text{ kJ}$. This is closest to **choice (C)**.

3. B

The work done by the engine is equal to the change in kinetic energy of the car: $W = \Delta K = \frac{1}{2}m(v_f^2 - v_i^2) = \frac{1}{2}(2000 \text{ kg})\left(900 \frac{\text{m}^2}{\text{s}^2} - 0\right) = 900{,}000 \text{ J}$. The average power therefore is $P = \frac{W}{t} = \frac{900{,}000 \text{ J}}{6 \text{ s}} = 150{,}000 \text{ W} = 150 \text{ kW}$.

4. D

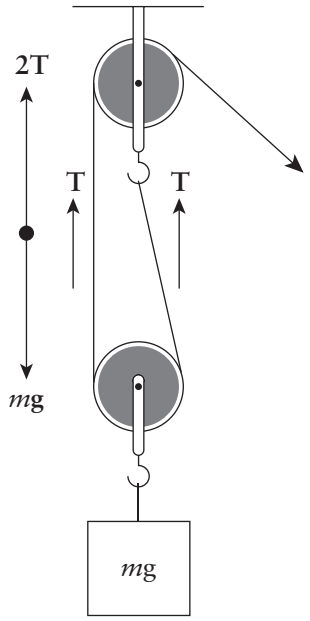
Assuming negligible air resistance, conservation of energy states that the total mechanical energy of the block is constant as it falls. At the starting height of 5 m, the block only has potential energy equal to $U = mgh \approx 40 \text{ kg} \times 10 \frac{\text{m}}{\text{s}^2} \times 5 \text{ m} = 2000$ J. Because the kinetic energy at this point is 0 J, the total mechanical energy is 2000 J at any point during the block's descent.

5. C

An isochoric process, by definition, is one in which the gas system undergoes no change in volume. If the gas neither expands nor is compressed, then no work is performed. Remember that work in a thermodynamic system is the area under a P–V curve; if the change in volume is 0, then the area under the curve is also 0.

6. B

To calculate the tension force in each rope, first draw a free body diagram:



From the force diagram, notice that there are two tension forces pulling the mass up. The net force for this system ($\mathbf{F}_{net}$) is equal to $2\mathbf{T} - m\mathbf{g}$. Now we can use Newton's second law:

$$\begin{aligned} \mathbf{F}_{net} &= m\mathbf{a} \\ 2\mathbf{T} - m\mathbf{g} &= m\mathbf{a} \\ \mathbf{T} = \frac{m(\mathbf{a}+\mathbf{g})}{2} &\approx \frac{(10\text{ kg})\left(2\frac{\text{m}}{\text{s}^2} + 10\frac{\text{m}}{\text{s}^2}\right)}{2} \\ &= 5 \times 12 = 60\text{ N} \end{aligned}$$

7. C

Gravity is a conservative force because it is pathway independent and it does not dissipate mechanical energy. Air resistance and friction—**choices (A)** and **(B)**—are nonconservative forces that dissipate energy thermally. Convection is not a force, but a method of heat transfer, eliminating **choice (D)**.

8. A

In uniform circular motion, the displacement vector and force vector are always perpendicular; therefore, no work is done. Potential energy is constant for an object in uniform circular motion, whether it is the gravitational potential energy of a satellite orbiting the Earth or the electrical potential energy of an electron orbiting the nucleus of an idealized atom. In both cases, potential energy does not change and does not depend on the position of the object around the circle, eliminating **choice (D)**.

9. B

The work–energy theorem relates the total work done on an object by all forces to the change in kinetic energy experienced by the same object. While the work done by a force is indeed proportional to the magnitude of the force, it is also proportional to the displacement of the object, eliminating **choice (A)**. The change in kinetic energy is equal—not proportional—to the total work done on the object; further, it is the net force, not *any* force, that relates to the work done on an object, eliminating **choice (C)**. Finally, the change in kinetic energy of the object is equal to the work done by all of the forces acting on the object combined, not just the applied force, which eliminates **choice (D)**.

10. D

Elastic potential energy, like kinetic energy, is related to the square of another variable, as shown by the equation $U = \frac{1}{2}kx^2$. Increasing the displacement by a factor of 2 increases the potential energy by a factor of $2^2 = 4$.

11. A

Sarah will not bounce higher than Josh. Assuming that mechanical energy is conserved, Sarah and Josh will start with a given amount of potential energy, which is converted into kinetic energy, then elastic potential energy, then kinetic energy again with no loss of energy from the system, eliminating **choice (D)**. By this logic, both individuals should return to the same starting height. Josh starts with $U = mgh \approx 80\text{ kg} \times 10\frac{\text{m}}{\text{s}^2} \times 20\text{ m} = 16{,}000\text{ J}$ of potential energy. At the moment he hits the net, all of this potential energy has been converted into kinetic energy. Therefore,

$$\begin{aligned} K = \frac{1}{2}mv^2 \rightarrow v &= \sqrt{\frac{2K}{m}} \\ &= \sqrt{\frac{2 \times 16{,}000}{80}} = \sqrt{400} = 20\frac{\text{m}}{\text{s}} \end{aligned}$$

eliminating **choice (B)**. Josh will experience a greater force upon impact because the net exerts a force proportional to weight; the higher the weight, the larger the force exerted by the net, eliminating **choice (C)**.

12. B

At terminal velocity, the force of gravity and force of air resistance are equal in magnitude, leading to translational equilibrium. Thus, statement I is true. If these forces have the same magnitude and act over the same displacement, then the work performed is the same as well, making statement III true. Even though the net force is equal to zero, there are still forces acting on the parachutist, making statement II false.

13. B

Mechanical advantage is a ratio of the output force generated given a particular input force. Efficiency is a ratio of the useful work performed by a system compared to the work performed on the system.

14. C

In the absence of nonconservative forces, all changes potential energy must be met by an equal change in kinetic energy. Note that it is the difference in potential energy that is the same as the difference in kinetic energy, not the proportionality, eliminating **choice (B)**. Both **choices (A)** and **(D)** could be true statements but do not necessarily have to be—the object's mass could have been quadrupled while its height was halved.

15. A

Horsepower is a unit of power, as evidenced by the name and the conversion factor given in the question stem. Power is a rate of energy expenditure over time. Given unlimited time, both cars are capable of unlimited increases in (kinetic) energy, meaning that they have unlimited maximum velocities. The fact that Car B has a higher power rating means that it will reach any given velocity faster than Car A, eliminating **choice (B)**. There is not enough information to make any judgments on the efficiency of the cars, eliminating **choice (C)**. While it may take longer for Car A to reach a given velocity, both cars have unlimited maximum velocities according to the information given in the stem, eliminating **choice (D)**.

Concept Summary 100

Introduction

Thermodynamics is the study of the flow of energy in the universe, as that flow relates to work, heat, entropy, and the different forms of energy. Classical thermodynamics concerns itself only with observations that can be made at the macroscopic level, such as measurements of temperature, pressure, volume, and work. Although the MCAT will test entropy from a thermodynamic rather than probabilistic understanding, we will briefly discuss the statistical model of entropy because it clarifies much of the confusion that arises from a characterization of entropy as a measure of "disorder."

This chapter reviews the laws of thermodynamics with a specific focus on the zeroth, first, and second laws. We will examine how the zeroth law leads to the formulation of temperature scales. Thermal expansion will be discussed as an example of the relationship between thermal energy and physical properties like length, volume, and conductivity. We will then take a moment to examine thermodynamic terminology and functions that are also intimately related to the concepts discussed in Chapter 7 of *MCAT General Chemistry Review*. In the context of the first law—the conservation of energy—we will discuss the relationship between internal energy, heat, and work, and characterize specific heat and heat of transformation. We will also review the various processes by which a system goes from one equilibrium state to another and connect work, discussed in Chapter 2 of *MCAT Physics and Math Review*, with heat. Finally, we will investigate the second law of thermodynamics through the concepts of entropy and its measurement. The third law of thermodynamics is not directly tested on the MCAT, so we will only briefly mention it.

3.1 Zeroth Law of Thermodynamics

Key Concept

The zeroth law of thermodynamics states the transitive property in thermal systems: If $a = b$ and $b = c$, then $a = c$.

The **zeroth law of thermodynamics** is based on a simple observation: when one object is in thermal equilibrium with another object, say a cup of warm tea and a metal stirring stick, and the second object is in thermal equilibrium with a third object, such as your hand, then the first and third object are also in thermal equilibrium. As such, when brought into thermal contact, no net heat will flow between these objects. Note that thermal contact does not necessarily imply physical contact, as objects can be in thermal contact across space.

TEMPERATURE

Key Concept

Temperature is a physical property of matter related to the average kinetic energy of the particles. Differences in temperature determine the direction of heat transfer.

The formulation of the zeroth law—that no net heat flows between objects in thermal equilibrium, and the corollary that heat flows between two objects *not* in thermal equilibrium—actually arose from studies of temperature. At any given time, all substances have a particular **temperature**. In everyday language, we use the term temperature to describe qualitatively how hot or cold something is, but in thermodynamics, it has a more precise meaning. At the molecular level, temperature is proportional to the average kinetic energy of the particles that make up the substance. At the macroscopic level, it is the difference in temperature between two objects that determines the direction of heat flow. When possible, heat moves spontaneously from materials that have higher temperatures to materials that have lower temperatures. **Heat** itself refers to the transfer of thermal energy from a hotter object with higher temperature (energy) to a colder object with lower temperature (energy). If no net heat flows between two objects in thermal contact, then we can say that their temperatures are equal and they are in **thermal equilibrium**.

Since the 18th century, scales have been developed to quantify the temperature of matter with thermometers. Some of these systems are still in common use, including the **Fahrenheit** (°**F**), **Celsius** (°**C**), and **Kelvin** (**K**) scales. Fahrenheit and Celsius are the oldest scales still in common use and are relatively convenient because they are based on the phase changes for water, as shown in Table 3.1. In the Celsius scale, 0° and 100° define the freezing and boiling temperatures of water. In the Fahrenheit scale, these phase change temperatures are defined as 32° and 212°.

	°F	°C	K
Absolute Zero	−460	−273	0
Freezing Point of Water	32	0	273
Boiling Point of Water	212	100	373

Table 3.1. Relevant Points in the Three Major Temperature Scales

The Kelvin scale is most commonly used for scientific measurements and is one of the seven SI base units. It defines as the zero reference point **absolute zero**, the theoretical temperature at which there is no thermal energy, and sets the freezing point of water as 273.15 K. The **third law of thermodynamics** states that the entropy of a perfectly-organized crystal at absolute zero is zero. Note that there are no negative temperatures on the Kelvin scale because it starts from absolute zero. Although the Kelvin and Celsius scales have different zero reference points, the size of their units is the same. That is to say, a change of one degree Celsius equals a change of one unit kelvin. Because there are 180 degrees between water's phase changes on the Fahrenheit scale, rather than 100 degrees as on both the Celsius and the Kelvin scales, the size of the Fahrenheit unit is smaller. The following formulas can be used to convert from one scale to another:

$$F = \frac{9}{5}C + 32$$
$$K = C + 273$$

Equation 3.1

where F, C, and K are the temperatures in Fahrenheit, Celsius, and Kelvin, respectively.

Example: If a meteorologist says that the temperature will reach a high of 86°F today, what will be the high temperature in °C and in K?

Solution: To convert from Fahrenheit to Celsius, use:

$$F = \frac{9}{5}C + 32 \rightarrow C = \frac{5}{9}(F - 32)$$
$$C = \frac{5}{9}(86 - 32) = \frac{5}{9}(54) = 30°C$$

Now convert from Celsius to Kelvin:

$$K = C + 273 = 30 + 273 = 303\ K$$

MCAT Expertise

The only time Fahrenheit is used routinely on the MCAT is for body temperature, which is 98.6°F or 37°C. In the rare occasion that it is used for a quantitative analysis question, conversions will be given.

THERMAL EXPANSION

It has long been noted that some physical properties of matter change when the matter gets hotter or colder. Length, volume, solubility, and even the conductivity of matter change as a function of temperature. The relationship between temperature and a physical property of some matter was used to develop the temperature scales with which we are familiar today. For example, Daniel Fahrenheit developed the temperature scale that bears his name by placing a thermometer filled with mercury into a bath of ice, water, and ammonium chloride. The cold temperature caused the mercury to contract, and when the level in the glass tube stabilized at a lower level, he marked this as the zero reference on the scale. He then placed the same mercury thermometer in a mixture of ice and water (that is, at the freezing point for water). The slightly

warmer temperature of this mixture caused the mercury to rise in the glass column, and when it stabilized at this higher level, Fahrenheit assigned it a value of 32°. When he stuck the thermometer under his (or someone else's) tongue, he marked the even higher mercury level as 100° (not 98.6°). The details of how and why Fahrenheit came to choose these numbers (and the history of their adjustment since Fahrenheit first developed the scale) are beyond the scope of this discussion; rather, what is important to note is that a change in some physical property of one kind of matter—in this case, the height of a column of mercury—can be correlated to certain temperature markers, such as the phase changes for water. Once the scale has been set in reference to the decided-upon temperature markers, then the thermometer can be used to take the temperature of any other matter, in accordance with the zeroth law.

Real World

It is because of thermal expansion that bridges and sidewalks have gaps between their segments; they allow for thermal expansion without damaging integrity.

Mnemonic

When the temperature of an object changes, its length changes **a lot** ($\alpha L \Delta T$).

Because the property of **thermal expansion** was integral to the development of thermometers, let's look a little more closely at this phenomenon. A change in the temperature of most solids results in a change in their length. Rising temperatures cause an increase in length, and falling temperatures cause a decrease in length. The amount of length change is proportional to the original length of the solid and the increase in temperature according to the equation

$$\Delta L = \alpha L \Delta T$$

Equation 3.2

where ΔL is the change in length, α is the coefficient of linear expansion, L is the original length, and ΔT is the change in temperature. The **coefficient of linear expansion** is a constant that characterizes how a specific material's length changes as the temperature changes. This usually has units of K^{-1}, although it may sometimes be quoted as $°C^{-1}$. This difference is inconsequential because the unit size for the Kelvin and Celsius scales is the same.

Example: A metal rod of length 2 m has a coefficient of linear expansion of 10^{-6} K^{-1}. It is cooled from 1080°C to 80°C. What is the final length of the rod?

Solution: By using the information given in the problem, we can substitute directly into the thermal expansion formula:

$$\Delta L = \alpha L \Delta T = (10^{-6}\ K)(2\ m)(80\ K - 1080\ K) = -2 \times 10^{-3}\ m$$

The negative sign represents a decrease in length. The original length was 2 m; therefore, the final length is $2 - (2 \times 10^{-3}) = 1.998$ m.

Liquids also experience thermal expansion, but the only meaningful parameter of expansion is volume expansion. The formula for volumetric thermal expansion is applicable to both liquids and solids:

$$\Delta V = \beta V \Delta T$$

Equation 3.3

where ΔV is the change in volume, β is the coefficient of volumetric expansion, V is the original volume, and ΔT is the change in temperature. The **coefficient of volumetric expansion** is a constant that characterizes how a specific material's volume changes as the temperature changes. Its value is equal to three times the coefficient of linear expansion for the same material ($\beta = 3\alpha$).

Example: Suppose that a thermometer with 1 mL of mercury is taken from a freezer with a temperature of –25°C and placed near an oven at 225°C. If the coefficient of volume expansion of mercury is $1.8 \times 10^{-4}\ K^{-1}$, by how much will the liquid expand?

Solution: Use the information given to plug into the volumetric expansion formula:

$$\Delta V = \beta V \Delta T = (1.8 \times 10^{-4}\ K^{-1})(1\ mL)(225°C - (-25°C))$$
$$= (1.8 \times 10^{-4})(250) = 450 \times 10^{-4}\ mL = 0.045\ mL.$$

MCAT Concept Check 3.1:

Before you move on, assess your understanding of the material with these questions.

1. What does the zeroth law of thermodynamics say?

_____

_____

_____

2. What is the maximum distance that two objects can be from one another and still adhere to the zeroth law of thermodynamics?

_____

3. How do the initial length of an object and the amount it expands for a given temperature change relate to one another?

_____

_____

4. True or False: The Kelvin scale is the most accurate measurement method for temperature because it is based on absolute zero.

3.2 Systems

Physicists and chemists tend to classify the world on the basis of observable phenomena and interactions between objects. Before moving on, we need to become familiar with some of the jargon that these fields have in common—specifically, thermodynamic systems and state functions. Note that the same jargon is discussed in Chapter 7 of *MCAT General Chemistry Review*.

SYSTEM TYPES

A **system** is the portion of the universe that we are interested in observing or manipulating. The rest of the universe is considered the **surroundings**.

Isolated Systems

Isolated systems are not capable of exchanging energy or matter with their surroundings. As a result, the total change in internal energy must be zero. Isolated systems are very rare, although they can be approximated. A bomb calorimeter attempts to insulate a reaction from the surroundings to prevent energy transfer, and the entire universe can be considered an isolated system because there are no surroundings.

Closed Systems

Closed systems are capable of exchanging energy, but not matter, with the surroundings. The classic experiments involving gases in vessels with movable pistons are examples of closed systems. For thermodynamic purposes, most of what will be encountered on Test Day will be a closed system or will approximate a closed system.

Open Systems

Open systems can exchange both matter and energy with the environment. In an open system, not only does the matter carry energy, but more may be transferred in the form of heat or work. A boiling pot of water, human beings, and uncontained combustion reactions are all examples of open systems.

STATE FUNCTIONS

State functions are thermodynamic properties that are a function of only the current equilibrium state of a system. In other words, state functions are defined by the fact that they are independent of the path taken to get to a particular equilibrium state. The state functions include pressure (P), density (ρ), temperature (T), volume (V), enthalpy (H), internal energy (U), Gibbs free energy (G), and entropy (S). On the other hand, **process functions**, such as work and heat, describe the path taken to get to from one state to another.

MCAT Concept Check 3.2:

Before you move on, assess your understanding of the material with these questions.

1. Which of the following thermodynamic systems transfer matter? Transfer energy?

System Type	Transfers Matter	Transfers Energy
Closed		
Isolated		
Open		

2. What is the difference between a state function and a process function?
   - State function:

     _____
   - Process function:

     _____

3. List at least five common state functions:
   - _____
   - _____
   - _____
   - _____
   - _____

3.3 First Law of Thermodynamics ★★★★

We have already encountered the first law of thermodynamics in our discussion of the conservation of mechanical energy in Chapter 2 of *MCAT Physics and Math Review*. Remember that in the absence of nonconservative forces, the sum of kinetic and potential energies is constant in a system. Now, in our present discussion of thermodynamics, we will look more closely at the relationship between internal energy, heat, and work. Essentially, the **first law of thermodynamics** states that the change in the total internal energy of a system is equal to the amount of energy transferred in the form of **heat** to the system, minus the amount of energy transferred from the system in the form of **work**. The internal energy of a system can

Key Concept

The first law of thermodynamics tells us that an increase in the total internal energy of a system is caused by transferring heat into the system or performing work on the system. The total internal energy of a system will decrease when heat is lost from the system or work is performed by the system.

be increased by adding heat, doing work on the system, or some combination of both processes. The change in internal energy is calculated from the equation

$$\Delta U = Q - W$$

Equation 3.4

where ΔU is the change in the system's internal energy, Q is the energy transferred into the system as heat, and W is the work done by the system. To use this equation properly, one must carefully apply the following sign convention shown in Table 3.2.

Variable	Positive Value	Negative Value
Change in Internal Energy (ΔU)	Increasing temperature	Decreasing temperature
Heat (Q)	Heat flows into system	Heat flows out of system
Work (W)	Work is done by the system (expansion)	Work is done on the system (compression)

Table 3.2. Sign Convention for the First Law of Thermodynamics

The first law is really just a particular iteration of the more universal physical law of energy conservation: energy can be neither created nor destroyed; it can only be changed from one form to another. Because the first law accounts for all work and all heat processes impacting the system, the presence of nonconservative forces poses no problem because the energy transfer associated with friction, air resistance, or viscous drag will be accounted for in the first law equation. For example, when a car "burns rubber," all the smoke and noise coming from the back tires is a clear indication that mechanical energy is not being conserved. However, if we include the energy transfers associated with the frictional forces in our consideration of the change in internal energy of the system, then we can confidently say that no energy has been lost at all: there may be a "loss" of energy from the car as a result of the friction, but that precise amount of energy can be "found" elsewhere—as thermal energy in the atoms and molecules of the surrounding road and air.

HEAT

Key Concept

Heat is the process of energy transfer between two objects at different temperatures and will continue until the two objects come into thermal equilibrium at the same temperature.

In Chapter 2 of *MCAT Physics and Math Review*, we defined work as the process by which energy is transferred as the result of force being applied through some distance. We noted that work and heat are the only two processes by which energy can be transferred from one object to another. As discussed earlier in this chapter, the zeroth law of thermodynamics says that objects in thermal contact are in thermal equilibrium when their temperatures are the same. The corollary of this is the **second law of thermodynamics**: objects in thermal contact and not in thermal equilibrium will exchange heat energy such that the object with a higher temperature will give off heat energy to the object with a lower temperature until both objects

have the same temperature at thermal equilibrium. **Heat**, then, is defined as the process by which a quantity of energy is transferred between two objects as a result of a difference in temperature. As we will discuss further in our examination of the second law, heat can never spontaneously transfer energy from a cooler object to a warmer one without work being done on the system.

The SI unit for heat is the joule (J), which should not be surprising because it is based on energy. Heat can also be measured in the units of calorie (cal), nutritional Calorie (Cal), or the British thermal unit (BTU). The nutritional Calorie ("big C") is not the same thing as the calorie ("little c"); one Calorie is equal to 1000 calories or 1 kcal.

The conversion factors between the units of heat are as follows:

$$1 \text{ Cal} \equiv 10^3 \text{ cal} = 4184 \text{ J} = 3.97 \text{ BTU}$$

Heat Transfer

For energy to be transferred between objects, they must be in thermal contact with each other. This does not necessarily mean that the objects are touching. Like force, energy can travel tremendous distances and does not require a medium to pass through. There are three means by which heat can transfer energy: conduction, convection, and radiation.

Conduction is the direct transfer of energy from molecule to molecule through molecular collisions. As this definition would suggest, there must be direct physical contact between the objects. At the atomic level, the particles of the hotter matter transfer some of their kinetic energy to the particles of the cooler matter through collisions between the particles of the two materials. Metals are described as the best heat conductors because metallic bonds contain a density of atoms embedded in a sea of electrons, which facilitate rapid energy transfer. Gases tend to be the poorest heat conductors because there is so much space between individual molecules that energy-transferring collisions occur relatively infrequently. An example of heat transfer through conduction is the heat that is rapidly, and painfully, conducted to your fingers when you touch a hot stove.

Convection is the transfer of heat by the physical motion of a fluid over a material. Because convection involves flow, only liquids and gases can transfer heat by this means. In convection, if the fluid has a higher temperature, it will transfer energy to the material. Most restaurants and some home kitchens have convection ovens, which use fans to circulate hot air inside the oven. Because the heat is being transferred to the food by both convection and radiation rather than only by radiation, convection ovens cook more rapidly than radiation-only

Key Concept

One calorie (little c) is the amount of heat required to raise 1 g of water one degree Celsius. One Calorie (big C) is the amount of heat required to raise 1 kg of water 1 degree Celsius, equal to 1000 calories.

ovens. Convection may also be used to wick heat energy away from a hot object. In laboratory experiments, for example, a running cold water bath may be used to rapidly cool a reaction.

Radiation is the transfer of energy by electromagnetic waves. Unlike conduction and convection, radiation can transfer energy through a vacuum. Radiation is the method by which the Sun is able to warm the Earth. Most home kitchens have radiant ovens, which use either electrical coils or gas flames to heat the insulated metal box that forms the body of the oven. The hot metal box then radiates the energy through the open space of the oven, where it is absorbed by whatever food is placed inside.

Specific Heat

When heat energy is added to or removed from a system, the temperature of that system will change in proportion to the amount of heat transfer, unless the system is undergoing a phase change during which the temperature is constant. This relationship between heat and temperature for a substance is called the specific heat. The **specific heat** (c) of a substance is defined as the amount of heat energy required to raise one gram of a substance by one degree Celsius or one unit kelvin. For example, the specific heat of liquid water is one calorie per gram per unit kelvin $\left(1\,\frac{\text{cal}}{\text{g}\cdot\text{K}}\right)$. Equivalently, this can be expressed as $4.184\,\frac{\text{J}}{\text{g}\cdot\text{K}}$. The specific heat for a substance changes according to its phase. The MCAT will generally provide specific heat values as necessary, although you are expected to know the specific heat of water in calories. The equation that relates the heat gained or lost by an object and the change in temperature of that object is

$$q = mc\Delta T$$

Equation 3.5

where m is the mass, c is the specific heat of the substance, and ΔT is the change in temperature (in Celsius or kelvins). Because the unit size for the Celsius and Kelvin scales is the same, the change in temperature will be the same for temperatures measured in Celsius or kelvins.

Heat of Transformation

When a substance is undergoing a phase change, such as from solid to liquid or liquid to gas, the heat that is added or removed from the system does not result in a change in temperature. In other words, phase changes occur at a constant temperature, and the temperature will not begin to change until all of the substance has been converted from one phase into the other. For example, water melts at 0°C. No matter how much heat is added to a mass of ice at 0°C, the temperature of the equilibrated system will not rise until all the ice has been melted into liquid water.

MCAT Expertise

The specific heat of water (in calories) is a constant you are expected to know for Test Day. Its value is $1\,\frac{\text{cal}}{\text{g}\cdot\text{K}}$.

Mnemonic

The equation for heat transfer, given a specific heat, is the same as the test you're studying for! $q = mc\Delta T$ looks a lot like "q equals MCAT."

We've determined that adding heat raises the temperature of a system because the particles in that system now have a greater average kinetic energy, and it's true that molecules have greater degrees of freedom of movement in the liquid state than in the solid state (and even more so in the gas state). However, phase changes are related to changes in potential energy, not kinetic energy. The molecules of water in ice, for example, aren't truly frozen in place and unable to move. The molecules rotate, vibrate, and wiggle around. The bonds within each molecule are also free to bend and stretch. Of course, the molecules are held in relatively stable positions by the hydrogen bonds that form between them, but they still have a fairly significant amount of kinetic energy. The potential energy, however, is quite low because of the stability provided by the relative closeness of one molecule to another and by the hydrogen bonds.

Now, think about what happens when one adds heat to ice that is at 0°C. The heat energy causes the water molecules to begin to move away from each other by breaking free of the hydrogen bonds between them. Because the water molecules are being held less rigidly in place, they now have greater degrees of freedom of movement and their average potential energy increases. In statistical mechanics, one would say that this increased freedom of movement permits a greater number of **microstates** for the water molecules. For example, instead of only being able to move up and down or sway side-to-side, a water molecule may now have more freedom of movement and be able to rock forward and back. In gaining additional directions and forms of motion, however, the amount of up-and-down or side-to-side motion must decrease, thus keeping the average kinetic energy of liquid water at 0°C the same as solid water at 0°C. In summary, while liquid water may have a greater number of microstates due to increased freedom of movement, its average kinetic energy is the same as solid water at the same temperature.

When heat energy is added to or removed from a system that is experiencing a phase change, the amount of heat that is added or removed cannot be calculated with the equation $q = mc\Delta T$ because there is no temperature change during a phase change. Instead, the following equation is used:

$$q = mL$$

Equation 3.6

where q is the amount of heat gained or lost from the material, m is the mass of the substance, and L is the **heat of transformation** or **latent heat** of the substance.

The phase change from liquid to solid (**freezing** or **solidification**) or solid to liquid (**melting** or **fusion**) occurs at the **melting point**. The corresponding heat of transformation is called the **heat of fusion**. The phase change from liquid to gas (**boiling**, **evaporation**, or **vaporization**) or gas to liquid (**condensation**) occurs

Bridge

It is important to know the common terms used for phase changes:

- Solid to liquid: fusion or melting
- Liquid to solid: freezing or solidification
- Liquid to gas: boiling, evaporation, or vaporization
- Gas to liquid: condensation
- Solid to gas: sublimation
- Gas to solid: deposition

These phase changes are discussed in Chapter 7 of *MCAT General Chemistry Review*.

Real World

It is because of the heat of transformation that sweating is such an efficient cooling mechanism. When sweat evaporates, the heat of vaporization is absorbed from the surface of the body. This is also why a hot day seems so much more intense when it is very humid out. The sweat is less likely to evaporate due to the dampness of the environment, so less heat can be lost from the surface of the skin through sweating.

at the **boiling point**. The corresponding heat of transformation is called the **heat of vaporization**. The relevant heats of fusion and vaporization will be provided on Test Day.

Example: Silver has a melting point of 962°C and a heat of fusion of approximately $1.05 \times 10^5 \frac{\text{J}}{\text{kg}}$. The specific heat of silver is $233 \frac{\text{J}}{\text{kg} \cdot \text{K}}$. Approximately how much heat is required to completely melt a 1 kg silver chain with an initial temperature of 20°C?

Solution: Before melting the chain, we must first heat the chain to the melting point. To figure out how much heat is required, we use this formula:

$$\begin{aligned} q &= mc\Delta T \\ &= (1\text{ kg})\left(233 \frac{\text{J}}{\text{kg} \cdot \text{K}}\right)(942\text{ K}) \approx 200 \times 975 \\ &= 1.95 \times 10^5\text{ J (actual } = 2.19 \times 10^5\text{ J)} \end{aligned}$$

This tells us we have to add 219 kJ of heat to the chain just to get its temperature to the melting point. The chain is still in the solid phase. To melt it, we must continue to add heat in accordance with this formula:

$$\begin{aligned} q &= mL \\ &= (1\text{ kg})\left(1.05 \times 10^5 \frac{\text{J}}{\text{kg}}\right) = 1.05 \times 10^5\text{ J} \end{aligned}$$

The total heat needed to melt the solid silver chain is 219 kJ + 105 kJ = 324 kJ.

THERMODYNAMIC PROCESSES

In the last chapter, we gave significant consideration to work as a change of energy in a system, both as a function of force and displacement and as a function of volume and pressure. We will briefly review the latter and its relationship to heat transfer within a system. Keep in mind that work accomplished by a change in displacement is not likely to be motivated by heat transfer, and any heat transfer that does occur is most likely a result of friction dissipating mechanical energy from the system.

During any thermodynamic process, a system goes from some initial equilibrium state with an initial pressure, temperature, and volume to some other equilibrium state, which may be at a different final pressure, temperature, or volume. These thermodynamic processes can be represented in graphical form with volume on the *x*-axis and pressure (or temperature) on the *y*-axis.

Process	First law of thermodynamics reduces to:
Isothermal ($\Delta U = 0$)	$Q = W$
Adiabatic ($Q = 0$)	$\Delta U = -W$
Isobaric (constant pressure)	(No special form)
Isovolumetric (isochoric) ($W = 0$)	$\Delta U = Q$

Table 3.3. Special Types of Thermodynamic Processes

The MCAT focuses on three particular thermodynamic processes as special cases of the first law, as shown in Table 3.3. In each of these cases, some physical property is held constant during the process. These processes are **isothermal** (constant temperature, and therefore no change in internal energy), **adiabatic** (no heat exchange), and **isovolumetric** (no change in volume, and therefore no work accomplished; also called **isochoric**). **Isobaric** processes are those that occur at a constant pressure. Figure 3.1 shows the different types of thermodynamic behaviors for a gas.

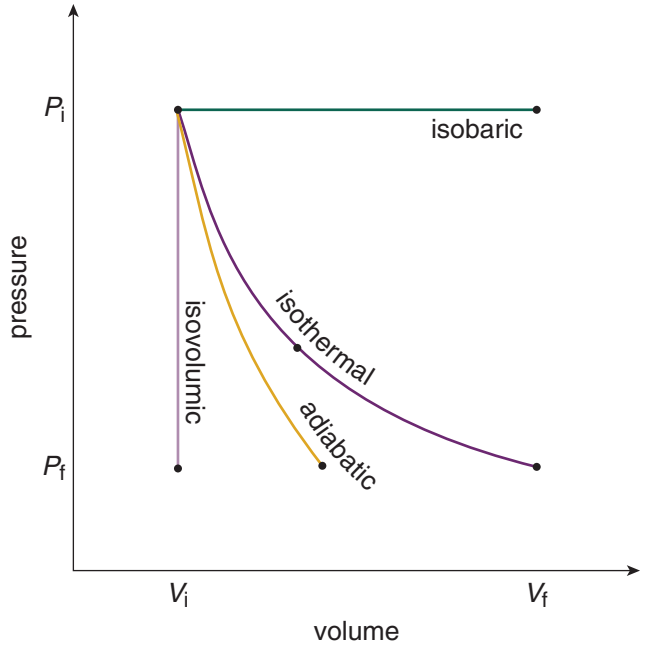

Figure 3.1. Thermodynamic Behaviors of Gases

Figure 3.2 shows a closed-loop thermodynamic process. Because the work on a P–V graph is simply the area under the curve, the work done in this closed-loop process is the area inside the loop.

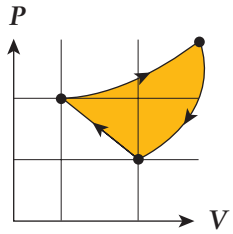

Figure 3.2. A Closed-Loop Process
The work is the area inside the loop.

Example: A gas in a cylinder is kept at a constant pressure of 3.5×10^5 Pa while 300 kJ of heat are added to it, causing the gas to expand from 0.9 m^3 to 1.5 m^3. Find the work done by the gas and the change in internal energy of the gas.

Solution: The pressure is held constant through the entire process so the work can be found using the equation:

$$W = P\Delta V$$
$$= (3.5 \times 10^5 \text{ Pa})(1.5 \text{ m}^3 - 0.9 \text{ m}^3) = 2.1 \times 10^5 \text{ J}$$

The change in internal energy can be found from the first law of thermodynamics:

$$\Delta U = Q - W = 3 \times 10^5 \text{ J} - 2.1 \times 10^5 \text{ J} = 0.9 \times 10^5 \text{ J} = 90 \text{ kJ}$$

MCAT Concept Check 3.3:
Before you move on, assess your understanding of the material with these questions.

1. Describe the relationship between internal energy, work, and heat in words.

_____

_____

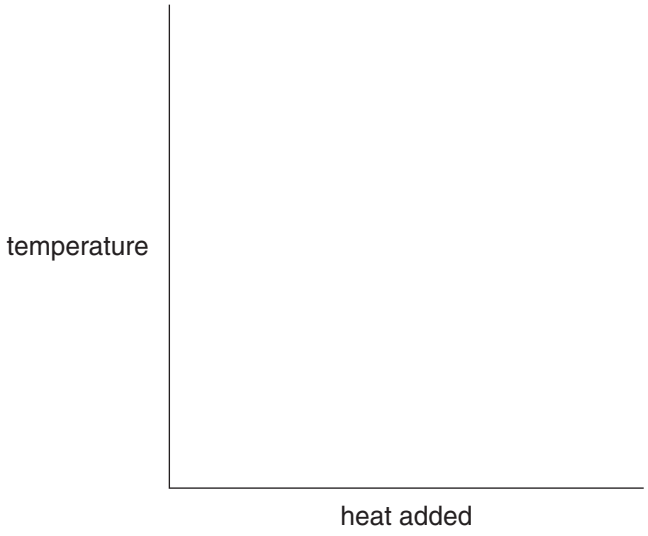
2. Define the following forms of heat transfer:
   - Conduction:

     _____
   - Convection:

     _____
   - Radiation:

     _____

3. Draw a representative graph of the temperature of a solid object as it is heated and goes through two phase changes to become a gas.



4. How is work calculated in P–V diagrams?

_____

_____

3.4 Second Law of Thermodynamics and Entropy ★★

The **second law of thermodynamics** states that objects in thermal contact and not in thermal equilibrium will exchange heat energy such that the object with a higher temperature will give off heat energy to the object with a lower temperature until both objects have the same temperature at thermal equilibrium. As such, energy is constantly being dispersed.

ENERGY DISPERSION

Consider each of the following scenarios: hot tea cooling down, a frozen drink melting, iron rusting, buildings crumbling, balloons deflating, and living things dying and decaying. These scenarios share a common denominator. In each of them, energy of some form is going from being localized or concentrated to being spread out or dispersed. The thermal energy in the hot tea is spreading out to the cooler air that surrounds it. The thermal energy in the warmer air is spreading out to the cooler frozen drink. The chemical energy in the bonds of elemental

iron and oxygen is released and dispersed as a result of the formation of the more stable, lower-energy bonds of iron oxide (rust). The potential energy of the building is released and dispersed in the form of light, sound, and heat as the building crumbles and falls. The energy of the pressurized air is released to the surrounding atmosphere as the balloon deflates. The chemical energy of all the molecules and atoms in living flesh is released into the environment during the process of death and decay.

ENTROPY

The **second law of thermodynamics** states that energy spontaneously disperses from being localized to becoming spread out if it is not hindered from doing so. Pay attention to this: *the usual way of thinking about entropy as "disorder" must not be taken too literally, a trap that many students fall into. Be very careful in thinking about entropy as disorder*. The old analogy between a messy (disordered) room and entropy is deficient and may not only hinder understanding but actually increase confusion.

Entropy is the measure of the spontaneous dispersal of energy at a specific temperature: *how much* energy is spread out, or *how widely* spread out energy becomes in a process. In the discussion of microstates earlier, we considered that when ice melts, the freedom of movement of the water molecules increases. If the water remains at the melting point, it will have the same average kinetic energy as molecules of ice; the difference between the two is the number of available microstates. That is, while both water and ice at 0°C have the same kinetic energy, the energy is dispersed over a larger number of microstates in liquid water. Liquid water therefore has higher entropy and, by extension, it is indeed less organized than ice. The equation for calculating the change in entropy is:

$$\Delta S = \frac{Q_{rev}}{T}$$

Equation 3.7

where ΔS is the change in entropy, Q_{rev} is the heat that is gained or lost in a reversible process, and T is the temperature in kelvin. The units of entropy are usually $\frac{J}{mol \cdot K}$. When energy is distributed into a system at a given temperature, its entropy increases. When energy is distributed out of a system at a given temperature, its entropy decreases.

Example: If, in a reversible process, 6.66×10^4 J of heat is used to change a 200 g block of ice to water at a temperature of 273 K, what is the change in the entropy of the system? (Note: The heat of fusion of ice = 333 $\frac{\text{J}}{\text{g}}$.)

Solution: We know that during a phase change, the temperature is constant; in this case, 273 K. From the information given,

$$\Delta S = \frac{Q_{\text{rev}}}{T} = \frac{6.66 \times 10^4 \text{ J}}{273 \text{ K}} = 244 \frac{\text{J}}{\text{K}}$$

The amount of heat was exactly enough to completely melt the block of ice without changing the temperature of the resulting liquid water; therefore, T is constant.

Notice that the second law states that energy will spontaneously disperse; it does not say that energy can never be localized or concentrated. However, the concentration of energy will not happen spontaneously in a closed system. Work usually must be done to concentrate energy. For example, refrigerators work against the direction of spontaneous heat flow (that is, they counteract the flow of heat from the "warm" exterior of the refrigerator to the "cool" interior), thereby "concentrating" energy outside of the system in the surroundings. As a result, refrigerators consume a lot of energy to accomplish this movement of energy against the temperature gradient.

The second law has been described as *time's arrow* because there is a unidirectional limitation on the movement of energy by which we recognize *before and after* or *new and old*. For example, you would instantly recognize whether a video recording of an explosion was running forward or backward. Another way of understanding this is to say that energy in a closed system will spontaneously spread out and entropy will increase if it is not hindered from doing so. Remember that a system can be variably defined to include the entire universe; in fact, the second law ultimately claims that the entropy of the universe is increasing.

$$\Delta S_{\text{universe}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} > 0$$

Equation 3.8

When describing processes, physicists often use terms such as natural, unnatural, reversible, or irreversible. These terms confuse students but needlessly so because these terms are descriptive of observable phenomena. For example, we expect that when a hot object is brought into thermal contact with a cold object, the hot object will transfer heat energy to the cold object until both are in thermal equilibrium (that is, at the same temperature). This is a **natural process** and also one that we would describe as **irreversible**: we are not surprised that the two objects eventually reach a

Key Concept

The universe is a closed, expanding system, so you know that the entropy of the universe is always increasing. The more space that appears with the expansion of the universe, the more space there is for the entire universe's energy to be distributed and the total entropy of the universe to increase irreversibly.

common temperature, but we would be shocked if all of a sudden the hot object became hotter and the cold object became colder. This would be an **unnatural process**.

To define a **reversible reaction**, let's consider a system of ice and liquid water in equilibrium at 0°C. If we place this mixture of ice and liquid water into a thermostat (device for regulating temperature) that is also at 0°C and allow infinitesimal amounts of heat to be absorbed by the ice from the thermostat so that the ice melts to liquid water at 0°C and the thermostat remains at 0°C, then the increase in the entropy of the system (the water) will be exactly equal to the entropy decrease of the surroundings (the thermostat). The net change in the entropy of the system and its surroundings is zero. Under these conditions, the process is reversible. The key to a reversible reaction is making sure that the process goes so slowly—requiring an infinite amount of time—that the system is always in equilibrium and no energy is lost or dissipated. To be frank, no real processes are reversible; we can only approximate a reversible process. Note how physicists define reversible processes: These are processes that can spontaneously reverse course. For example, while water can be put through cycles of freezing and melting innumerable times, ice melting on the warm countertop would not be expected to suddenly freeze if it remains in the warm environment. The liquid water will need to be placed in an environment that is cold enough to cause the water to freeze, and once frozen in the cold environment, the ice would not be expected to begin melting spontaneously. The freezing and melting of water in real life are therefore irreversible processes in *physics* while still being *chemically* reversible.

MCAT Concept Check 3.4:

Before you move on, assess your understanding of the material with these questions.

1. Describe entropy on a macroscopic level and in statistical terms.
   - Macroscopic:

     _____

     _____
   - Statistical:

     _____

     _____

2. What is the relationship between the entropy of a system and its surroundings for any thermodynamic process?

   _____

   _____

Conclusion

This chapter reviewed the zeroth law of thermodynamics, which reflects the observation that objects at the same temperature are in thermal equilibrium and the net heat exchanged between them is zero. We may consider the zeroth law to be *ex post facto* because it provides the thermodynamic explanation for the function of thermometers and temperature scales, which had been developed many years prior to the law's formulation. We then took some time to define basic thermodynamic terms for systems and state functions. Examination of the first law of thermodynamics revealed that the energy of a closed system (up to and including the universe) is constant, such that the total internal energy of a system (the sum of all its potential and motional energies) equals the heat gained by the system minus the work done by the system. Finally, we carefully investigated the second law of thermodynamics and the concept of entropy. We understand entropy as a measure not only of "disorder" but of the degree to which energy is spread out through a system, up to and including the universe. We now understand that the constant energy of the universe is progressively and irreversibly spreading out and will continue to spread out until there is an even distribution of energy throughout the universe. Many of these concepts will make a reappearance throughout our discussions of general chemistry, and will certainly be seen on the MCAT. In the next chapter, we'll investigate fluids, the final mechanical concept for Test Day.

CONCEPT SUMMARY

Zeroth Law of Thermodynamics

- The **zeroth law of thermodynamics** states that objects are in thermal equilibrium when they are at the same temperature.
- Objects in thermal equilibrium experience no net exchange of heat energy.
- **Temperature** is a qualitative measure of how hot or cold an object is; quantitatively, it is related to the average kinetic energy of the particles that make up a substance.
- **Thermal expansion** describes how a substance changes in length or volume as a function of the change in temperature.

Systems

- A thermodynamic **system** is the portion of the universe that we are interested in observing, whereas the **surroundings** include everything that is not part of the system.
  - **Isolated systems** do not exchange matter or energy with the surroundings.
  - **Closed systems** exchange energy but not matter with their surroundings.
  - **Open systems** exchange both energy and matter with their surroundings.
- **State functions** are pathway independent and are not themselves defined by a process. Pressure, density, temperature, volume, enthalpy, internal energy, Gibbs free energy, and entropy are all state functions.
- **Process functions** describe the pathway from one equilibrium state to another. Work and heat are process functions.

First Law of Thermodynamics

- The **first law of thermodynamics** is a statement of conservation of energy: the total energy in the universe can never decrease or increase.
- For a closed system, the total internal energy is equal to the heat flow into the system minus the work done by the system.
- **Heat** is the process of energy transfer between two objects at different temperatures that occurs until the two objects come into thermal equilibrium (reach the same temperature).
  - **Specific heat** is the amount of energy necessary to raise one gram of a substance by one degree Celsius or one kelvin.
  - The specific heat of water is $1 \frac{\text{cal}}{\text{g} \cdot \text{K}}$.
  - During a phase change, heat energy causes changes in the particles' potential energy and energy distribution (entropy), but not kinetic energy. Therefore, there is no change in temperature. This is the **heat of transformation**.

- There are four special types of thermodynamic systems in which a given variable is held constant:
  - For **isothermal processes**, the temperature is constant, and the change in internal energy is therefore 0.
  - For **adiabatic processes**, no heat is exchanged.
  - For **isobaric processes**, the pressure is held constant.
  - For **isovolumetric** (**isochoric**) **processes**, the volume is held constant and the work done by or on the system is 0.

Second Law of Thermodynamics and Entropy

- The **second law of thermodynamics** states that in a closed system (up to and including the entire universe), energy will spontaneously and irreversibly go from being localized to being spread out (dispersed).
- **Entropy** is a measure of how much energy has spread out or how spread out energy has become.
- On a statistical level, as the number of available **microstates** increases, the potential energy of a molecule is distributed over that larger number of microstates, increasing entropy.
- Every **natural process** is ultimately **irreversible**; under highly controlled conditions, certain equilibrium processes such as phase changes can be treated as essentially **reversible**.

ANSWERS TO CONCEPT CHECKS

3.1

1. The zeroth law of thermodynamics states that when two objects are both in thermal equilibrium with a third object, they are in thermal equilibrium with each other. By extension, no heat flows between two objects in thermal equilibrium.
2. While there may be a distance at which thermal equilibrium is impractical, there is no theoretical maximum distance. As long as two objects are in thermal contact and at the same temperature, they are in thermal equilibrium.
3. Expansion is a result of an increase in dimension at all points along an object. If an object is initially longer, it will experience a greater expansion. This is also represented in the formula for thermal expansion because there is a direct relationship between length change and the initial length of an object.
4. False. As we will discuss in Chapter 11 of *MCAT Physics and Math Review*, accuracy is related to an instrument, rather than the scale. In addition, Kelvin uses the same scale as Celsius, so there are no practical differences in terms of accuracy.

3.2

1.

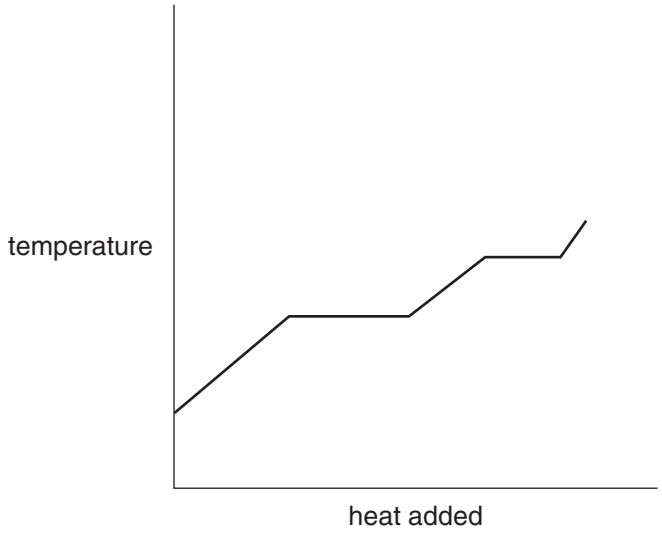
System Type	Transfers Matter	Transfers Energy
Closed	No	Yes
Isolated	No	No
Open	Yes	Yes

2. State functions are variables independent from the path taken to achieve a particular equilibrium and are properties of a given system at equilibrium; they may be dependent on one another. Process functions define the path (or how the system got to its state) through variables such as Q (heat) or W (work).
3. State functions include pressure (P), density (ρ), temperature (T), volume (V), enthalpy (H), internal energy (U), Gibbs free energy (G), and entropy (S).

3.3

1. The change in the internal energy of a system is equal to heat put into a system minus the work done by the system. This is the first law of thermodynamics.
2. Conduction is heat exchange by direct molecular interactions. Convection is heat exchange by fluid movement. Radiation is heat exchange by electromagnetic waves, and does not depend on matter.

3.



4. In a P–V graph, work is the area under the curve (or within a closed loop).

3.4

1. On a macroscopic level, entropy can be thought of as the tendency toward disorder. Statistically, entropy is the measure of the spontaneous dispersal of energy at a specific temperature, increasing the number of available microstates for a given molecule.
2. The entropy of a system and its surroundings will never decrease; it will always either remain zero or increase.

EQUATIONS TO REMEMBER

(3.1) **Temperature conversions:** $F = \frac{9}{5}C + 32$

$K = C + 273$

(3.2) **Thermal expansion equation:** $\Delta L = \alpha L \Delta T$

(3.3) **Volume expansion equation:** $\Delta V = \beta V \Delta T$

(3.4) **First law of thermodynamics:** $\Delta U = Q - W$

(3.5) **Heat gained or lost (with temperature change):** $q = mc\Delta T$

(3.6) **Heat gained or lost (phase change):** $q = mL$

(3.7) **Entropy and heat:** $\Delta S = \frac{Q_{rev}}{T}$

(3.8) **Second law of thermodynamics:** $\Delta S_{universe} = \Delta S_{system} + \Delta S_{surroundings} > 0$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. If an object with an initial temperature of 300 K increases its temperature by 1°C every minute, by how many degrees Fahrenheit will its temperature have increased in 10 minutes?

A. 6°F
B. 10°F
C. 18°F
D. 30°C

2. Which of the following choices correctly identifies the following three heat transfer processes?

I. Heat transferred from the Sun to the Earth

II. A metal spoon heating up when placed in a pot of hot soup

III. A rising plume of smoke from a fire

A. I. Radiation; II. Conduction; III. Convection
B. I. Conduction; II. Radiation; III. Convection
C. I. Radiation; II. Convection; III. Conduction
D. I. Convection; II. Conduction; III. Radiation

3. A 20 m steel rod at 10°C is dangling from the edge of a building and is 2.5 cm from the ground. If the rod is heated to 90°C, will the rod touch the ground? (Note: $\alpha = 1.1 \times 10^{-5}\ \text{K}^{-1}$)

A. Yes, because it expands by 3.2 cm.
B. Yes, because it expands by 2.6 cm.
C. No, because it expands by 2.2 cm.
D. No, because it expands by 1.8 cm.

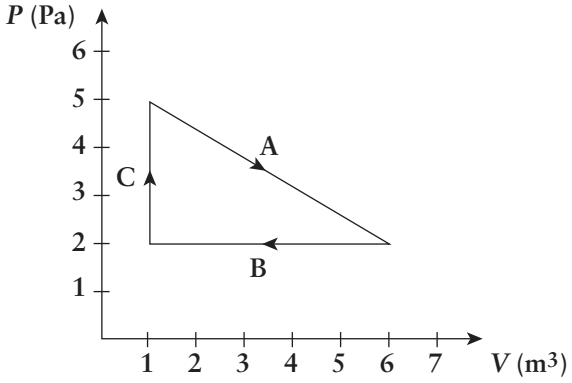
4. What is the final temperature of a 5 kg silver pendant that is left in front of an electric heater, absorbing heat energy at a rate of 100 W for 10 minutes? Assume the pendant is initially at 20°C and that the specific heat of silver is $233\ \frac{\text{J}}{\text{kg} \cdot \text{K}}$.

A. 29°C
B. 59°C
C. 72°C
D. 100°C

5. How much heat is required to completely melt 500 g gold earrings, given that their initial temperature is 25°C? (The melting point of gold is 1064°C, its heat of fusion is $6.37 \times 10^4\ \frac{\text{J}}{\text{kg}}$, and its specific heat is $126\ \frac{\text{J}}{\text{kg} \cdot \text{K}}$.)

A. 15 kJ
B. 32 kJ
C. 66 kJ
D. 97 kJ

6. Given the cycle shown, what is the total work done by the gas during the cycle?



A. –10 J
B. 0 J
C. 7.5 J
D. 17.5 J

7. In an adiabatic compression process, the internal energy of the gas:

A. increases because the work done on the gas is negative.
B. increases because the work done on the gas is positive.
C. decreases because the work done on the gas is negative.
D. decreases because the work done on the gas is positive.

8. The entropy of a system can:

A. never decrease.
B. decrease when the entropy of the surroundings increases by at least as much.
C. decrease when the system is isolated and the process is irreversible.
D. decrease during an adiabatic reversible process.

9. A student making a coffee cup calorimeter fails to use a second coffee cup and inadequately seals the lid. What was her initial goal, and what was the result of this mistake?

A. She was trying to create an isolated system but created an open system instead.
B. She was trying to create an isolated system but created a closed system instead.
C. She was trying to create a closed system but created an open system instead.
D. She was trying to create a closed system but created an isolated system instead.

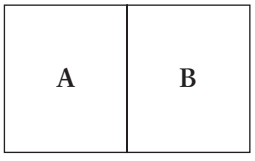
10. A certain substance has a specific heat of $1\ \frac{\text{J}}{\text{mol} \cdot \text{K}}$ and a melting point of 350 K. If one mole of the substance is currently at a temperature of 349 K, how much energy must be added in order to melt it?

A. More than 1 J
B. Exactly 1 J
C. Less than 1 J but more than 0 J
D. Less than 0 J

11. Which of the following is NOT a state function?

A. Internal energy
B. Heat
C. Temperature
D. Entropy

12. The figure shown depicts a thick metal container with two compartments. Compartment A is full of a hot gas, while compartment B is full of a cold gas. What is the primary mode of heat transfer in this system?



A. Radiation
B. Convection
C. Conduction
D. Enthalpy

13. Substances A and B have the same freezing and boiling points. If solid samples of both substances are heated in the exact same way, substance A boils before substance B. Which of the following would NOT explain this phenomenon?

A. Substance B has a higher specific heat.
B. Substance B has a higher heat of vaporization.
C. Substance B has a higher heat of fusion.
D. Substance B has a higher internal energy.

14. In experiment A, a student mixes ink with water and notices that the two liquids mix evenly. In experiment B, the student mixes oil with water; in this case, the liquids separate into two different layers. The entropy change is:

A. positive in experiment A and negative in experiment B.
B. positive in experiment A and zero in experiment B.
C. negative in experiment A and positive in experiment B.
D. zero in experiment A and negative in experiment B.

15. Which of the following processes is LEAST likely to be accompanied by a change in temperature?

A. The kinetic energy of a gas is increased through a chemical reaction.
B. Energy is transferred to a solid via electromagnetic waves.
C. A boiling liquid is heated on a hot plate.
D. A warm gas is mixed with a cold gas.

Explanations to Discrete Practice Questions

1. C

The kelvin unit and Celsius degree are the same size; that is, a change of 10 K is equal to a change of 10°C. One degree Celsius is equal to 1.8 degrees Fahrenheit; therefore, 10°C = 18°F.

2. A

Because there is essentially only empty space between the Sun and the Earth, the only means of heat transfer is by radiation—electromagnetic waves that propagate across space. When a metal spoon is placed in a pot of hot soup, the molecules in the soup collide with those on the surface of the spoon, thereby transferring heat by conduction. Finally, fire warms the air above it, and the warmed air is less dense than the surrounding air, so it rises. A rising column of warm air means that heat is being transported in the air mass, which is simply the process of convection. The smoke particles ride along with the upward moving air current and create a plume of smoke.

3. D

First, find the change in length due to thermal expansion:

$$\Delta L = \alpha L \Delta T = (1.1 \times 10^{-5}\ \text{K}^{-1})(20\ \text{m})(80\ \text{K})$$
$$= 0.0176\ \text{m} = 1.76\ \text{cm}$$

Because the rod is originally 2.5 cm above the ground and its length increases by 1.76 cm, we can conclude that it will not touch the ground after the thermal expansion process is completed.

4. C

To answer this question, first remember that watts are equal to joules per second; in other words, power is energy transfer over time. In 10 minutes, the pendant absorbs the following amount of energy:

$$E = P \times t = (100\ \text{W})(10\ \text{min})\left(\frac{60\ \text{s}}{1\ \text{min}}\right) = 6 \times 10^4\ \text{J}$$

Now we can find the final temperature from this equation:

$$q = mc\Delta T$$
$$6 \times 10^4\ \text{J} = (5\ \text{kg})\left(233\ \frac{\text{J}}{\text{kg} \cdot \text{K}}\right)\Delta T$$
$$52°\text{C} = \Delta T$$

The final temperature is thus 20 + 52 = 72°C.

5. D

First determine how much heat is required to raise the temperature of the gold earrings to the melting point of gold. Then, calculate the heat required to actually melt the earrings (the latent heat). The total heat required to melt the earrings completely will be the sum of the two heats. The heat required to raise the temperature of the earrings from 25°C to 1064°C is

$$q = mc\Delta T = (0.5\ \text{kg})\left(126\frac{\text{J}}{\text{kg} \cdot \text{K}}\right)(1039\ \text{K})$$
$$\approx 60 \times 1000 = 60\ \text{kJ}$$

Thus, it takes about 60 kJ of heat to bring the earrings to their melting point. The next step is to calculate how much heat is needed to melt the earrings. For this, use the heat of fusion (the latent heat) of gold:

$$q = mL = (0.5\ \text{kg})\left(6.37 \times 10^4\ \frac{\text{J}}{\text{kg}}\right) = 32\ \text{kJ}$$

So overall, it requires approximately 60 + 32 = 92 kJ of heat to melt the gold earrings. Notice that we can heavily approximate the numbers used in our calculations because the answer choices are so spread out. The closest answer is **choice (D)**.

6. C

The total work done by the cycle is the sum of the work of paths A, B, and C, or the area within the cycle. Because the area bounded by A, B, and C is a triangle with a base of 5 m^3 and a height of 3 Pa, we can calculate the area as $\frac{1}{2}(5\ m^3)(3\ Pa) = 7.5$ J. Clockwise loops tend to do positive work on the environment, while counterclockwise loops do negative work.

7. B

To answer the question, make sure you understand all the terms. An adiabatic process means that there is no exchange of heat; in other words, $Q = 0$. When a gas is compressed, positive work is being done *on* the gas (rather than *by* the gas), so the value for work done by the gas will be negative ($W < 0$). Based on this, we can determine how the internal energy of the gas changes by using the first law of thermodynamics ($\Delta U = Q - W$). If $Q = 0$ and W is negative, then ΔU is positive.

8. B

The entropy of a system can decrease as long as the entropy of its surroundings increases by at least as much. On the other hand, the entropy of an isolated system increases for all real (irreversible) processes. This adheres to the second law of thermodynamics, which says that energy will be dispersed and entropy of the universe will remain constant or increase during all processes.

9. A

Calorimeters are our best approximations of isolated systems, where neither energy nor matter is exchanged with the environment. By failing to use an insulating layer and failing to fully contain the system, heat can be exchanged with the environment and matter may be dispersed, creating an open system.

10. A

To find the amount of heat needed to bring the substance to its melting point, you can use the specific heat. To heat one mole of the substance one unit kelvin, it would take 1 J of heat. After the substance reaches its melting point, additional heat is needed to actually induce the phase change. Therefore, the total amount of heat required is greater than 1 J.

11. B

State functions are any that are independent of the path taken to achieve a given state and which are not themselves defined as a process, such as pressure, density, temperature, volume, enthalpy, internal energy, Gibbs free energy, and entropy. Heat and work are process functions that are pathway dependent.

12. C

In this situation, heat will transfer from the warm gas to the metal and then to the cold gas. **Choice (B)**, convection, requires flow of a fluid to cause heat transfer. In this case, the gas is not flowing, but rather is in contact with the metal. **Choice (A)**, heat transfer through radiation, is also implausible not only because gases are unlikely to emit heat in the form of waves, but also because the radiation would be unlikely to penetrate the thick metal container. Enthalpy, **choice (D)**, is not a form of heat transfer. Conduction, **choice (C)**, is the most likely option; it happens when two substances make direct contact with one another. Here, gas A makes contact with the metal container, which makes contact with gas B.

13. D

Saying that substance B has a higher internal energy cannot explain the phenomenon because the internal energy is irrelevant; the heat involved in the process is related only to the specific heat, the heat of fusion, and the heat of vaporization. All of the other choices could explain the phenomenon. The heat required to melt the solid is determined by the heat of fusion, **choice (C)**. The heat required to bring the liquid to its boiling point is determined by the specific heat, **choice (A)**. The heat required to boil the liquid is determined by the heat of vaporization, **choice (B)**.

14. B

When the ink randomly intersperses throughout the water, the final state is more disordered than the initial state, so the entropy change of the system is positive. When the oil separates from the water, the final state is just as ordered as the initial state (because the oil and the water are still completely separate), so the entropy change is zero. You can also answer this question by noticing the reversibility of the two experiments. Experiment A has a positive entropy change because it is irreversible, while experiment B has no entropy change because the reaction is reversible. According to the second law of thermodynamics, the overall entropy change of a system and its surroundings can never be negative in a thermodynamic process that moves from one equilibrium state to another.

15. C

If a substance is undergoing a phase change, any added heat will be used toward overcoming the heat of transformation of the phase change. During the phase change, the temperature will remain constant. Temperature is a measure of the kinetic energy of the molecules in a sample, so a change in kinetic energy, **choice (A)**, is essentially the same thing as a change in temperature. The heat transfer by radiation described in **choice (B)** will definitely change the temperature of the solid as long as it is not in the process of melting. **Choice (D)** describes heat transfer by convection, in which the warm gas will transfer heat to the cold gas until they both reach an intermediate temperature.

Concept Summary 136

Introduction

Hidden beneath the waves of the Mediterranean Sea, at depths of more than 4,000 meters, lie three lakes. The water in these "seas under the sea" is so salty—five to ten times saltier than the seawater that sits above it—that its extreme density prevents it from mixing with the ocean water above, forming a layer of separation not unlike that between the oil and water in a bottle of salad dressing. These underwater lakes behave eerily like their more common cousins found at sea level. They have tides, shore lines, beach ridges, and swash zones. When deep sea exploratory vessels set down on their surfaces, the vessels bob up and down, causing ripples to emanate outward like a stone dropped in a pond.

Suboceanic lakes and rivers present a particularly fascinating opportunity to illustrate the physics of fluids and solids. This chapter covers the important concepts and principles of fluid mechanics as they are tested on the MCAT. We will begin with a review of some important terms and measurements, including density and pressure. Our next topic will be hydrostatics, the branch of fluid mechanics that characterizes the behavior of fluids at rest. We'll then turn our attention to fluid dynamics, including Bernoulli's equation and the aerodynamics of flight. Finally, the chapter concludes with a discussion of fluid dynamics in physiology, examining the properties that motivate the movement of blood and air within the body.

4.1 Characteristics of Fluids and Solids ★★★★

Fluids are characterized by their ability to flow and conform to the shapes of their containers. **Solids**, on the other hand, do not flow and are rigid enough to retain a

shape independent of their containers. Both liquids and gases are fluids. The natural gas (methane) that many of us use to cook flows through pipes to the burners of our stove and ovens, and the air that we breathe flows in and out of our lungs, filling the spaces of our respiratory tract and the alveoli.

Fluids and solids share certain characteristics. Both can exert forces perpendicular to their surface, although only solids can withstand **shear** (**tangential**) **forces**. Fluids can impose large perpendicular forces; falling into water from a significant height can be just as painful as falling onto a solid surface.

DENSITY

All fluids and solids are characterized by the ratio of their mass to their volume. This is known as **density**, which is a scalar quantity and therefore has no direction. The equation for density is

$$\rho = \frac{m}{V}$$

Equation 4.1

where ρ (rho) represents density, m is mass, and V is volume. The SI units for density are $\frac{\text{kg}}{\text{m}^3}$, but you may find it convenient to use $\frac{\text{g}}{\text{mL}}$ or $\frac{\text{g}}{\text{cm}^3}$, both of which may be seen on the MCAT. Remember that a milliliter and a cubic centimeter are the same volume. A word of caution: students sometimes assume that if the mL and the cm^3 are equivalent, then so must be the liter and the m^3. This is absolutely not the case; in fact, there are 1000 liters in a cubic meter. For the MCAT, it is important to know the density of water, which is $1\,\frac{\text{g}}{\text{cm}^3} \equiv 1000\,\frac{\text{kg}}{\text{m}^3}$.

The weight of any volume of a given substance with a known density can be calculated by multiplying the substance's density by its volume and the acceleration due to gravity. This is a calculation that appears frequently when working through buoyancy problems on Test Day:

$$\mathbf{F}_g = \rho V \mathbf{g}$$

Equation 4.2

The density of a fluid is often compared to that of pure water at 1 atm and 4°C, a variable called **specific gravity**. It is at this combination of pressure and temperature that water has a density of exactly $1\,\frac{\text{g}}{\text{cm}^3}$. The specific gravity is given by

$$SG = \frac{\rho}{1\,\frac{\text{g}}{\text{cm}^3}}$$

Equation 4.3

This is a unitless number that is usually expressed as a decimal. The specific gravity can be used as a tool for determining if an object will sink or float in water, as described later in this chapter.

Example: Find the specific gravity of benzene, given that its density is 877 $\frac{kg}{m^3}$.

Solution: The ratio of the density of benzene to the density of water is the specific gravity. Either the numerator must be converted to $\frac{g}{cm^3}$ or the denominator (the density of water) must be given in $\frac{kg}{m^3}$:

$$SG = \frac{\rho}{1000\ \frac{kg}{m^3}} = \frac{877}{1000} = 0.877$$

MCAT Expertise

If an object's density is given in $\frac{g}{cm^3}$, its specific gravity is simply its density as a dimensionless number. This is because the density of water in $\frac{g}{cm^3}$ is 1.

PRESSURE

Pressure is a ratio of the force per unit area. The equation for pressure is

$$P = \frac{F}{A}$$

Equation 4.4

where P is pressure, F is the magnitude of the normal force vector, and A is the area. The SI unit of pressure is the **pascal** (**Pa**), which is equivalent to the newton per square meter $\left(1\ Pa = 1\ \frac{N}{m^2}\right)$. Other commonly used units of pressure are millimeters of mercury (mmHg), torr, and the atmosphere (atm). Millimeters of mercury and torr are identical units. The unit of atmosphere is based on the average atmospheric pressure at sea level. The conversions between Pa, mmHg, torr, and atm are as follows:

$$1.013 \times 10^5\ Pa = 760\ mmHg \equiv 760\ torr = 1\ atm$$

Pressure is a scalar quantity, and therefore has a magnitude but no direction. It is easy to assume that pressure has a direction because it is related to a force, which is a vector. However, note that it is the magnitude of the normal force that is used. No matter where one positions a given surface, the pressure exerted on that surface within a closed container will be the same, neglecting gravity. For example, if we placed a surface inside a closed container filled with gas, the individual molecules, which are moving randomly within the space, will exert pressure that is the same at all points within the container. Because the pressure is the same at all points along the walls of the container and within the space of the container itself, pressure applies in all directions at any point and, therefore, is a scalar rather than a vector. Of course, because pressure is a ratio of force to area, when unequal pressures are exerted against objects, the forces acting on the object will add in vectors, possibly

MCAT Expertise

If you ever forget the units of a variable, you can derive them from equations. You know that pressure equals force over area. Because you know the units of force (N) and area (m^2), you can solve for the base units of pascal by plugging these units into the equation: $\frac{N}{m^2}$.

resulting in acceleration. It's this difference in pressure that causes air to rush into and out of the lungs during respiration, windows to burst outward during a tornado, and the plastic covering a broken car window to bubble outward when the car is moving. Note that when gravity is present, this also results in a pressure differential, which we will explore with hydrostatics later in this chapter.

Example: The window of a skyscraper measures 2.0 m by 3.5 m. If a storm passes by and lowers the pressure outside the window to 0.997 atm while the pressure inside the building remains at 1 atm, what is the net force pushing on the window?

Solution: Because the pressures are different on the two sides of this window, there will be a net force pushing on it in the direction of the lower pressure (outside the window). The difference in pressure itself can be used to determine the net force:

$$\begin{aligned} F_{net} &= P_{net}A \\ &= (P_{outside} - P_{inside})A \\ &= (1 - 0.997\ \text{atm})\left(\frac{1.013 \times 10^5\ \text{Pa}}{1\ \text{atm}}\right)(2.0\ \text{m} \times 3.5\ \text{m}) \\ &\approx (0.003)(10^5)(7.0) = 2100\ \text{N (actual} = 2128\ \text{N)} \end{aligned}$$

Absolute Pressure

At this very moment, countless trillions of air molecules are exerting tremendous pressure on our bodies, with a total force of about 2×10^5 N! Of course, we don't actually feel all this pressure because our internal organs exert a pressure that perfectly balances it.

Atmospheric pressure changes with altitude. Residents of Denver (5280 feet above sea level) experience atmospheric pressure equal to 632 mmHg (0.83 atm), whereas travelers making their way through Death Valley (282 feet below sea level) experience atmospheric pressure equal to 767 mm Hg (1.01 atm). Atmospheric pressure impacts a number of processes, including hemoglobin's affinity for oxygen and the boiling of liquids.

Absolute (hydrostatic) pressure is the total pressure that is exerted on an object that is submerged in a fluid. Remember that fluids include both liquids and gases. The equation for absolute pressure is

$$P = P_0 + \rho g z$$

Equation 4.5

where P is the absolute pressure, P_0 is the **incident** or **ambient pressure** (the pressure at the surface), ρ is the density of the fluid, g is acceleration due to gravity, and z is the depth of the object. Do not make the mistake of assuming that P_0 always stands for atmospheric pressure. In open air and most day-to-day situations P_0 is equal to 1 atm, but in other fluid systems, the surface pressure may be higher or lower than atmospheric pressure. In a closed container, such as a pressure cooker, the pressure at the surface may be much higher than atmospheric pressure. This is, in fact, exactly the point of a pressure cooker, which allows food to cook at higher temperatures. This is because the increased pressure raises the boiling point of water in the food, thus reducing the cooking time and preventing loss of moisture.

Gauge Pressure

When you check the pressure in your car or bike tires using a device known as a gauge, you are measuring the **gauge pressure**, which is the difference between the absolute pressure inside the tire and the atmospheric pressure outside the tire. In other words, gauge pressure is the amount of pressure in a closed space above and beyond atmospheric pressure. This is a more common pressure measurement than absolute pressure, and the equation is:

$$P_{\text{gauge}} = P - P_{\text{atm}} = (P_0 + \rho g z) - P_{\text{atm}}$$

Equation 4.6

Note that when $P_0 = P_{\text{atm}}$, then $P_{\text{gauge}} = P - P_0 = \rho g z$ at a depth z.

Example: A diver in the ocean is 20 m below the surface. What is the absolute pressure she experiences? What is the gauge pressure at her depth? (Note: The density of sea water is 1025 $\frac{\text{kg}}{\text{m}^3}$.)

Solution: First, we use the equation for absolute pressure in a liquid:

$$P = P_{\text{atm}} + \rho g z = 1.013 \times 10^5 \text{ Pa} + \left(1025 \frac{\text{kg}}{\text{m}^3}\right)\left(9.8 \frac{\text{m}}{\text{s}^2}\right)(20 \text{ m})$$
$$\approx 3 \times 10^5 \text{ Pa (actual} = 3.02 \times 10^5 \text{ Pa)}$$

Now, use the equation for gauge pressure:

$$P_{\text{gauge}} = P - P_{\text{atm}} = (3.02 - 1.013) \times 10^5 \text{ Pa} = 2.01 \times 10^5 \text{ Pa}$$

Real World

A useful way to remember the two parts of the absolute pressure equation is to think of diving into a swimming pool. At the surface of the water, the absolute pressure is usually equal to the atmospheric pressure (P_0). But if you dive into the pool, the water exerts an extra pressure on you ($\rho g z$), in addition to the surface pressure. You feel this extra pressure on your eardrums.

MCAT Concept Check 4.1:
Before you move on, assess your understanding of the material with these questions.

1. How does gauge pressure relate to the pressure exerted by a column of fluid?

_____

_____

2. What is the relationship between weight and density?

_____

_____

3. What is the SI unit for pressure? What are other common units of pressure?
   - SI unit:

     _____
   - Other units:

     _____

4. True or False: Density is a scalar quantity.

4.2 Hydrostatics ★★★

Hydrostatics is the study of fluids at rest and the forces and pressures associated with standing fluids. A proper understanding of hydrostatics is important for the MCAT because the testmakers frequently include passages and questions on hydraulics and buoyancy.

Real World

When the air pressure changes above a large body of water, the water level rises or falls to re-establish pressure equilibrium between the air and the water. The surface of a water body directly below a high-pressure air pocket forms a very small but measurable valley of water. A low-pressure air system has the opposite effect, creating a hill of water.

PASCAL'S PRINCIPLE

For fluids that are incompressible—that is, fluids with volumes that cannot be reduced by any significant degree through application of pressure—a change in pressure will be transmitted undiminished to every portion of the fluid and to the walls of the containing vessel. This is **Pascal's principle**. For example, an unopened carton of milk could be considered an incompressible fluid in a closed container. If one were to squeeze the container, exerting an increased pressure on the sides of the milk carton, the applied pressure would be transmitted through the entire volume of milk. If the cap were to suddenly pop off, the resulting geyser of milk would be evidence of this increased pressure.

One application of Pascal's principle can be seen in **hydraulic systems**. These systems take advantage of the near-incompressibility of liquids to generate mechanical

advantage, which, as we've seen in our discussion of inclined planes and pulleys in Chapter 2 of *MCAT Physics and Math Review*, allows us to accomplish a certain amount of work more easily by applying reduced forces. Many heavy machines use hydraulics, including car brakes, bulldozers, cranes, and lifts.

Figure 4.1 shows a simple diagram of a hydraulic lift. Let's determine how such a lift could allow an auto mechanic to raise a heavy car with far less force than the weight of the car. We have a closed container that is filled with an incompressible liquid. On the left side of the lift, there is a piston of cross-sectional area A_1. When this piston is pushed down the column, it exerts a force with a magnitude equal to F_1 and generates a pressure equal to P_1. The piston displaces a volume of liquid equal to A_1d_1 (the cross-sectional area times the distance gives a volume). Because the liquid inside is incompressible, the same volume of fluid must be displaced on the right side of the hydraulic lift, where we find a second piston with a much larger surface area, A_2. The pressure generated by piston 1 is transmitted undiminished to all points within the system, including to A_2. As A_2 is larger than A_1 by some factor, the magnitude of the force, F_2, exerted against A_2 must be greater than F_1 by the same factor so that $P_1 = P_2$, according to Pascal's principle.

$$P = \frac{F_1}{A_1} = \frac{F_2}{A_2}$$

$$F_2 = F_1\left(\frac{A_2}{A_1}\right)$$

Equation 4.7

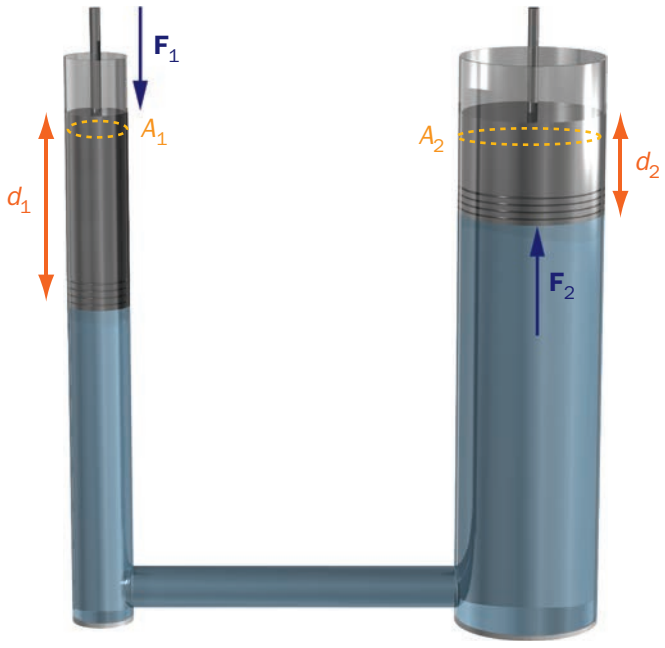

Figure 4.1. Hydraulic Lift

What this series of equations shows us is that hydraulic machines generate output force by magnifying an input force by a factor equal to the ratio of the cross-sectional area of the larger piston to that of the smaller piston. This does not violate the law of energy conservation; an analysis of the input and output work in a frictionless system reveals that there indeed is conservation of energy. As mentioned above, the volume of fluid displaced by piston 1 is equal to the volume of fluid displaced at piston 2.

$$V = A_1 d_1 = A_2 d_2$$
$$d_2 = d_1\left(\frac{A_1}{A_2}\right)$$

Combining the equations for pressure and volume, we can generate an equation for work as the product of constant pressure and volume change, as this is an isobaric process.

$$W = P\Delta V = \frac{F_1}{A_1}(A_1 d_1) = \frac{F_2}{A_2}(A_2 d_2)$$
$$= F_1 d_1 = F_2 d_2$$

Key Concept

Remember when applying Pascal's principle that the larger the area, the larger the force, although this force will be exerted through a smaller distance.

This shows us the familiar form of work as the product of the magnitude of force and displacement (times the cosine of the angle between them, which is 0° in this case). Because the factor by which d_1 is larger than d_2 is equal to the factor by which F_2 is larger than F_1, we see that no additional work has been done or unaccounted for; the greater force F_2 is moving through a smaller distance d_2. Therefore, an auto mechanic needs only to exert a small force over a small area through a large distance to generate a much larger force over a larger area through a smaller distance.

Example: A hydraulic press has a piston of radius 5 cm, which pushes down on an enclosed fluid. A 45 kg weight rests on this piston. Another piston in contact with this system has a radius of 20 cm. Taking g = 10 $\frac{\text{m}}{\text{s}^2}$, what force is needed on the larger piston to keep the press in equilibrium?

Solution: Use Pascal's principle:

$$P = \frac{F_1}{A_1} = \frac{F_2}{A_2}$$
$$F_2 = F_1\left(\frac{A_2}{A_1}\right) = m_1 g\left(\frac{\pi r_2^2}{\pi r_1^2}\right) = m_1 g\left(\frac{r_2}{r_1}\right)^2$$
$$F_2 = (45\text{ kg})\left(10\,\frac{\text{m}}{\text{s}^2}\right)\left(\frac{20\text{ cm}}{5\text{ cm}}\right)^2 = 450(4)^2 = 7200\text{ N}$$

ARCHIMEDES' PRINCIPLE

You've probably heard some version of this story before: Archimedes, a physicist in ancient Greece, was tasked by his king to determine the metallic composition of a certain crown given to the king as a gift. Archimedes knew that he could do this by finding the crown's volume and mass, which would allow him to find its density and compare that density to those of known metals. Weighing the crown would be easy enough, but he was having trouble finding a way to measure its volume without melting it down and ruining its workmanship. Then one day, while getting into his bath, the water that overflowed from the tub gave him the idea to submerge the crown in water and measure the volume of the displaced liquid—*Eureka!*

The principle that derives from the story is one of Archimedes' lasting contributions to the field of physics. **Archimedes' principle** deals with the **buoyancy** of objects when placed in a fluid. It helps us understand how ships stay afloat and why we feel lighter when we're swimming. The principle states that a body wholly or partially immersed in a fluid will be buoyed upwards by a force equal to the weight of the fluid that it displaces.

Just as Archimedes' body and his crown caused the water level to rise in the tub, any object placed in a fluid will cause a volume of fluid to be displaced equal to the volume of the object that is submerged. Because all fluids have density, the volume of fluid displaced will correspond to a certain mass of that fluid. The mass of the fluid displaced exerts a force equal to its weight against the submerged object. This force, which is always directed upward, is called the buoyant force, and its magnitude is given by:

$$F_{buoy} = \rho_{fluid} V_{fluid\ displaced} g = \rho_{fluid} V_{submerged} g$$

Equation 4.8

When an object is placed in a fluid, it will sink into the fluid only to the point at which the volume of displaced fluid exerts a force that is equal to the weight of the object. If the object becomes completely submerged and the volume of displaced fluid still does not exert a buoyant force equal to the weight of the object, the object will accelerate downward and sink to the bottom. This will be the case if an object is more dense than the fluid it's in—a gold crown will sink to the bottom of the bathtub because it is more dense than water. On the other hand, an object that is less dense than water, such as a block of wood or an ice cube, will stop sinking (and start floating) because it is less dense than water. These objects will submerge enough of their volume to displace a volume of water equal to the object's weight.

One way to conceptualize the buoyant force is that it is the force of the liquid trying to return to the space from which it was displaced, thus trying to push the object up and out of the water. This is an important concept because the buoyant force is due to the liquid itself, not the object. If two objects placed in a fluid displace the same

MCAT Expertise

The most common mistake students make using the buoyancy equation is to use the density of the object rather than the density of the fluid. Remember always to use the density of the fluid itself.

Key Concept

An object will float if its average density is less than the average density of the fluid it is immersed in. It will sink if its average density is greater than that of the fluid.

volume of fluid, they will experience the same magnitude of buoyant force even if the objects themselves have different masses.

How can one determine how much of a floating object lies below the surface? To do this, one can make comparisons of density or specific gravity. Remember that an object will float, no matter what it is made of and no matter how much mass it has, if its average density is less than or equal to the density of the fluid into which it is placed. If we express the object's specific gravity as a percent, this directly indicates the percent of the object's volume that is submerged (when the fluid is pure water). For instance, the density of ice is 0.92 $\frac{g}{cm^3}$, so its specific gravity is 0.92. An ice cube floating in a glass of water has 92 percent of its volume submerged in the water—only 8 percent is sitting above the surface. Therefore, any object with a specific gravity less than or equal to 1 will float in water and any object with a specific gravity greater than 1 will sink in water. A specific gravity of exactly 1 indicates that 100 percent of the object will be submerged but it will not sink.

Real World

At first it may seem strange that cruise ships, constructed of dense metals and weighing thousands of kilograms, can float on water. But remember that any object will float if its average density is less than that of water. The steel hull of the ship would sink by itself, but all the air submerged beneath the water level, between the ship's lower decks, lowers the ship's average density to be less than that of water.

Real World

The Dead Sea, located between Israel and Jordan, is the deepest hypersaline lake in the world. Having a salt content of about 35 percent, it is almost nine times saltier than the ocean. All of this dissolved salt makes for some of the densest water on the surface of the Earth, with a specific gravity of 1.24. Humans have a specific gravity around 1.1; thus, in most bodies of water, we have a tendency to sink—but in the Dead Sea, one is unable to do anything but float.

Example: A wooden block floats in the ocean with half its volume submerged. Find the density of the wood ρ_b. (Note: The density of sea water is 1025 $\frac{kg}{m^3}$.)

Solution: The magnitude of the weight of the block of total volume V_b is

$$F_{g,b} = m_b g = \rho_b V_b g$$

The weight of the displaced seawater is the buoyant force and is given by

$$F_{buoy} = m_{water} g = \rho_{water} V_{water} g$$

V_{water} is the volume of displaced water, which is also the volume of the part of the block that is submerged $\left(\frac{V_b}{2}\right)$. Because the block is floating, the buoyant force equals the block's weight:

$$F_{g,b} = F_{buoy}$$

$$\rho_b V_b g = \rho_{water}\left(\frac{V_b}{2}\right)g$$

$$\rho_b = \frac{\rho_{water}}{2} = \frac{1025\ \frac{kg}{m^3}}{2} = 512.5\ \frac{kg}{m^3}$$

MOLECULAR FORCES IN LIQUIDS

Water striders are insects in that have the ability to walk on water. Water striders are able to glide across the water's surface without sinking, even though they are denser than water, because of a special physical property of liquids at the interface between a liquid and a gas. **Surface tension** causes the liquid to form a thin but strong layer like a "skin" at the liquid's surface. Surface tension results from **cohesion**, which is the attractive force that a molecule of liquid feels toward other molecules of the same liquid. Consider the intermolecular forces between the separate molecules of liquid water. For those molecules below the surface, there are attractive intermolecular forces coming from all sides; these forces balance out. However, on the surface, the molecules only have these strong attractive forces from the molecules below them, which pulls the surface of the liquid toward the center. This establishes tension in the plane of the surface of the water; when there is an indentation on the surface (say, caused by a water strider's foot) then the cohesion can lead to a net upward force.

Real World

Remember that cohesion occurs between molecules with the same properties. In a container of both water and oil, the water molecules will be cohesive with other water molecules, and the oil will be cohesive with other oil molecules.

Another force that liquid molecules experience is **adhesion**, which is the attractive force that a molecule of the liquid feels toward the molecules of some other substance. For example, adhesive forces cause water molecules to form droplets on the windshield of a car even though gravity is pulling them downward. When liquids are placed in containers, a **meniscus**, or curved surface in which the liquid "crawls" up the side of the container a small amount, will form when the adhesive forces are greater than the cohesive forces. A **backwards** (**convex**) **meniscus** (with the liquid level higher in the middle than at the edges) occurs when the cohesive forces are greater than the adhesive forces. Mercury, the only metal that is liquid at room temperature, forms a backward meniscus when placed in a container. Both types of menisci are shown in Figure 4.2.

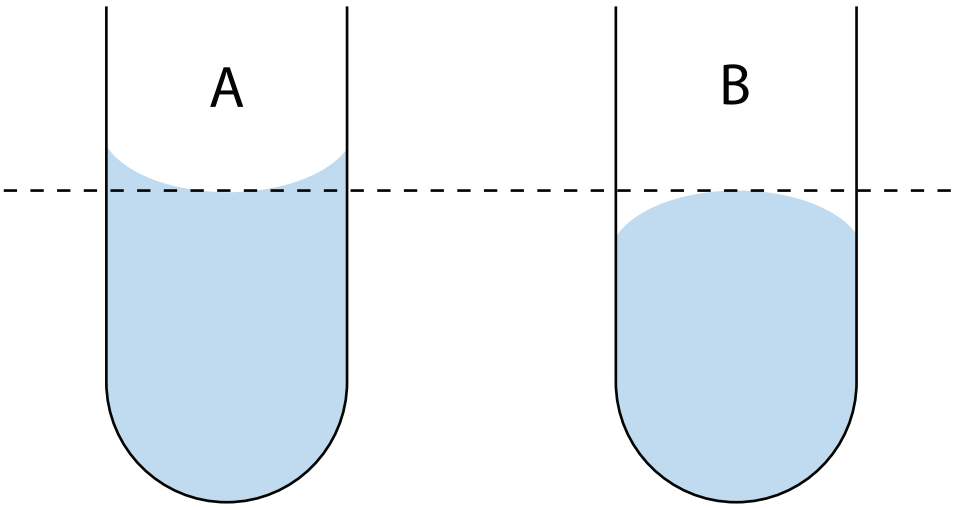

Figure 4.2. Types of Menisci
(A) A concave meniscus (more common); (B) A convex (backwards) meniscus. The dotted line indicates where measurements of depth or volume should be taken with each type of meniscus.

MCAT Concept Check 4.2:
Before you move on, assess your understanding of the material with these questions.

1. Contrast cohesion and adhesion.
   - Cohesion:

     _____

   - Adhesion:

     _____

2. What would the meniscus of a liquid that experiences equal cohesive and adhesive forces look like?

   _____

   _____

3. A block is fully submerged three inches below the surface of a fluid, but is not experiencing any acceleration. What can be said about displaced volume of fluid and the buoyant force?

   _____

   _____

4. True or False: To determine the volume of an object by fluid displacement it must have a specific gravity greater than 1.

5. To which side of a hydraulic lift would the operator usually apply a force—the side with the larger cross-sectional area, or the side with the smaller cross-sectional area? Why?

   _____

   _____

4.3 Fluid Dynamics

As the term suggests, **fluid dynamics** is the study of fluids in motion. This is perhaps one of the most fascinating areas of physics because its applications to real life are everywhere. Many aspects of our world, from water delivery to our homes to blood flow through our arteries and veins, can be analyzed and explained (at least in part)

by the principles of fluid dynamics. The MCAT presents a relatively simplified version of the topic, making important assumptions such as rigid-walled containers and uniform density of fluids.

VISCOSITY

Some fluids flow very easily, while others barely flow at all. The resistance of a fluid to flow is called **viscosity** (η). Increased viscosity of a fluid increases its **viscous drag**, which is a nonconservative force that is analogous to air resistance. Thin fluids, like gases, water, and dilute aqueous solutions, have low viscosity and so they flow easily. Objects can move through these fluids with low viscous drag. Whole blood, vegetable oil, honey, cream, and molasses are thick fluids and flow more slowly. Objects can move through these fluids, but with significantly more viscous drag.

All fluids (except superfluids, which are not tested on the MCAT) are viscous to one degree or another; those with lower viscosities are said to behave more like ideal fluids, which have no viscosity and are described as **inviscid**. Because viscosity is a measure of a fluid's internal resistance to flow, more viscous fluids will "lose" more energy while flowing. Unless otherwise indicated, viscosity should be assumed to be negligible on Test Day, thus allowing Bernoulli's equation (explained later in this chapter) to be an expression of energy conservation for flowing fluids.

Key Concept

Low-viscosity fluids have low internal resistance to flow and behave like ideal fluids. Assume conservation of energy in low-viscosity fluids with laminar flow.

The SI unit of viscosity is the pascal–second $\left(\text{Pa} \cdot \text{s} = \frac{\text{N} \cdot \text{s}}{\text{m}^2}\right)$.

LAMINAR AND TURBULENT FLOW

When a fluid is moving, its flow can be laminar or turbulent. **Laminar flow** is smooth and orderly, and is often modeled as layers of fluid that flow parallel to each other, as shown in Figure 4.3.

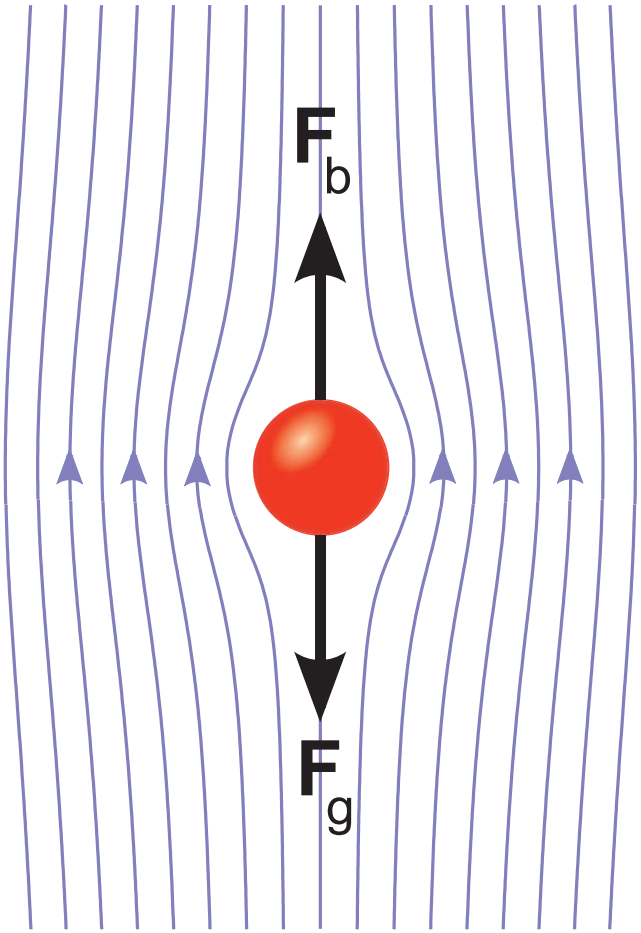

Figure 4.3. Laminar Flow around an Object Sinking in a Fluid
When the gravitational force is larger than the buoyant force, an object will sink. Laminar flow is characterized by smooth flow lines around the object.

The layers will not necessarily have the same linear speed. For example, the layer closest to the wall of a pipe flows more slowly than the more interior layers of fluid.

Poiseuille's Law

With laminar flow through a pipe or confined space, it is possible to calculate the rate of flow using **Poiseuille's law**:

$$Q = \frac{\pi r^4 \Delta P}{8\eta L}$$

Equation 4.9

where Q is the flow rate (volume flowing per time), r is the radius of the tube, ΔP is the pressure gradient, η (eta) is the viscosity of the fluid, and L is the length of the pipe. This equation is rarely tested in full; most often, MCAT passages and questions focus on the relationship between the radius and pressure gradient.

Note that the relationship between the radius and pressure gradient is inverse exponential to the fourth power—even a very slight change in the radius of the tube has a significant effect on the pressure gradient, assuming a constant flow rate.

Turbulence and Speed

Turbulent flow is rough and disorderly. Turbulence causes the formation of **eddies**, which are swirls of fluid of varying sizes occurring typically on the downstream side of an obstacle, as shown in Figure 4.4.

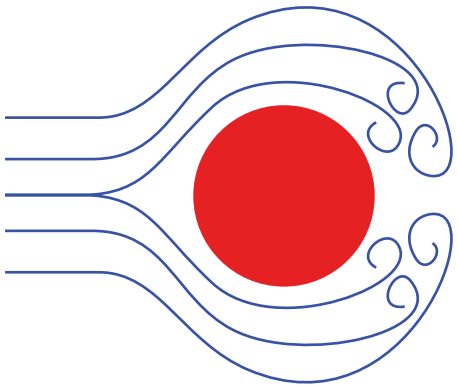

Figure 4.4. Turbulent Flow around an Object in a Wind Chamber
When the speed exceeds the critical speed, laminar flow becomes turbulent, generating eddies on the downstream side of the object.

In unobstructed fluid flow, turbulence can arise when the speed of the fluid exceeds a certain **critical speed**. This critical speed depends on the physical properties of the fluid, such as its viscosity and the diameter of the tube. When the critical speed for a fluid is exceeded, the fluid demonstrates complex flow patterns, and laminar flow occurs only in the thin layer of fluid adjacent to the wall, called the **boundary layer**. The flow speed immediately at the wall is zero and increases uniformly throughout the layer. Beyond the boundary layer, however, the motion is highly irregular and turbulent. A significant amount of energy is dissipated from the system as a result of the increased frictional forces. Calculations of energy conservation, such as Bernoulli's equation, cannot be applied to turbulent flow systems. Luckily, the MCAT always assumes laminar (nonturbulent) flow for such questions.

For a fluid flowing through a tube of diameter D, the critical speed, v_c, can be calculated as

$$v_c = \frac{N_R \eta}{\rho D}$$

Equation 4.10

where v_c is the critical speed, N_R is a dimensionless constant called the Reynolds number, η is the viscosity of the fluid, and ρ is the density of the fluid. The **Reynolds number** depends on factors such as the size, shape, and surface roughness of any objects within the fluid.

STREAMLINES

Because the movement of individual molecules of a fluid is impossible to track with the unaided eye, it is often helpful to use representations of the molecular movement called **streamlines**. Streamlines indicate the pathways followed by tiny fluid elements (sometimes called fluid particles) as they move. The velocity vector of a fluid particle will always be tangential to the streamline at any point. Streamlines never cross each other.

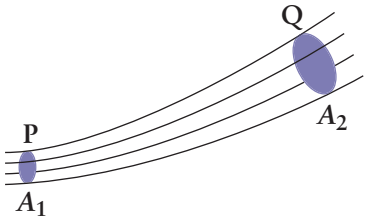

Figure 4.5. Streamlines
The stream's cross-sectional area increases from P to Q.

Figure 4.5 shows a fluid within an invisible tube as it passes from P to Q. The streamlines indicate some, but not all, of the pathways for the fluid along the walls of the tube. You'll notice that the tube gets wider toward Q, as indicated by the streamlines that are spreading out over the increased cross-sectional area. This leads us to consider the relationship between flow rate and the cross-sectional area of the container through which the fluid is moving. Once again, we can assume that the fluid is incompressible (which means that we are not considering a flowing gas). Because the fluid is incompressible, the rate at which a given volume (or mass) of fluid passes by one point must be the same for all other points in the closed system. This is essentially an expression of conservation of matter: if x liters of fluid pass a

point in a given amount of time, then x liters of fluid must pass all other points in the system in the same amount of time. Thus, we can very clearly state, without any exceptions, the **flow rate** (that is, the volume per unit time) is constant for a closed system and is independent of changes in cross-sectional area.

While the flow rate is constant, the linear speed of the fluid does change relative to cross-sectional area. **Linear speed** is a measure of the linear displacement of fluid particles in a given amount of time. Notably, the product of linear speed and cross-sectional area is equal to the flow rate. We've already said that the volumetric rate of flow for a fluid must be constant throughout a closed system. Therefore,

$$Q = v_1 A_1 = v_2 A_2$$

Equation 4.11

Key Concept

While flow rate is constant in a tube regardless of cross-sectional area, linear speed of a fluid will increase with decreasing cross-sectional area.

where Q is the flow rate, v_1 and v_2 are the linear speeds of the fluid at points 1 and 2, respectively, and A_1 and A_2 are the cross-sectional areas at these points. This equation is known as the **continuity equation**, and it tells us that fluids will flow more quickly through narrow passages and more slowly through wider ones. Therefore, in Figure 4.5 earlier, while the flow rate at points P and Q are the same, the linear speed is faster at point P than point Q.

BERNOULLI'S EQUATION

Before we cover Bernoulli's equation itself, let's approach a flowing fluid from two perspectives that we've already discussed. First, the continuity equation arises from the conservation of mass of fluids. Liquids are essentially incompressible, so the flow rate within a closed space must be constant at all points. The continuity equation shows us that for a constant flow rate, there is an inverse relationship between the linear speed of the fluid and the cross-sectional area of the tube: fluids have higher speeds through narrower tubes.

Second, fluids that have low viscosity and demonstrate laminar flow can also be approximated to be conservative systems. The total mechanical energy of the system is constant if we discount the small viscous drag forces that occur in all real liquids.

Combining these principles of conservation, we arrive at **Bernoulli's equation**:

$$P_1 + \frac{1}{2}\rho v_1^2 + \rho g h_1 = P_2 + \frac{1}{2}\rho v_2^2 + \rho g h_2$$

Equation 4.12

where P is the absolute pressure of the fluid, ρ is the density of the fluid, v is the linear speed, g is acceleration due to gravity, and h is the height of the fluid

above some datum. Some of the terms of Bernoulli's equation should look vaguely familiar. The term $\frac{1}{2}\rho v^2$ is sometimes called the **dynamic pressure**, and is the pressure associated with the movement of a fluid. This term is essentially the kinetic energy of the fluid divided by volume $\left(\rho = \frac{m}{V}\right)$. The term $\rho g h$ looks like the expression for gravitational potential energy, and is essentially the pressure associated with the mass of fluid sitting above some position. Finally, let's consider how the absolute pressure fits into this conservation equation. If one multiplies the unit of pressure $\left(\frac{\text{N}}{\text{m}^2}\right)$ by meters over meters, we obtain $\frac{\text{N} \cdot \text{m}}{\text{m}^3} = \frac{\text{J}}{\text{m}^3}$. Pressure can therefore be thought of as a ratio of energy per cubic meter, or **energy density**. Systems at higher pressure have a higher energy density than systems at lower pressure. Finally, the combination of $P + \rho g h$ gives us the **static pressure**, and is the same equation as that for absolute pressure (although h is used here to imply height above a certain point, whereas z was used earlier to imply depth below a certain point). Bernoulli's equation states, then, that the sum of the static pressure and dynamic pressure will be constant within a closed container for an incompressible fluid not experiencing viscous drag. In the end, Bernoulli's equation is nothing other than a statement of energy conservation: more energy dedicated toward fluid movement means less energy dedicated toward static fluid pressure. The inverse of this is also true—less movement means more static pressure. One example of this principle that you may have previously encountered is how the shape of an airplane's wing helps generate lift, as shown in Figure 4.6.

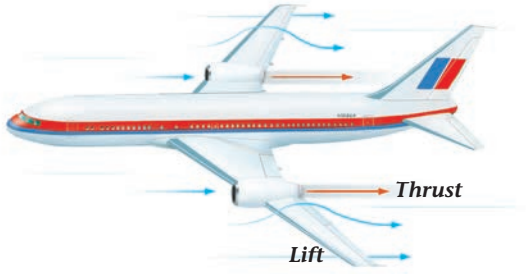

Figure 4.6. Aerodynamics of an Airplane

Propeller and jet engines generate thrust by pushing air backward. In both cases, because the wing top is curved, air streaming over it must travel farther and thus faster than air passing underneath the flat bottom. According to Bernoulli's equation, the slower air below exerts more force on the wing than the faster air above, thereby lifting the plane. Another example of Bernoulli's equation in action is the use of **pitot tubes**. These are specialized measurement devices that determine the speed of fluid flow by determining the difference between the static and dynamic pressure of the fluid at given points along a tube.

A common application of Bernoulli's equation on the MCAT is the **Venturi flow meter**, as shown in Figure 4.7.

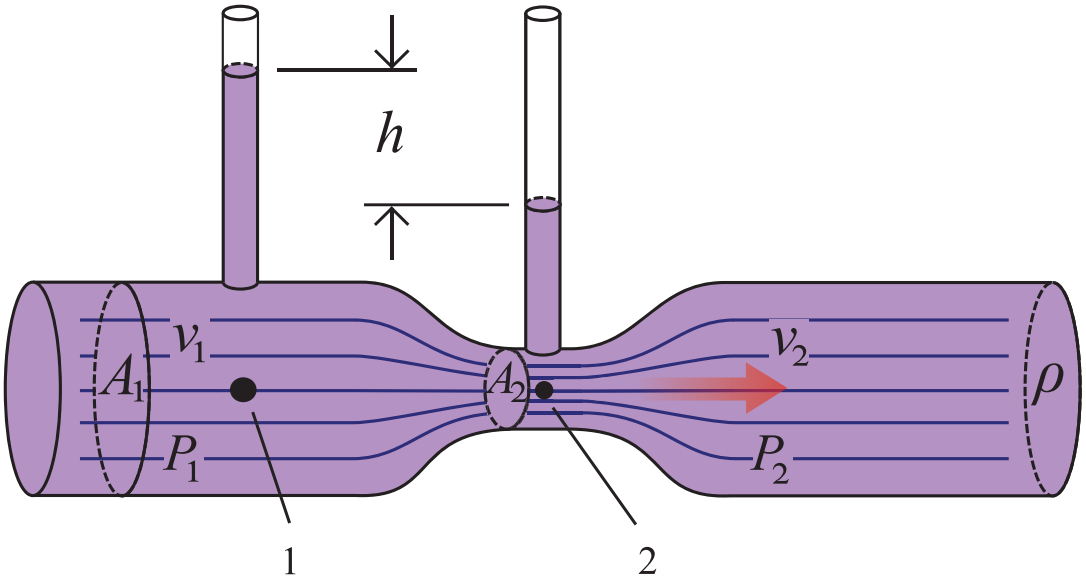

Figure 4.7. Venturi Flow Meter
As the tube narrows, the linear speed increases at point 2. Thus, the pressure exerted on the walls decreases, causing the column above the tube to have a lower height at point 2.

When considering Bernoulli's equation in this example, start by noting that the average height of the tube itself remains constant. Therefore, the ρgh term remains constant at points 1 and 2. Note that the h shown in Figure 4.7 is difference in height between the two columns at points 1 and 2, not h from Bernoulli's equation, which corresponds to the average height of the tube above a datum. As the cross-sectional area decreases from point 1 to point 2, the linear speed must increase according to the continuity equation. Then, as the dynamic pressure increases, the absolute pressure must decrease at point 2. With a lower absolute pressure, the column of fluid sticking up from the Venturi tube will be lower at point 2. This phenomenon is often called the **Venturi effect**.

Example: An office building with a bathroom 40 m above the ground has its water supply enter the building at ground level through a pipe with an inner diameter of 4 cm. If the linear speed at the ground floor is 3 $\frac{m}{s}$ and at the bathroom is 8 $\frac{m}{s}$, determine the cross-sectional area of the pipe in the bathroom. If the pressure in the bathroom is 3×10^5 Pa, what is the required pressure at ground level?

Solution: The cross-sectional area of the pipe in the bathroom is calculated using the continuity equation, where point 1 is the ground level and point 2 is the bathroom:

$$A_1 v_1 = A_2 v_2 \rightarrow A_2 = \frac{A_1 v_1}{v_2}$$

$$A_2 = \frac{\left(\pi r_1^2\right) v_1}{v_2} = \frac{(\pi)\left(2 \times 10^{-2}\ \text{m}\right)^2 \left(3\ \frac{\text{m}}{\text{s}}\right)}{\left(8\ \frac{\text{m}}{\text{s}}\right)} \approx \frac{36 \times 10^{-4}}{8}$$

$$= 4.5 \times 10^{-4}\ \text{m}^2\ (\text{actual} = 4.71 \times 10^{-4}\ \text{m}^2)$$

The pressure can be found from Bernoulli's equation:

$$P_1 + \frac{1}{2}\rho v_1^2 + \rho g h_1 = P_2 + \frac{1}{2}\rho v_2^2 + \rho g h_2$$

$$P_1 = P_2 + \rho\left[\frac{v_2^2 - v_1^2}{2} + g(h_2 - h_1)\right]$$

$$= 3 \times 10^5\ \text{Pa} + \left(1000\ \frac{\text{kg}}{\text{m}^3}\right)\left[\frac{\left(8\ \frac{\text{m}}{\text{s}}\right)^2 - \left(3\ \frac{\text{m}}{\text{s}}\right)^2}{2} + \left(9.8\ \frac{\text{m}}{\text{s}^2}\right)(40\ \text{m})\right]$$

$$\approx 3 \times 10^5 + 1000\left[\frac{55}{2} + 400\right]$$

$$= 3 \times 10^5 + 4.28 \times 10^5 = 7.28 \times 10^5\ \text{Pa}\ (\text{actual} = 7.20 \times 10^5\ \text{Pa})$$

MCAT Concept Check 4.3:

Before you move on, assess your understanding of the material with these questions.

1. Define the following terms:
   - Dynamic pressure:

     _____
   - Static pressure:

     _____

- Pitot tube:

_____

- Viscosity:

_____

- Laminar flow:

_____

- Turbulence:

_____

2. How do the following concepts relate to one another: Venturi effect, Bernoulli's equation, and continuity equation? What relationship does each describe?

_____

_____

_____

_____

3. What variables does flow rate depend on?

_____

_____

4.4 Fluids in Physiology ★★

As a future student of medicine, you may feel that the abstract application of physics and math can often seem unimportant or tedious. However, these disciplines are exceptionally important in physiology. The movement of blood, lymph, and air throughout the body and lungs follow basic principles of fluid dynamics and pressure, with some minor alterations. We will focus primarily on the circulatory system, but also briefly discuss pressure and flow as they relate to gas exchange.

CIRCULATORY SYSTEM

The circulatory system is a **closed loop** that has a nonconstant flow rate. This nonconstant flow is a result of valves, gravity, the physical properties of our vessels (elasticity, in particular), and the mechanics of the heart. In particular, the nonconstant flow can be felt and measured as a **pulse**. In addition to these features, there is a loss

of volume from the circulation as a result of a difference between osmotic (oncotic) and hydrostatic pressures. This fluid is eventually returned to the circulation as a result of lymphatic flow, but it is problematic for applications of the continuity equation. An important point to note is that despite these differences, blood volume entering the heart is always equal to blood volume leaving the heart during a single cycle.

As blood flows away from the heart, each vessel has a progressively higher resistance until the capillaries; however, the total resistance of the system decreases because the increased number of vessels are in parallel with each other. Like parallel resistors in circuits, the equivalent resistance is therefore lower for the capillaries in parallel than in the aorta. Return flow to the heart is facilitated by mechanical squeezing of the skeletal muscles, which increases pressure in the limbs and pushes blood to the heart, and the expansion of the heart, which decreases pressure in the heart and pulls blood in. Finally, the pressure gradients created in the thorax by inhalation and exhalation also motivate blood flow. Venous circulation holds approximately three times as much blood as arterial circulation. Heart murmurs, which result from structural defects of the heart, are heard because of turbulent blood flow.

RESPIRATORY SYSTEM

The respiratory system is also mediated by changes in pressure, and follows the same resistance relationship as the circulatory system. During inspiration, there is a negative pressure gradient that moves air into the lungs. During expiration, this gradient reverses. An additional point to note is that when air reaches the alveoli, it has essentially no speed.

MCAT Concept Check 4.4:

Before you move on, assess your understanding of the material with these questions.

1. Under what conditions could the continuity equation be applied to human circulation?

_____

_____

2. During exhalation, how does the total resistance of the encountered airways change as air leaves the alveoli to escape the nose and mouth?

_____

_____

_____

3. How does flow in the venae cavae relate to flow in the main pulmonary artery?

_____

_____

Conclusion

The behavior of fluids impacts every moment of our lives. Even if we are nowhere near an ocean or a lake, we are quite literally submerged in a vast expanse of fluid, a mix of gases known as the atmosphere, which exerts forces on all of the surfaces of our bodies. Whenever we take a bath or submerge an object in water, we experience the effect of buoyant forces exerted by the displaced fluid. When we water our gardens, take a shower, or ride in a car with open windows, we experience the speeds, forces, and pressures of a fluid on the move. In the world of medicine, one must consider fluids, flowing and at rest, when evaluating the function of the respiratory and circulatory systems: conditions as varied as asthma and heart murmurs are related to the way in which the body causes fluids to flow. The balance of hydrostatic and oncotic pressures is important for maintaining the proper balance of fluid in the peripheral tissues of the body.

Now that you have the basic concepts of hydrostatics and fluid dynamics, learn to apply them to MCAT passages and questions through your Kaplan practice materials. Don't be intimidated by the seeming complexity of buoyant force problems and applications of Bernoulli's equation. Remember that all fluids, whether liquid or gas, exert buoyant forces against objects that are placed in them as a function of the weight of the fluid displaced. Remember that incompressible fluids demonstrate an inverse relationship between their dynamic pressure (as a function of speed) and their static pressure. This chapter concludes the section of this book focusing on mechanics; in the next two chapters, we'll turn our attention to electrostatics and electricity.

CONCEPT SUMMARY

Characteristics of Fluids and Solids

- **Fluids** are substances that have the ability to flow and conform to the shape of their containers.
  - Fluids can exert perpendicular forces, but cannot exert shear forces.
  - Liquids and gases are the two phases of matter that are fluids.
- **Solids** do not flow and they retain their shape regardless of their containers.
- **Density** is the mass per unit volume of a substance (fluid or solid).
- **Pressure** is defined as a measure of force per unit area; it is exerted by a fluid on the walls of its container and on objects placed in the fluid.
  - It is a scalar quantity; its value has magnitude only, and no direction.
  - The pressure exerted by a gas against the walls of its container will always be perpendicular (normal) to the container walls.
- **Absolute pressure** is the sum of all pressures at a certain point within a fluid; it is equal to the pressure at the surface of the fluid (usually atmospheric pressure) plus the pressure due to the fluid itself.
- **Gauge pressure** is the name for the difference between absolute pressure and atmospheric pressure. In liquids, gauge pressure is caused by the weight of the liquid above the point of measurement.

Hydrostatics

- **Pascal's principle** states that a pressure applied to an incompressible fluid will be distributed undiminished throughout the entire volume of the fluid
- **Hydraulic machines** operate based on the application of Pascal's principle to generate mechanical advantage.
- **Archimedes' principle** governs the buoyant force. When an object is placed in a fluid, the fluid generates a **buoyant force** against the object that is equal to the weight of the fluid displaced by the object.
  - The direction of the buoyant force is always opposite to the direction of gravity.
  - If the maximum buoyant force is larger than the force of gravity on the object, the object will float. This will be true if the object is less dense than the fluid it is in.
  - If the maximum buoyant force is smaller than the force of gravity on the object, the object will sink. This will be true if the object is more dense than the fluid it is in.
- Fluids experience **cohesive** forces with other molecules of the same fluid and **adhesive** forces with other materials; cohesive forces give rise to **surface tension**.

Fluid Dynamics

- Fluid dynamics is a set of principles regarding actively flowing fluids.
- **Viscosity** is a measurement of a fluid's internal friction. **Viscous drag** is a nonconservative force generated by viscosity.
- Fluids can move with either **laminar flow** or **turbulent flow**.
  - The rate of laminar flow is determined by the relationships in **Poiseuille's law**.
  - On the MCAT, incompressible fluids are assumed to have laminar flow and very low viscosity while flowing, allowing us to assume conservation of energy.
- The **continuity equation** is a statement of the conservation of mass as applied to fluid dynamics.
- **Bernoulli's equation** is an expression of conservation of energy for a flowing fluid. This equation states that the sum of the **static pressure** and the **dynamic pressure** will be constant between any two points in a closed system.
- For a horizontal flow, there is an inverse relationship between pressure and speed, and in a closed system, there is a direct relationship between cross-sectional area and pressure exerted on the walls of the tube known as the **Venturi effect**.

Fluids in Physiology

- The circulatory system behaves as a closed system with nonconstant flow.
- Resistance decreases as the total cross-sectional area increases.
  - Arterial circulation is primarily motivated by the heart.
  - Venous circulation has three times the volume of arterial circulation and is motivated by the skeletal musculature and expansion of the heart.
- Inspiration and expiration create a pressure gradient not only for the respiratory system, but for the circulatory system as well.
- Air at the alveoli has essentially zero speed.

ANSWERS TO CONCEPT CHECKS

4.1

1. Gauge pressure is equal to the pressure exerted by a column of fluid plus the ambient pressure above the fluid, minus atmospheric pressure. When atmospheric pressure is the only pressure above the fluid column, then gauge pressure equals the fluid pressure.
2. Weight is density times volume and acceleration due to gravity.
3. The SI unit of pressure is the pascal. Other common units include mmHg, torr, and atm.
4. True. Density is directionless, and is thus a scalar quantity.

4.2

1. Cohesion is the attractive force experienced by molecules of a fluid for one another. Adhesion is the attractive force experienced by molecules of a fluid for a different material (usually a solid).
2. If adhesive and cohesive forces are equal, then no meniscus would form and the liquid surface would be flat.
3. The displaced volume is equal to the volume of the block. The buoyant force is equal to the weight of the block, and is equal to the weight of the displaced fluid. By extension, the block and the fluid in which it is immersed must have the same density.
4. False. A fluid with a low specific gravity can be used instead of water to determine volumes of objects that would otherwise float in water.
5. The operator usually applies a force to the side with the smaller cross-sectional area. Because pressure is the same on both sides of the lift, a smaller force can be applied on the smaller surface area to generate the desired pressure.

4.3

1. Dynamic pressure is the pressure associated with flow, and is represented by $\frac{1}{2}\rho v^2$. Static pressure is the pressure associated with position; static pressure is sacrificed for dynamic pressure during flow. A pitot tube is a device that measures static pressure during flow to calculate speed. Viscosity is a measure of the resistance of a liquid to flow. Laminar flow is flow in which there are no eddies and in which streamlines roughly parallel each other. Turbulence is the presence of backflow or current eddies.
2. The continuity equation describes the relationship of flow and cross-sectional area in a tube, while Bernoulli's equation describes the relationship between height, pressure, and flow. The Venturi effect is the direct relationship between cross-sectional area and pressure, and results from the combined relationships of the Bernoulli and continuity equations.
3. Flow rate depends on the radius of the tube, pressure gradient, viscosity, and length of the tube.

4.4

1. The continuity equation cannot be applied to human circulation. The presence of pulses, the elasticity of the vessels, and the nature of the pressure gradient preclude this type of analysis. Poiseuille's law should instead be used for isolated segments.
2. Total resistance increases as the air exits the body despite the increase in the diameter of the airways. This is because there are fewer airways in parallel with each other.
3. In theory, there should be equal flow in the venae cavae and the main pulmonary trunk. In reality, the flow in the venae cavae is actually slightly less than in the pulmonary trunk because some of the blood entering the right side of the heart is actually from cardiac (coronary) circulation, not systemic circulation.

EQUATIONS TO REMEMBER

(4.1) **Density:** $\rho = \frac{m}{V}$

(4.2) **Weight of a volume of fluid:** $F_g = \rho V g$

(4.3) **Specific gravity:** $SG = \frac{\rho}{1\ \frac{g}{cm^3}}$

(4.4) **Pressure:** $P = \frac{F}{A}$

(4.5) **Absolute pressure:** $P = P_0 + \rho g z$

(4.6) **Gauge pressure:** $P_{gauge} = P - P_{atm} = (P_0 + \rho g z) - P_{atm}$

(4.7) **Pascal's principle:** $P = \frac{F_1}{A_1} = \frac{F_2}{A_2}$

$$F_2 = F_1\left(\frac{A_2}{A_1}\right)$$

(4.8) **Buoyant force:** $F_{buoy} = \rho_{fluid} V_{fluid\ displaced} g = \rho_{fluid} V_{submerged} g$

(4.9) **Poiseuille's law:** $Q = \frac{\pi r^4 \Delta P}{8\eta L}$

(4.10) **Critical speed:** $v_c = \frac{N_R \eta}{\rho D}$

(4.11) **Continuity equation:** $Q = v_1 A_1 = v_2 A_2$

(4.12) **Bernoulli's equation:** $P_1 + \frac{1}{2}\rho v_1^2 + \rho g h_1 = P_2 + \frac{1}{2}\rho v_2^2 + \rho g h_2$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. Objects A and B are submerged at a depth of 1 m in a liquid with a specific gravity of 0.877. Given that the density of object B is one-third that of object A and that the gauge pressure of object A is 3 atm, what is the gauge pressure of object B? (Note: Assume atmospheric pressure is 1 atm and $g = 9.8 \frac{m}{s^2}$.)

A. 1 atm
B. 2 atm
C. 3 atm
D. 9 atm

2. An anchor made of iron weighs 833 N on the deck of a ship. If the anchor is now suspended in seawater by a massless chain, what is the tension in the chain? (Note: The density of iron is 7800 $\frac{kg}{m^3}$ and the density of seawater is 1025 $\frac{kg}{m^3}$.)

A. 100 N
B. 724 N
C. 833 N
D. 957 N

3. Two wooden balls of equal volume but different density are held beneath the surface of a container of water. Ball A has a density of 0.5 $\frac{g}{cm^3}$, and ball B has a density of 0.7 $\frac{g}{cm^3}$. When the balls are released, they will accelerate upward to the surface. What is the relationship between the acceleration of ball A and that of ball B?

A. Ball A has the greater acceleration.
B. Ball B has the greater acceleration.
C. Balls A and B have the same acceleration.
D. It cannot be determined from information given.

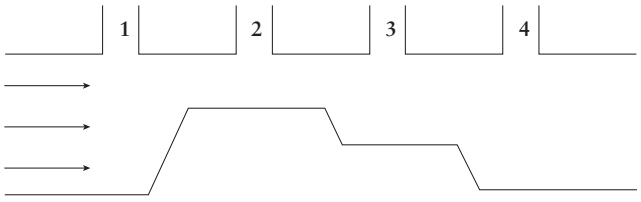
4. Water flows from a pipe of diameter 0.15 m into one of diameter 0.2 m. If the speed in the 0.15 m pipe is 4.88 $\frac{m}{s}$, what is the speed in the 0.2 m pipe?

A. 1.3 $\frac{m}{s}$
B. 2.7 $\frac{m}{s}$
C. 3.7 $\frac{m}{s}$
D. 6.5 $\frac{m}{s}$

5. A hydraulic lever is used to lift a heavy hospital bed, requiring an amount of work *W*. When the same bed with a patient is lifted, the work required is doubled. How can the cross-sectional area of the platform on which the bed is lifted be changed so that the pressure on the hydraulic lever remains constant?

A. The cross-sectional area must be doubled.
B. The cross-sectional area must be halved.
C. The cross-sectional area must be divided by four.
D. The cross-sectional area must remain constant.

6. The figure shown represents a section through a horizontal pipe of varying diameters into which four open vertical pipes connect. If water is allowed to flow through the pipe in the direction indicated, in which of the vertical pipes will the water level be lowest?



A. Pipe 1
B. Pipe 2
C. Pipe 3
D. Pipe 4

7. The speed of blood in the aorta is much higher than the speed of blood through a capillary bed. How can this fact be explained using the continuity equation, assuming that we are interested in average flow and that there is no net fluid loss?

A. The aorta is located higher than the capillary bed.
B. The pressure in the aorta is the same as the pressure in the capillary bed.
C. The cross-sectional area of all the capillaries added together is much greater than the cross-sectional area of the aorta.
D. The cross-sectional area of a capillary is much smaller than the cross-sectional area of the aorta.

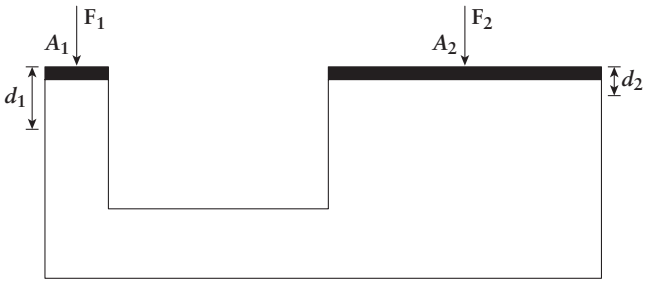
8. Which of the following data sets is sufficient to determine the linear speed through an area of a rigid pipe?

A. The cross sectional area in another segment of pipe and the cross sectional area in the region of interest
B. The Reynolds number, viscosity of the fluid, density, and diameter of the pipe
C. The radius of the pipe, pressure gradient, viscosity, and length of the pipe
D. The absolute pressure and density

9. A large cylinder is filled with equal volumes of two immiscible fluids. A balloon is submerged in the first fluid; the gauge pressure in the balloon at the deepest point in the first fluid is found to be 3 atm. Next, the balloon is lowered all the way to the bottom of the second fluid, where the hydrostatic pressure in the balloon reads 8 atm. What is the ratio of the gauge pressure accounted for by the first fluid to the gauge pressure accounted for by the second fluid?

A. 1:3
B. 3:4
C. 3:5
D. 3:8

10. An hydraulic system is designed to allow water levels to change depending on a force applied at the top of the tank as shown. If a force, F_1, of 4 N is applied to a square, flexible cover where $A_1 = 16$, and the area $A_2 = 64$, what force must be applied to A_2 to keep the water levels from changing?



A. 4 N
B. 16 N
C. 32 N
D. No force needs to be applied.

11. Balls A and B of equal mass are submerged in a swimming pool, as shown below. Which will produce a greater buoyant force?

A. Ball A
B. Ball B
C. The forces will be equal.
D. It is impossible to know without knowing the volume of each ball.

12. Bernoulli's equation is the reason for the upward force that permits airplane flight. Which statement best summarizes the equation's relationship to flight?

A. The speed of airflow is equal on the top and bottom of a wing, resulting in nonturbulent flight.
B. The speed of airflow is greater over the curved top of the wing, resulting in less pressure on the top of the wing and the production of a net upward force on the wing, in turn resulting in flight.
C. The speed of airflow on the flat bottom of the wing is greater than over the curved top of the wing, resulting in more pressure below the wing and the production of a net upward force on the wing, in turn resulting in flight.
D. The weight of the wing is directly proportional to the weight of the air it displaces.

13. A low-pressure weather system can decrease the atmospheric pressure from 1 atm to 0.99 atm. By what percent will this decrease the force on a rectangular window from the outside? (Note: Assume the window is 6 m by 3 m and the glass is 3 cm thick.)

A. 1%
B. 10%
C. $\frac{1}{3}$ %
D. 30%

14. Two fluids, A and B, have densities of x and $2x$, respectively. They are tested independently to assess absolute pressure at varying depths. At what depths will the pressure below the surface of these two fluids be equal?

A. Whenever the depth of fluid A is one-half that of fluid B
B. Whenever the depth of fluid A equals that of fluid B
C. Whenever the depth of fluid A is 2 times that of fluid B
D. Whenever the depth of fluid A is 4 times that of fluid B

15. A water tower operator is interested in increasing the pressure of a column of water that is applied to a piston. She hopes that increasing the pressure will increase the force being applied to the piston. The only way to increase the pressure is to alter the speed of the water as it flows through the pipe to the piston. How should the speed of the water be changed to increase the pressure and force?

A. Increase the speed
B. Decrease the speed
C. Release water intermittently against the pipe
D. The speed of water will not change pressure at the piston.

Explanations to Discrete Practice Questions

1. C

The absolute and gauge pressures depend only on the density of the fluid, not that of the object. When the pressure at the surface is equal to atmospheric pressure, the gauge pressure is given by $P_{gauge} = \rho g z$, where ρ represents the density of the fluid, not the object. These objects are also at the same depth, so they must have the same gauge pressure.

2. B

The tension in the chain is the difference between the anchor's weight and the buoyant force because the object is in translational equilibrium: $\mathbf{T} = \mathbf{F}_g - \mathbf{F}_{buoy}$. The object's weight is 833 N, and the buoyant force can be found using Archimedes' principle. The magnitude of the buoyant force is equal to the weight of the seawater that the anchor displaces:

$$F_{buoy} = \rho_w V_w g$$

Because the anchor is submerged entirely, the volume of the water displaced is equal to the volume of the anchor, which is equal to its mass divided by its density $\left(V_A = \frac{m_A}{\rho_A}\right)$. We are not given the anchor's mass, but its value must be the magnitude of the weight of the anchor divided by g. Putting all of this together, we can obtain the buoyant force:

$$F_{buoy} = \rho_w V_w g = \rho_w V_A g = \rho_w \left(\frac{m_A}{\rho_A}\right) g = \rho_w \left(\frac{F_g}{\rho_A g}\right) g = F_g \left(\frac{\rho_w}{\rho_A}\right)$$

$$= 833 \text{ N} \left(\frac{1025 \frac{\text{kg}}{\text{m}^3}}{7800 \frac{\text{kg}}{\text{m}^3}}\right) \approx 100 \text{ N (actual = 109 N)}$$

Lastly, we can obtain the tension from the initial equation $\mathbf{T} = \mathbf{F}_g - \mathbf{F}_{buoy}$:

$$\mathbf{T} = 833 \text{ N} - 109 \text{ N} = 724 \text{ N}$$

3. A

Using Newton's second law, $F_{net} = ma$, we obtain the following equation:

$$F_{buoy} - mg = ma$$

Thus,

$$a = \frac{F_{buoy} - mg}{m} = \frac{F_{buoy}}{m} - g$$

Both balls experience the same buoyant force because they are in the same liquid and have the same volume ($F_{buoy} = \rho V g$). Thus, the ball with the smaller mass experiences the greater acceleration. Because both balls have the same volume, the ball with the smaller density has the smaller mass ($m = \rho V$), which is ball A.

4. B

It is known that water flows faster through a narrower pipe. The speed is inversely proportional to the cross-sectional area of the pipe because the same volume of water must pass by each point at each time interval. Let A be the 0.15 m pipe and B the 0.20 m pipe, and use the continuity equation:

$$v_A A_A = v_B A_B$$

where v is the speed and A is the cross-sectional area of the pipe. Because v is inversely proportional to the cross-sectional area, and the area is proportional to the square of the diameter $A = \pi r^2 = \frac{\pi d^2}{4}$, we obtain the following:

$$v_B = \frac{v_A\left(\frac{\pi d_A^2}{4}\right)}{\left(\frac{\pi d_B^2}{4}\right)} = v_A\left(\frac{d_A}{d_B}\right)^2$$

$$v_B = 4.88\left(\frac{0.15}{0.20}\right)^2$$

$$v_B \approx 5\left(\frac{9}{16}\right) = \text{a bit less than 3}$$

Choice (B) most closely matches our result and is thus the correct answer.

5. A

This question tests our understanding of Pascal's principle, which states that a change in pressure applied to an enclosed fluid is transmitted undiminished to every portion of the fluid and to the walls of the containing vessel. We are told that the work required to lift the bed with the patient is double the work needed to lift just the bed. In other words, the force required doubles when both the bed and the patient have to be lifted. To maintain the same pressure, we must double the cross-sectional area of the platform of the hydraulic lever on which the patient and the bed are lifted.

6. B

It is not necessary to do any calculations to answer this question. The open vertical pipes are exposed to the same atmospheric pressure; therefore, differences in the heights of the columns of water in the vertical pipes is dependent only on the differences in hydrostatic pressures in the horizontal pipe. Because the horizontal pipe has variable cross-sectional area, water will flow the fastest and the hydrostatic pressure will have its lowest value where the horizontal pipe is narrowest; this is called the Venturi effect. As a result, pipe 2 will have the lowest water level.

7. C

The continuity equation states that the flow rate of a fluid must remain constant from one cross-section to another. In other words, when an ideal fluid flows from a pipe with a large cross-sectional area to one that is narrower, its speed increases. This can be illustrated through the equation $A_1v_1 = A_2v_2$. If blood flows much more slowly through the capillaries, we can infer that the cross-sectional area is larger. This might seem surprising at first glance, but given that each blood vessel divides into thousands of little capillaries, it is not hard to imagine that adding the cross-sectional areas of each capillary from an entire capillary bed results in an area that is larger than the cross-sectional area of the aorta.

8. C

The data given in **choice (C)** are sufficient to determine the flow rate through Poiseuille's law, which can then be used to determine the linear speed by dividing by the cross-sectional area (which could be determined from the radius, as well). **Choice (A)** would be sufficient if we also knew the flow rate in the other segment of pipe; one could use the continuity equation to determine the linear speed. The data in **choice (B)** could be used to determine the critical speed at which turbulent flow begins, but there is no indication that there is turbulent flow. The data in **choice (D)** could be used to determine the depth of an object in a fluid.

9. B

The first step in answering this question is defining the different types of pressures. Atmospheric pressure is the pressure at the top of the first fluid exerted by air (at sea level, it is equal to 1 atm). Gauge pressure is the pressure inside the balloon above and beyond atmospheric pressure; gauge pressure is the total (absolute or hydrostatic) pressure inside the balloon minus the atmospheric pressure. Gauge pressure depends on the density of the fluid, the constant of gravity, and the depth at which the object is submerged. Hydrostatic or absolute pressure is the total pressure in the balloon (that is, the gauge pressure and the atmospheric pressure together). Because we are given the gauge pressure at the bottom of the first fluid as 3 atm, our task now is to calculate the gauge pressure accounted for by the second fluid. The hydrostatic pressure at the bottom of the cylinder is 8 atm. One of these atmospheres is atmospheric pressure pushing on the fluids. Another 3 atmospheres are accounted for by the first fluid that is pushing on the second fluid. Thus, the gauge pressure due to the second fluid is 8 – 1 – 3 = 4 atm. The ratio of the gauge pressures is therefore 3:4.

10. B

This is a basic restatement of Pascal's principle that a force applied to an area will be transmitted through a fluid. This will result in changing fluid levels through the system. The relationship is stated as $F_2 = \frac{F_1 A_2}{A_1}$. Plugging in the numbers gives an answer of 16 N.

11. A

The buoyant force (F_{buoy}) is equal to the weight of water displaced, which is quantitatively expressed as

$$F_{buoy} = m_{fluid\ displaced}g = \rho_{fluid} V_{fluid\ displaced} g$$

The volume of displaced fluid is equal to the volume of the ball. The density of the fluid remains constant. Therefore, because ball A has a larger volume, it will displace more water and experience a larger buoyant force.

12. B

Airplane wings have curved upper surfaces and flat lower surfaces, which causes the air to flow faster over the top of the wing because it has further to travel to the edge of the wing than the air over the flat bottom surface. Increased air speed will mean lower pressure within the fluid. This will result in higher pressure below the wing and an upward force.

13. A

This question is a simple application of the definition of pressure, which is force per area. If pressure decreases 1 percent and area does not change, the force will be decreased by 1 percent. Note that the other measurements given do not play a role in our calculations.

14. C

The equation for absolute (hydrostatic) pressure is $P = P_0 + \rho g z$, where P_0 is the pressure at the surface, ρ is the density of the fluid, g is acceleration due to gravity, and z is the depth in the fluid. If the density of fluid B is twice that of fluid A, then the depth in fluid A will have to be twice that in fluid B to obtain the same absolute pressure:

$$\begin{aligned} P_0 + \rho_A g z_A &= P_0 + \rho_B g z_B \\ (x) g z_A &= (2x) g z_B \\ z_A &= 2 z_B \end{aligned}$$

15. B

This is a basic interpretation of Bernoulli's equation that states, at equal heights, speed and pressure of a fluid are inversely related (the Venturi effect). Decreasing the speed of the water will therefore increase its pressure. An increase in pressure over a given area will result in increased force being transmitted to the piston.

Concept Summary 173

Introduction

Electrostatics is the study of stationary charges and the forces that are created by and which act upon these charges. Without electrical charge, we would not be able to do many of the activities that we enjoy or consider essential to basic living. But living with electrical charge can also be dangerous and even deadly: magnify the small shock you receive from a doorknob after walking across a carpet, and you have the equivalent of a lightning bolt strong enough to stop a heart. This same concept can be used in life-saving therapy as well: cardioversion and defibrillation create a strong electrical current through the heart's conduction system that attempts to resynchronize a pulse.

In this chapter, we will review the basic concepts essential to understanding charges and electrostatic forces including conductors and insulators. We will review Coulomb's law, which describes the attractions and repulsions between charged objects. Next, we will describe the electric fields that all charges create, which allow them to exert forces on other charges. After we've discussed how charges set up these fields, we'll observe the behavior of charges that are placed into these fields. In particular, we will note the motional behavior of these test charges inside a field in relation to the electrical potential difference, or voltage, between two points in space. We can then determine the change in electrical potential energy as the charge moves from a position of some electrical potential to another. Next, we will describe the electric dipole and solve a problem involving one of the molecular dipoles most important to life on this planet: the water molecule. Finally, we will explore the topic of magnetic fields and forces.

5.1 Charges

Charged subatomic particles come in two varieties. One, the **proton**, has a positive charge; the other, the **electron**, has a negative charge. While opposite charges exert **attractive** forces, like charges—those that have the same sign—exert **repulsive** forces. Unlike the force of gravity, which is always an attractive force, the electrostatic force may be repulsive or attractive depending on the signs of the charges that are interacting.

MCAT Expertise

While many of the particles we discuss in electrostatics are very, very tiny, do not forget that they still do have mass. We can use equations such as the kinetic energy equation when solving problems with charged particles, and the MCAT will sometimes require us to do just that.

Most matter is electrically neutral, as a balance of positive and negative charges ensures a relative degree of stability. When charges are out of balance, the system can become electrically unstable. Even materials that are normally electrically neutral can acquire a net charge as result of friction. When you shuffle your feet across the carpet, negatively charged particles are transferred from the carpet to your feet, and these charges spread out over the total surface of your body. The shock that occurs when your hand gets close enough to a metal doorknob allows that excess charge to jump from your fingers to the knob, which acts as a **ground**—a means of returning charge to the earth. **Static charge buildup** or **static electricity** is more significant in drier air because lower humidity makes it easier for charge to become and remain separated.

Key Concept

The fundamental unit of charge is $e = 1.60 \times 10^{-19}$ C. A proton and an electron each have this amount of charge; the proton is positively charged ($q = +e$), while the electron is negatively charged ($q = -e$).

The SI unit of charge is the **coulomb**, and the fundamental unit of charge is

$$e = 1.60 \times 10^{-19}\ \text{C}$$

A proton and an electron each have this amount of charge, although the proton is positively charged ($q = +e$) while the electron is negatively charged ($q = -e$). Even though the proton and the electron share the same magnitude of charge, they do not share the same mass; the proton has a much greater mass than the electron.

Like mass and energy, electric charge is **governed by a law of conservation of charge**. This law states that charge can neither be created nor destroyed.

INSULATORS AND CONDUCTORS

Insulators and conductors vary in their ability to both hold and transfer charges. An **insulator** will not easily distribute a charge over its surface and will not transfer that charge to another neutral object very well—especially not to another insulator. On a molecular level, the electrons of insulators tend to be closely linked with their respective nuclei. By extension, most nonmetals are insulators. Experimentally, insulators serve as dielectric materials in capacitors as well as in isolating electrostatic experiments from the environment to prevent grounding.

In contrast, when a **conductor** is given a charge, the charges will distribute approximately evenly upon the surface of the conductor. Conductors are able to transfer and transport charges and are often used in circuits or electrochemical cells. Conductors are often conceptualized as nuclei surrounded by a sea of free electrons that are able to move rapidly throughout the material and are only loosely associated with the positive charges. Conductors are generally metals, although ionic (electrolyte) solutions are also effective conductors. Figure 5.1 demonstrates the behaviors of an insulator and a conductor when a negative charge is placed on them.

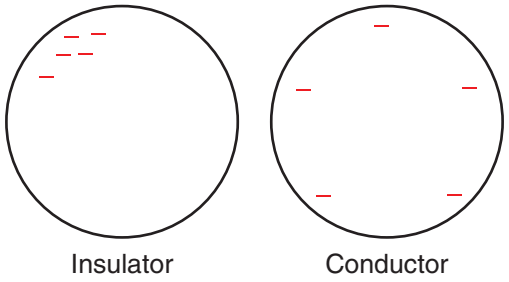

Figure 5.1. A Negatively Charged Insulator and Conductor
Insulators will not distribute charge over their surface; conductors will.

MCAT Concept Check 5.1:
Before you move on, assess your understanding of the material with these questions.

1. When placed one meter apart from each other, which will experience a greater acceleration: one coulomb of electrons or one coulomb of protons?

_____

2. Categorize the following materials as either conductors or insulators: blood, hair, copper, glass, iron, sulfuric acid, distilled water

   - Conductors:

   _____

   - Insulators:

   _____

3. What is the net charge of an object with one coulomb of electrons and 3 moles of neutrons?

_____

5.2 Coulomb's Law

Coulomb's law quantifies the magnitude of the electrostatic force F_e between two charges:

$$F_e = \frac{kq_1q_2}{r^2}$$

Equation 5.1

where F_e is the magnitude of the electrostatic force, k is Coulomb's constant, q_1 and q_2 are the magnitudes of the two charges, and r is the distance between the charges. **Coulomb's constant** (also called the **electrostatic constant**) is a number that depends on the units used in the equation. In SI units, $k = \frac{1}{4\pi\varepsilon_0} = 8.99 \times 10^9 \frac{\text{N} \cdot \text{m}^2}{\text{C}^2}$, where ε_0 represents the **permittivity of free space**, $8.85 \times 10^{-12} \frac{\text{C}^2}{\text{N} \cdot \text{m}^2}$. The direction of the force may be obtained by remembering that unlike charges attract and like charges repel. The force always points along the line connecting the centers of the two charges.

> **Example:** A positive charge is attracted to a negative charge a certain distance away. The charges are then moved so that they are separated by twice the distance. How has the force of attraction changed between them?
>
> **Solution:** Coulomb's law states that the force between two charges varies as the inverse of the square of the distance between them. Therefore, if the distance is doubled, the square of the distance is quadrupled, and the force is reduced to one-fourth of what it was originally. Note that it was not necessary to know the distance or the units being used.

A close examination of Coulomb's law reveals that it is remarkably similar in form to the equation for gravitational force. In the electrostatic force equation, the force magnitude is proportional to the charge magnitudes, and this is similar to the pro portional relationship between gravitational force and mass. In both equations, the

> **Example:** Negatively charged electrons are electrostatically attracted to positively charged protons. Because electrons and protons have mass, they will be gravitationally attracted to each other as well. What is the ratio of the electrostatic force to the gravitational force between an electron and proton? (Note: $m_p = 1.67 \times 10^{-27}$ kg, $m_e = 9.11 \times 10^{-31}$ kg, $e = 1.60 \times 10^{-19}$ C, $k = 8.99 \times 10^9 \frac{\text{N} \cdot \text{m}^2}{\text{C}^2}$, and $G = 6.67 \times 10^{-11} \frac{\text{N} \cdot \text{m}^2}{\text{kg}^2}$)

Bridge

Notice how Coulomb's law looks very similar to the gravitational force equation, but with a different constant and using charge rather than mass. It is this fact that should remind us that this equation is dealing with electrostatic force between two charges, just as the gravitation equation is dealing with the gravitational force between two bodies of mass. The gravitation equation is discussed in Chapter 1 of *MCAT Physics and Math Review*.

Solution: Both Coulomb's law and the universal law of gravitation state that the attractive forces between the electron and proton vary as the inverse of the square of the distance between them. The ratio between these forces can be calculated by dividing their magnitudes:

$$\frac{F_e}{F_g} = \frac{\left[\frac{kq_1q_2}{r^2}\right]}{\left[\frac{Gm_1m_2}{r^2}\right]} = \frac{kq_1q_2}{Gm_1m_2}$$

force magnitude is inversely proportional to the square of the distance of separation. These similarities ought to help you remember both equations on Test Day.

Now the values can be plugged in:

$$\frac{F_e}{F_g} = \frac{\left(8.99\times10^9\ \frac{N\cdot m^2}{C^2}\right)(1.60\times10^{-19}\ C)(1.60\times10^{-19}\ C)}{\left(6.67\times10^{-11}\ \frac{N\cdot m^2}{C^2}\right)(1.67\times10^{-27}\ kg)(9.11\times10^{-31}\ kg)}$$

$$\approx \frac{1.6}{6.67}\times10^{40} \approx 2.5\times10^{39}\ (\text{actual} = 2.27\times10^{39})$$

Note that the electrostatic attraction between the electron and proton is stronger than the gravitational attraction by a factor of almost 10^{40}. Also, note that setting up all of the variables before working out the math simplifies the process because a number of the variables cancel out during the division.

ELECTRIC FIELD

Every electric charge sets up a surrounding electric field, just like every mass creates a gravitational field. **Electric fields** make their presence known by exerting forces on other charges that move into the space of the field. Whether the force exerted through the electric field is attractive or repulsive depends on whether the stationary **test charge** q (the charge placed in the electric field) and the stationary **source charge** Q (which actually creates the electric field) are opposite charges (attractive) or like charges (repulsive).

The magnitude of an electric field can be calculated in one of two ways, both of which can be seen in the definitional equation for the electric field:

$$E = \frac{F_e}{q} = \frac{kQ}{r^2}$$

Equation 5.2

where E is the electric field magnitude in newtons per coulomb, F_e is the magnitude of the force felt by the test charge q, k is the electrostatic constant, Q is the source

Key Concept

Electric fields are produced by source charges (Q). When a test charge (q) is placed in an electric field (**E**), it will experience an electrostatic force ($\mathbf{F}_e$) equal to $q\mathbf{E}$.

charge magnitude, and r is the distance between the charges. The electric field is a vector quantity, and we will discuss the process of determining the direction of the electric field vector in a moment. Look closely: you can see that this equation for the electric field magnitude is derived simply by dividing both sides of Coulomb's law by the test charge q. In doing so, we arrive at two different methods for calculating the magnitude of the electric field at a particular point in space. The first method is to place a test charge q at some point within the electric field, measure the force exerted on that test charge, and define the electric field at that point in space as the ratio of the force magnitude to test charge magnitude $\left(\frac{F_e}{q}\right)$. One of the disadvantages of this method of calculation is that a test charge must actually be present in order for a force to be generated and measured. Sometimes, however, no test charge is actually within the electric field, so we need another way to measure the magnitude of that field.

Key Concept

By dividing Coulomb's law by the magnitude of the test charge, we arrive at two ways of determining the magnitude of the electric field at a point in space around the source charge.

The second method of calculating the electric field magnitude at a point in space does not require the presence of a test charge. We only need to know the magnitude of the source charge and the distance between the source charge and point in space at which we want to measure the electric field $\left(\frac{kQ}{r^2}\right)$. In this method, we need to know the value of the source charge to be able to calculate the electric field.

By convention, the direction of the electric field vector is given as the direction that a positive test charge would move in the presence of the source charge. If the source charge is positive, then the test charge would experience a repulsive force and would accelerate away from the positive source charge. On the other hand, if the source charge is negative, then the test charge would experience an attractive force and would accelerate toward the negative source charge. Therefore, positive charges have electric field vectors that radiate outward (that is, point away) from the charge, whereas negative charges have electric field vectors that radiate inward (point toward) the charge. These electric field vectors may be represented using field lines, as shown in Figure 5.2.

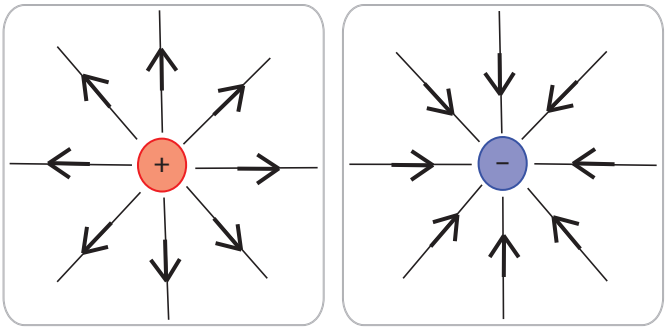

Figure 5.2. Field Lines around a Positive and Negative Source Charge

Key Concept

Field lines are used to represent the electric field vectors for a charge. They point away from a positive charge and point toward a negative charge. The denser the field lines, the stronger the electric field. Note that field lines of a single charge never cross each other.

Field lines are imaginary lines that represent how a positive test charge would move in the presence of the source charge. The field lines are drawn in the direction of the actual electric field vectors and also indicate the relative strength of the electric field

at a given point in the space of the field. When drawn on a sheet of paper, field lines look like the metal spokes of a bicycle wheel: the lines are closer together near the source charge and spread out at distances farther from the charge. Where the field lines are closer together, the field is stronger; where the lines are farther apart, the field is weaker. Because every charge exerts its own electric field, a collection of charges will exert a net electric field at a point in space that is equal to the vector sum of all the electric fields.

Because electric field and electrostatic force are both vector quantities, it is important to remember the conventions for their direction. If the test charge within a field is positive, then the force will be in the same direction as the electric field vector of the source charge; if the test charge is negative, then the force will be in the direction opposite to the field vector of the source charge.

MCAT Concept Check 5.2:

Before you move on, assess your understanding of the material with these questions.

1. What is the electric field midway between two negative charges in isolation?

   _____

2. What direction does a negative electrostatic force point? What direction does a positive electrostatic force point?

   - Negative electrostatic force:

     _____

   - Positive electrostatic force:

     _____

3. Draw the field lines for the electric field generated by an alpha particle $\left({}_{2}^{4}\mathrm{He}^{2+}\right)$:

4. How do distance and charge relate to electrostatic force and electric field?

   - Electrostatic force:

     _____

   - Electric field:

     _____

5.3 Electrical Potential Energy ★★

We have already defined potential energy as stored energy that can be used to do something or make something happen. There are different types of potential energy; gravitational, elastic, and chemical are three forms that you will need to know for Test Day. A fourth form is **electrical potential energy**. Similar to gravitational potential energy, this is a form of potential energy that is dependent on the relative position of one charge with respect to another charge or to a collection of charges. Electrical potential energy is given by the equation

$$U = \frac{kQq}{r}$$

Equation 5.3

If the charges are like charges (both positive or both negative), then the potential energy will be positive. If the charges are unlike (one positive and the other negative), then the potential energy will be negative. Remember that work and energy have the same unit (the joule), so we can define electrical potential energy for a charge at a point in space in an electric field as the amount of work necessary to bring the charge from infinitely far away to that point. Because $F_e = \frac{kQq}{r^2}$ and $W = Fd\cos\theta$, if we define d as the distance r that separates two charges and assume the force and displacement vectors to be parallel, then:

$$\Delta U = W = Fd\cos\theta = Fr \times 1 = \left(\frac{kQq}{r^2}\right)r = \frac{kQq}{r}$$

Consider two charges: a stationary negative source charge and a positive test charge that can be moved. Because these two charges are unlike, they will exert attractive forces between them. Therefore, the closer they are to each other, the more stable they will be. Opposite charges will have negative potential energy, and this energy will become increasingly negative as the charges are brought closer and closer together. Increasingly negative numbers are actually decreasing values because they are moving farther to the left of 0 on the number line. This decrease in energy represents an increase in stability.

Now let's consider two positive charges. As like charges, these will exert repulsive forces, and the potential energy of the system will be positive. Because like charges repel each other, the closer they are to each other, the less stable they will be. Remember that unlike gravitational systems, the forces of electrostatics can be either attractive or repulsive. In this case, the like charges will become more stable the farther apart they move because the magnitude of the electrical potential energy becomes a smaller and smaller positive number.

Key Concept

Electrical potential energy is the work necessary to move a test charge from infinity to a point in space in an electric field surrounding a source charge.

Key Concept

The electrical potential energy of a system will increase when two like charges move toward each other or when two opposite charges move apart. Conversely, the electrical potential energy of a system will decrease when two like charges move apart or when two opposite charges move toward each other.

Example: If a charge of $+2e$ and a charge of $-3e$ are separated by a distance of 3 nm, what is the potential energy of the system? (Note: e is the fundamental unit of charge equal to 1.6×10^{-19} C, and k is the electrostatic constant equal to $8.99 \times 10^{9} \frac{\text{N} \cdot \text{m}^2}{\text{C}^2}$.)

Solution: The equation for potential energy is $U = \frac{kQq}{r}$. From the question stem, we know that the charges are $+2e$ and $-3e$, and $r = 3 \text{ nm} = 3 \times 10^{-9}$ m. Plugging into the equation, we get:

$$U = \frac{\left(8.99 \times 10^{9} \frac{\text{N} \cdot \text{m}^2}{\text{C}^2}\right)\left(2 \times 1.6 \times 10^{-19} \text{ C}\right)\left(-3 \times 1.6 \times 10^{-19} \text{ C}\right)}{3 \times 10^{-9} \text{ m}}$$
$$\approx -45 \times 10^{-20} \text{ J} = -4.5 \times 10^{-19} \text{ J (actual} = -4.6 \times 10^{-19} \text{ J)}$$

MCAT Concept Check 5.3:

Before you move on, assess your understanding of the material with these questions.

1. How does a change in electrical potential energy from –4 J to –7 J reflect on the stability of a system?

_____

_____

2. Compare the relationship between electrical potential energy and Coulomb's law to the relationship between gravitational potential energy and the universal law of gravitation.

_____

_____

_____

3. How does electrical potential energy change between two particles as the distance between them increases?

_____

_____

_____

5.4 Electrical Potential

Electrical potential, discussed here, and electrical potential energy, discussed previously, sound like the same (or nearly the same) thing. They are not, although they are very closely related. In fact, **electrical potential** is defined as the ratio of the magnitude of a charge's electrical potential energy to the magnitude of the charge itself.

$$V = \frac{U}{q}$$

Equation 5.4

where V is the electrical potential measured in **volts (V)** and $1\ \text{V} = 1\ \frac{\text{J}}{\text{C}}$. Even if there is no test charge q, we can still calculate the electrical potential of a point in space in an electric field as long as we know the magnitude of the source charge and the distance from the source charge to the point in space in the field. By dividing $U = \frac{kQq}{r}$ by q, we get:

$$V = \frac{kQ}{r}$$

Equation 5.5

Electrical potential is a scalar quantity, and its sign is determined by the sign of the source charge Q. For a positive source charge, V is positive, but for a negative source charge, V is negative. For a collection of charges, the total electrical potential at a point in space is the scalar sum of the electrical potential due to each charge.

Because electrical potential is inversely proportional to the distance from the source charge, a potential difference will exist between two points that are at different distances from the source charge. If V_a and V_b are the electrical potentials at points a and b, respectively, then the **potential difference** between them, known as **voltage**, is $V_b - V_a$. From the equation for electrical potential above, we can further define potential difference as:

$$\Delta V = V_b - V_a = \frac{W_{ab}}{q}$$

Equation 5.6

where W_{ab} is the work needed to move a test charge q through an electric field from point a to point b. The work depends only on the potentials at the two points a and b and is independent of the actual pathway taken between a and b. Like gravitational force, the electrostatic force is a conservative force.

We've already seen that charges, if allowed, will move spontaneously in whatever direction results in a decrease in electrical potential energy. For a positive test charge, this means moving from a position of higher electrical potential to a position of lower electrical potential. The voltage, $\Delta V = V_b - V_a$, is negative in this case; because q is positive (for a positive test charge), W_{ab} must also be negative, which represents a decrease in electrical potential energy.

MCAT Expertise

$F_e = \frac{kQq}{r^2}$	$U = \frac{kQq}{r}$
$E = \frac{kQ}{r^2}$	$V = \frac{kQ}{r}$

These are essential equations for Test Day. Know how they relate to each other and when to use them. By memorizing Coulomb's law, you should be able to recreate the table through mathematical manipulation. From left to right, multiply by r; from top to bottom, divide by q.

Mnemonic

The "plus" end of a battery is the high-potential end, and the "minus" end of a battery is the low-potential end. Positive charge moves from + to – (the definition of current) while negative charge moves from – to +.

Key Concept

Electrical potential is the ratio of the work done to move a test charge from infinity to a point in an electric field surrounding a source charge divided by the magnitude of the test charge.

Now let's consider a negative test charge. A negative test charge will spontaneously move from a position of lower electrical potential to a position of higher electrical potential. The voltage, $\Delta V = V_b - V_a$, is positive in this case; because q is negative (for a negative test charge), W_{ab} must also be negative, which again represents a decrease in electrical potential energy. The takeaway: positive charges will spontaneously move in the direction that *decreases* their electrical potential (negative voltage), whereas negative charges will spontaneously move in the direction that *increases* their electrical potential (positive voltage)—yet, in both cases, the electrical potential *energy* is decreasing.

MCAT Concept Check 5.4:
Before you move on, assess your understanding of the material with these questions.

1. What is the difference between electrical potential and voltage?

_____

_____

_____

2. How will a charge that is placed at a point of zero electrical potential move relative to a source charge?

_____

_____

_____

3. True or False: The units of electrical potential energy and electrical potential are different.

Bridge

Create analogies between mechanics and electrostatics to familiarize yourself with these concepts. Electric field is like a gravitational field, and it exerts forces on charges much like a gravitational field exerts forces on masses. A test charge has a particular electrical potential energy at a given electrical potential, depending on the magnitude of its charge, much like a mass has a particular gravitational potential energy, depending on the magnitude of its mass. These mechanics concepts are discussed in Chapters 1 and 2 of *MCAT Physics and Math Review*.

5.5 Special Cases in Electrostatics ★

In this section, we will explore some of the unique setups in electrostatics that are common on the MCAT.

EQUIPOTENTIAL LINES

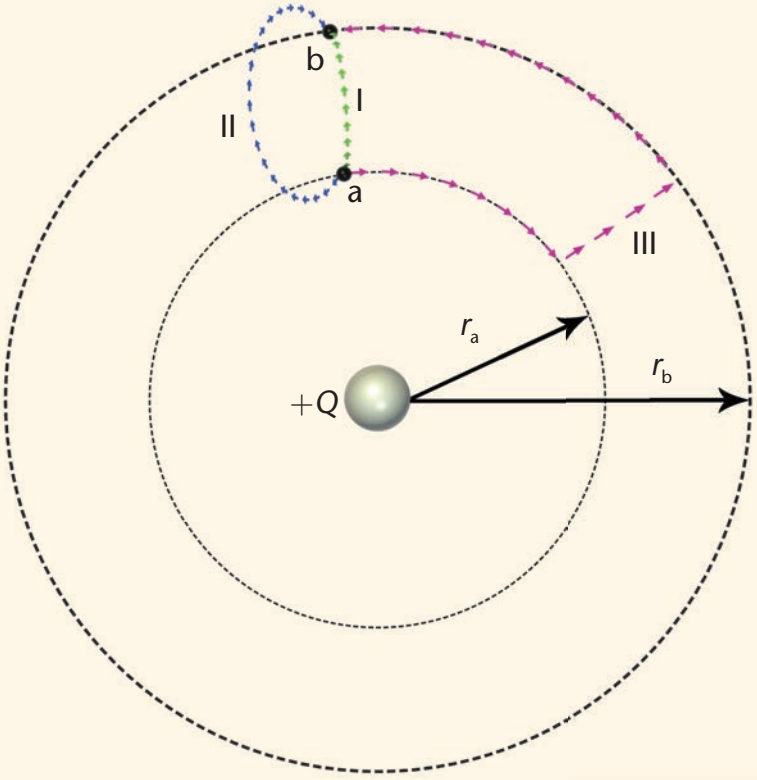
An **equipotential line** is a line on which the potential at every point is the same. That is, the potential difference between any two points on an equipotential line is zero. Drawn on paper, equipotential lines may look like concentric circles surrounding a source charge. In three-dimensional space, these equipotential lines would actually be spheres surrounding the source charge. From the equation for electrical potential, we can see that no work is done when moving a test charge q from one point on an

Bridge

Because the work to move a charge from one equipotential line to another does not depend on the path between them, we know that we are dealing only with conservative forces when moving the charge. Conservative and nonconservative forces are discussed in Chapter 2 of *MCAT Physics and Math Review*.

equipotential line to another. Work will be done in moving a test charge q from one line to another, but the work depends only on the potential difference of the two lines and not on the pathway taken between them. This is entirely analogous to the displacement of an object horizontally on a level surface. Because the object's height above the ground has not changed, its gravitational potential energy is unchanged. Furthermore, a change in the object's gravitational potential energy will not depend on the pathway taken from one height to another but only on the actual vertical displacement.

Example: In the diagram below, an electron goes from point a to point b in the vicinity of a very large positive charge. The electron could be made to follow any of the paths shown. Which path requires the least work to get the electron charge from a to b?



Solution: As stated, the work depends only on the potential difference and not on the path, so any of the paths shown would require the same amount of work in moving the electron from a to b. Note that because the source charge is positive, point b is at a *lower* electrical potential than point a. However, because the test charge is negative, the electrical potential energy is *higher* at point b than point a. This should make sense: the electron will have to gain energy to be moved farther away from positive source charge.

ELECTRIC DIPOLES

Much of the reactivity of organic compounds is based on separation of charge. The **electric dipole**, which results from two equal and opposite charges being separated a small distance *d* from each other, can be transient (as in the case of the moment-to-moment changes in electron distribution that create London dispersion forces) or permanent (as in the case of the molecular dipole of water or the carbonyl functional group).

The electric dipole can be visualized as a barbell: the equal weights on either end of the bar represent the equal and opposite charges separated by a small distance, represented by the length of the bar. We'll analyze the generic dipole in Figure 5.3 and then work through the specific example of one of the most important electric dipoles, the water molecule.

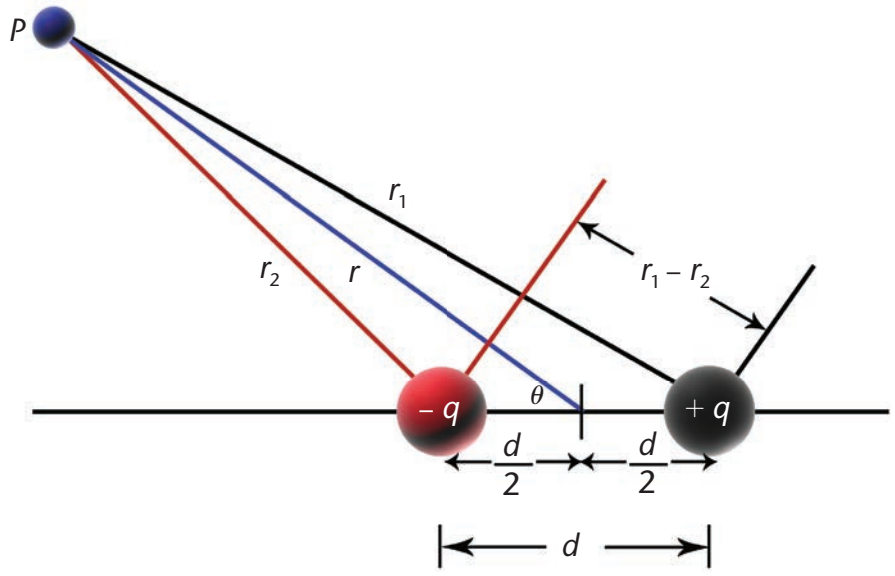


Figure 5.3. A Generic Dipole

The dipole in Figure 5.3 has charges $+q$ and $-q$ separated by a distance d. Notice that $+q$ and $-q$ are source charges, even though they are written in lowercase. Given the dipole, we may want to calculate the electrical potential at some point P near the dipole. The distance between the point in space and $+q$ is r_1; the distance between the point in space and $-q$ is r_2; the distance between the point in space and the midpoint of the dipole is r. We know that for a collection of charges, the electrical potential P is the scalar sum of the potentials due to each charge at that point. In other words,

$$V = \frac{kq}{r_1} - \frac{kq}{r_2}$$
$$= \frac{kq(r_2 - r_1)}{r_1 r_2}$$

For points in space relatively distant from the dipole (compared to d), the product of r_1 and r_2 is approximately equal to the square of r, and $r_1 - r_2$ is approximately equal to $d \cos \theta$. When we plug these approximations into the equation above, we get

$$V = \frac{kqd}{r^2}\cos\theta$$

Equation 5.7

The product of charge and separation distance is defined as the **dipole moment** (**p**) with SI units of C · m:

$$\mathbf{p} = q\mathbf{d}$$

Equation 5.8

The dipole moment is a vector, but its direction is defined differently by physicists and chemists. Physicists define the vector along the line connecting the charges (the dipole axis), with the vector pointing from the negative charge toward the positive charge. Chemists usually reverse this convention, having **p** point from the positive charge toward the negative charge. Sometimes, chemists draw a crosshatch at the tail end of the dipole vector to indicate that the tail end is the positive charge.

Example: The H_2O molecule has a dipole moment of 1.85 D. Calculate the electrical potential due to a water molecule at a point 89 nm away along the axis of the dipole. (Note: $k = 8.99 \times 10^9 \frac{N \cdot m^2}{C^2}$ and 1 D (debye) = 3.34×10^{-30} C · m)

Solution: Because the question asks for the potential along the axis of the dipole, the angle θ is 0°. Substitute the values into the equation for the dipole potential and multiply 1.85 D by 3.34×10^{-30} to convert it to C · m:

$$V = \frac{kqd}{r^2}\cos\theta = \frac{kp}{r^2}\cos\theta$$

$$= \frac{\left(8.99\times10^9\ \frac{N\cdot m^2}{C^2}\right)(1.85\ D)\left(\frac{3.34\times10^{-30}\ C\cdot m}{1\ D}\right)}{(89\times10^{-9}\ m)^2}$$

$$\approx \frac{\left(9\times10^9\right)\left(6\times10^{-30}\right)}{(8.1\times10^{-15})} = 7\times10^{-6}\ V\ (\text{actual} = 7.01\times10^{-6}\ V)$$

One very important equipotential line to be aware of is the plane that lies halfway between $+q$ and $-q$, called the **perpendicular bisector of the dipole**. Because the angle between this plane and the dipole axis is 90° (and cos 90° = 0), the electrical

potential at any point along this plane is 0. The magnitude of the electric field on the perpendicular bisector of the dipole can be approximated as

$$E = \frac{1}{4\pi\varepsilon_0} \times \frac{p}{r^3}$$

Equation 5.9

The electric field vectors at the points along the perpendicular bisector will point in the direction opposite to **p** (as defined directionally by physicists).

The dipole is a classic example of a setup upon which torques can act. In the absence of an electric field, the dipole axis can assume any random orientation. However, when the electric dipole is placed in a uniform external electric field, each of the equal and opposite charges of the dipole will experience a force exerted on it by the field. Because the charges are equal and opposite, the forces acting on the charges will also be equal in magnitude and opposite in direction, resulting in a situation of translational equilibrium. There will be, however, a net torque about the center of the dipole axis:

$$\begin{aligned}\tau &= \left(\frac{d}{2}\right)F_e \sin\theta + \left(\frac{d}{2}\right)F_e \sin\theta \\ &= dF_e \sin\theta \\ &= d(qE)\sin\theta \\ &= pE\sin\theta\end{aligned}$$

Thus, the net torque on a dipole can be calculated from the equation

$$\tau = pE \sin\theta$$

Equation 5.10

where p is the magnitude of the dipole moment ($p = qd$), E is the magnitude of the uniform external electric field, and θ is the angle the dipole moment makes with the electric field. This torque will cause the dipole to reorient itself so that its dipole moment, p, aligns with the electric field E, as shown in Figure 5.4.

MCAT Expertise

The dipole is a great example of how the MCAT can test kinematics and dynamics in an electrostatics setting. For a dipole at some angle in an external electric field, there will be translational equilibrium, but not rotational equilibrium. This is because the forces are opposite directions (left and right in Figure 5.4), but the torques are in the same direction (clockwise for both).

MCAT Expertise

The electric dipole is most likely to be tested qualitatively or in the context of a passage or reaction on Test Day. It is unlikely that these mathematical relations will be presented or tested without background.

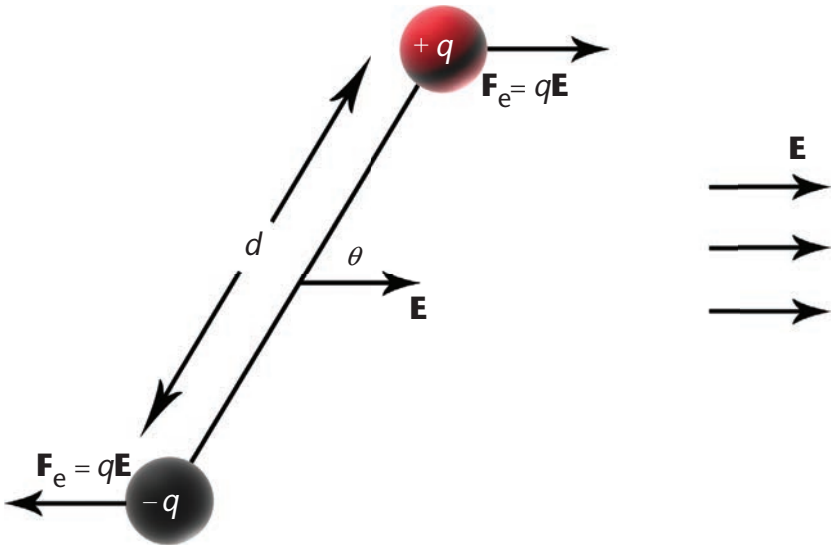

Figure 5.4. Torque on a Dipole from an External Electric Field

MCAT Concept Check 5.5:

Before you move on, assess your understanding of the material with these questions.

1. Define the following terms:
   - Equipotential lines:

     _____
   - Electric dipole:

     _____

2. What is the voltage between two points on an equipotential line? Will this voltage cause a charge to move along the line?

   _____

   _____

   _____

3. Why is the electrical potential at points along the perpendicular bisector of a dipole 0?

   _____

   _____

4. What is the behavior of an electric dipole when exposed to an external electric field?

_____

_____

5.6 Magnetism ★★★

Any moving charge creates a **magnetic field**. Magnetic fields may be set up by the movement of individual charges, such as an electron moving through space; by the mass movement of charge in the form of a current though a conductive material, such as a copper wire; or by permanent magnets. The SI unit for magnetic field strength is the **tesla** (**T**), where $1\ \mathrm{T} = 1\ \frac{\mathrm{N} \cdot \mathrm{s}}{\mathrm{m} \cdot \mathrm{C}}$. The size of the tesla unit is quite large, so small magnetic fields are sometimes measured in **gauss**, where $1\ \mathrm{T} = 10^4$ gauss.

Key Concept

Any moving charge, whether a single electron traveling through space or a current through a conductive material, creates a **magnetic field**. The SI unit for magnetic field strength is the tesla (T).

All materials can be classified as diamagnetic, paramagnetic, or ferromagnetic. **Diamagnetic materials** are made of atoms with no unpaired electrons and that have no net magnetic field. These materials are slightly repelled by a magnet and so can be called weakly antimagnetic. Diamagnetic materials include common materials that you wouldn't expect to get stuck to a magnet: wood, plastics, water, glass, and skin, just to name a few.

The atoms of both paramagnetic and ferromagnetic materials have unpaired electrons, so these atoms do have a net magnetic dipole moment, but the atoms in these materials are usually randomly oriented so that the material itself creates no net magnetic field. **Paramagnetic materials** will become weakly magnetized in the presence of an external magnetic field, aligning the magnetic dipoles of the material with the external field. Upon removal of the external field, the thermal energy of the individual atoms will cause the individual magnetic dipoles to reorient randomly. Some paramagnetic materials include aluminum, copper, and gold.

Ferromagnetic materials, like paramagnetic materials, have unpaired electrons and permanent atomic magnetic dipoles that are normally oriented randomly so that the material has no net magnetic dipole. However, unlike paramagnetic materials, ferromagnetic materials will become strongly magnetized when exposed to a magnetic field or under certain temperatures. Common ferromagnetic materials are include iron, nickel and cobalt. Bar magnets are ferromagnetic materials with a north and south pole. Field lines exit the north pole and enter the south pole. Because magnetic

field lines are circular, it is impossible to have a monopole magnet. If two bar magnets are allowed to interact, opposite poles will attract each other, while like poles will repel each other.

MAGNETIC FIELDS

Because any moving charge creates a magnetic field, we would certainly expect that a collection of moving charge, in the form of a current through a conductive wire, would produce a magnetic field in its vicinity. The configuration of the magnetic field lines surrounding a current-carrying wire will depend on the shape of the wire. Two special cases that are commonly tested on the MCAT include a long, straight wire and a circular loop of wire (with particular attention paid to the magnetic field at the center of that loop).

For an infinitely long and straight current-carrying wire, we can calculate the magnitude of the magnetic field produced by the current I in the wire at a perpendicular distance, r, from the wire as:

$$B = \frac{\mu_0 I}{2\pi r}$$

Equation 5.11

where B is the magnetic field at a distance r from the wire, μ_0 is the **permeability of free space** ($4\pi \times 10^{-7} \frac{\text{T} \cdot \text{m}}{\text{A}}$), and I is the current. The equation demonstrates an inverse relationship between the magnitude of the magnetic field and the distance from the current. Straight wires create magnetic fields in the shape of concentric rings. To determine the direction of the field vectors, use a **right-hand rule**. (This is one of two right-hand rules used in magnetism.) Point your thumb in the direction of the current and wrap your fingers around the current-carrying wire. Your fingers then mimic the circular field lines, curling around the wire.

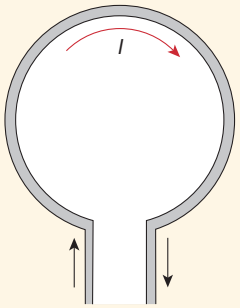
For a circular loop of current-carrying wire of radius r, the magnitude of the magnetic field at the center of the circular loop is given as:

$$B = \frac{\mu_0 I}{2r}$$

Equation 5.12

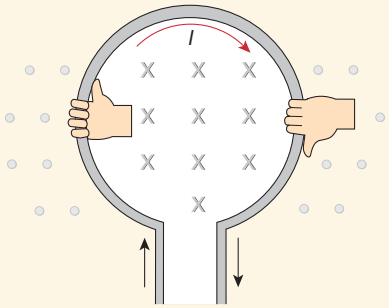
You'll notice that the two equations are quite similar—the obvious difference being that the equation for the magnetic field at the center of the circular loop of wire does not include the constant π. The less obvious difference is that the first expression gives the magnitude of the magnetic field at any perpendicular distance, r, from the current-carrying wire, while the second expression gives the magnitude of the magnetic field only at the center of the circular loop of current-carrying wire with radius r.

Example: Suppose a wire is formed into a loop that carries a current of 0.25 A in a clockwise direction, as shown here:



Determine the direction of the magnetic field produced by this loop within the loop and outside the loop. If the loop has a diameter of 1 m, what is the magnitude of the magnetic field at the center of the loop?

Solution: Use the right-hand rule to determine the direction of the magnetic field within and outside the loop, as shown here:



Align your right thumb with the current at any point in the loop. When you encircle the wire with the remaining fingers of your right hand, your fingers should point into the page within the loop and out of the page outside of the loop.

To determine the magnitude of the magnetic field at the center, use the equation for a loop of wire:

$$B = \frac{\mu_0 I}{2r}$$

$$= \frac{\left(4\pi \times 10^{-7} \frac{\text{T} \cdot \text{m}}{\text{A}}\right)(0.25\ \text{A})}{2 \times 0.5\ \text{m}} \approx 3.14 \times 10^{-7}\ \text{T} = 3.14 \times 10^{-3}\ \text{gauss}$$

MAGNETIC FORCES

Now that we've reviewed the ways in which magnetic fields can be created, let's examine the forces that are exerted by magnetic fields on moving charges. Magnetic fields exert forces only on other moving charges. That is, charges do not "sense" their own fields; they only sense the field established by some external charge or collection of charges. Therefore, in our discussion of the magnetic force on moving charges and on current-carrying wires, we will assume the presence of a fixed and uniform external magnetic field. Note that charges often have both electrostatic and magnetic forces acting on them at the same time; the sum of these electrostatic and magnetic forces is known as the **Lorentz force**.

Force on a Moving Charge

When a charge moves in a magnetic field, a **magnetic force** may be exerted on it, the magnitude of which can be calculated as follows:

$$F_B = qvB \sin\theta$$

Equation 5.13

where q is the charge, v is the magnitude of its velocity, B is the magnitude of the magnetic field, and θ is the smallest angle between the velocity vector **v** and the magnetic field vector **B**. Notice that the magnetic force is a function of the sine of the angle, which means that the charge must have a perpendicular component of velocity in order to experience a magnetic force. If the charge is moving parallel or antiparallel to the magnetic field vector, it will experience no magnetic force.

Here we will introduce the second **right-hand rule** that you should practice in anticipation of Test Day. To determine the direction of the magnetic force on a moving charge, first position your right thumb in the direction of the velocity vector. Then, put your fingers in the direction of the magnetic field lines. Your palm will point in the direction of the force vector for a positive charge, whereas the back of your hand will point in the direction of the force vector for a negative charge.

Key Concept

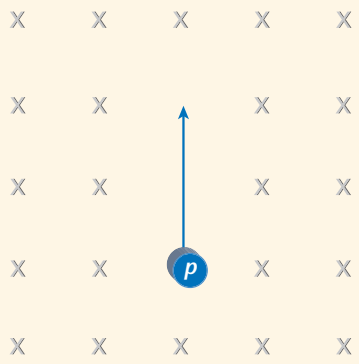
Remember that sin 0° and sin 180° equal zero. This means that any charge moving parallel or antiparallel to the direction of the magnetic field will experience no force from the magnetic field.

Mnemonic

Parts of the right-hand rule for magnetic force:

- Thumb—velocity (indicates direction of movement, like a hitchhiker's thumb)
- Fingers—field lines (fingers are parallel like the uniform magnetic field lines)
- Palm—force on a positive charge (you might give a "high five" to a positive person)
- Back of hand—force on a negative charge (you might give a backhand to a negative person)

Example: Suppose a proton is moving with a velocity of 15 $\frac{\text{m}}{\text{s}}$ toward the top of the page through a uniform magnetic field of 3.0 T directed into the page, as shown here:



What is the magnitude and direction of the magnetic force on the proton? Describe the motion that will result from this setup. (Note: The charge of a proton is 1.60×10^{-19} C, and its mass is 1.67×10^{-27} kg.)

Solution: Start by determining the magnitude of the force:

$$\begin{aligned} F_B &= qvB\sin\theta \\ &= (1.60\times10^{-19}\text{ C})\left(15\,\frac{\text{m}}{\text{s}}\right)(3.0\text{ T})\sin 90^\circ \\ &= 7.2\times10^{-18}\text{ N} \end{aligned}$$

To determine the direction, use the right-hand rule. Your thumb should point up the page in the direction of **v**. Your fingers should point into the page in the direction of **B**. Protons are positively charged; thus the force, $\mathbf{F}_B$, is in the direction of your palm, which is to the left. Note that **v** and $\mathbf{F}_B$ will always be perpendicular to each other; this implies that uniform circular motion will occur in this field, with $\mathbf{F}_B$ pointing radially inward toward the center of the circle.

If the centripetal force is the magnetic force, then we can set these two equations equal to each other:

$$F_c = F_B$$

$$\frac{mv^2}{r} = qvB\sin\theta$$

$$mv = qBr\sin 90^\circ$$

$$r = \frac{mv}{qB} = \frac{(1.67\times10^{-27}\text{ kg})\left(15\,\frac{\text{m}}{\text{s}}\right)}{(1.60\times10^{-19}\text{ C})(3.0\text{ T})} \approx 5\times10^{-8}\text{ m}\,(\text{actual} = 5.2\times10^{-8}\text{ m})$$

Thus, the proton will move in a circle with a radius of 52 nm.

Force on a Current-Carrying Wire

We've just examined the force that can be created by a magnetic field when a point charge moves through the field, so it should not come as a surprise that a current-carrying wire placed in a magnetic field may also experience a magnetic force. For a straight wire, the magnitude of the force created by an external magnetic field, F_B, is:

$$F_B = ILB \sin\theta$$

Equation 5.14

where I is the current, L is the length of the wire in the field, B is the magnitude of the magnetic field, and θ is the angle between **L** and **B**. The same right-hand rule can be used for a current-carrying wire in a field as for a moving point charge; just remember that current is considered the flow of positive charge.

Example: Suppose a wire of length 2.0 m is conducting a current of 5.0 A toward the top of the page and through a 30 gauss uniform magnetic field directed into the page. What is the magnitude and direction of the magnetic force on the wire?

Solution: Because 1 T = 10^4 gauss, 1 gauss = 10^{-4} T, and 30 gauss = 30×10^{-4} T = 3×10^{-3} T. The wire is conducting current toward the top of the page, and the magnetic field points into the page; therefore, the current is perpendicular to the magnetic field. The angle between them is $\theta = 90°$. Now, plug into the equation:

$$\begin{aligned} F_B &= ILB\sin\theta \\ &= (5.0\text{ A})(2.0\text{ m})(3\times10^{-3}\text{ T})(\sin 90^\circ) \\ &= 30\times10^{-3} = 3\times10^{-2}\text{ N} \end{aligned}$$

To determine the direction, use the right-hand rule. Your thumb should point up the page in the direction of **L**. Your fingers should point into the page in the direction of **B**. Current is a flow of positive charge; thus, the force, $\mathbf{F}_B$, is in the direction of your palm, which is to the left.

MCAT Concept Check 5.6:

Before you move on, assess your understanding of the material with these questions.

1. What are the requirements to have a nonzero electric field? A nonzero magnetic field? A nonzero magnetic force?
   - Nonzero electric field: _____
   - Nonzero magnetic field: _____
   - Nonzero magnetic force: _____

2. Which would experience a larger magnetic field: an object placed five meters to the left of a current carrying wire, or an object placed at the center of a circle with a radius of five meters. (Note: Assume the current is constant; $\mu_0 = 4\pi \times 10^{-7} \frac{T \cdot m}{A}$)

_____

_____

_____

3. For each of the following combinations of velocity and magnetic field directions, determine the direction of the magnetic force on the given particle:

v	B	Particle	F
Up the page	Left	Electron	
Into the page	Out of the page	Proton	
Right	Into the page	Proton	
Out of the page	Left	Electron	
Down the page	Right	Neutron	

Conclusion

In this chapter, we reviewed the very notion of charge, reminding ourselves that charge comes in two varieties: positive and negative. We also explored the fact that charges travel differently within insulators and conductors. We learned that charges establish electric fields through which they can exert forces on other charges. We relied on similarities between electrical and gravitational systems to better understand Coulomb's law and the nature of the forces that exist between charged particles. Don't forget that electrical forces can be repulsive as well as attractive, which is one of the differences between electrical and gravitational systems. Charges contain electrical potential energy, which we defined as their energy of position with respect to other charges. Charges move within an electric field from one position of

electrical potential to another; they will move spontaneously through an electrical potential difference, or voltage, in whichever direction results in a decrease in the charge's electrical potential energy. Then, we considered the geometry of the electric dipole and derived the equation for calculating the electrical potential at any point in space around the dipole. Finally, we considered magnetic fields and forces. In the next chapter, we'll examine moving charges as they interact with circuit elements and complete our understanding of electricity.

CONCEPT SUMMARY

Charges

- The SI unit of charge is the **coulomb**.
- **Protons** have a positive charge and **electrons** have a negative charge.
  - Both protons and electrons possess the fundamental unit of charge ($e = 1.60 \times 10^{-19}$ C).
  - Protons and electrons have different masses.
- Opposite charges exert **attractive** forces, and like charges exert **repulsive** forces.
- **Conductors** allow the free and uniform passage of electrons when charged.
- **Insulators** resist the movement of charge and will have localized areas of charge that do not distribute over the surface of the material.

Coulomb's Law

- **Coulomb's law** gives the magnitude of the electrostatic force vector between two charges. The force vector always points along the line connecting the centers of the two charges.
- Every charge generates an **electric field**, which can exert forces on other charges.
- The electric field is the ratio of the force that is exerted on a test charge to the magnitude of that charge.
  - Electric field vectors can be represented as **field lines** that radiate outward from positive source charges and radiate inward to negative source charges.
  - Positive test charges will move in the direction of the field lines; negative test charges will move in the direction opposite of the field lines.

Electrical Potential Energy

- **Electrical potential energy** is the amount of work required to bring the test charge from infinitely far away to a given position in the vicinity of a source charge.
- The electrical potential energy of a system will increase when two like charges move toward each other or when two opposite charges move further apart.
- The electrical potential energy of a system will decrease when two opposite charges move toward each other or when two like charges move further apart.

Electrical Potential

- **Electrical potential** is the electrical potential energy per unit charge.
- Different points in the space of an electric field surrounding a source charge will have different electrical potential values.

- Potential difference (**voltage**) is the change in electrical potential that accompanies the movement of a test charge from one position to another.
  - Potential difference is path independent and depends only on the initial and final positions of the test charge.
  - The units for both electrical potential and voltage are volts.
- Test charges will move spontaneously in whichever direction results in a decrease in their electrical potential energy.
  - Positive test charges will move spontaneously from high potential to low potential.
  - Negative test charges will move spontaneously from low potential to high potential.

Special Cases in Electrostatics

- **Equipotential lines** designate the set of points around a source charge or multiple source charges that have the same electrical potential.
  - Equipotential lines are always perpendicular to electric field lines.
  - Work will be done when a charge is moved from one equipotential line to another; the work is independent of the pathway taken between the lines.
  - No work is done when a charge moves from a point on an equipotential line to another point on the same equipotential line.
- Two charges of opposite sign separated by a fixed distance d generate an **electric dipole**.
  - In an external electric field, an electric dipole will experience a net torque until it is aligned with the electric field vector.
  - An electric field will not induce any translational motion in the dipole regardless of its orientation with respect to the electric field vector.

Magnetism

- **Magnetic fields** are created by magnets and moving charges.
- The SI unit for the magnetic field is the **tesla** (**T**; 1 T = 10,000 gauss).
- **Diamagnetic materials** possess no unpaired electrons and are slightly repelled by a magnet.
- **Paramagnetic materials** possess some unpaired electrons and become weakly magnetic in an external magnetic field.
- **Ferromagnetic materials** possess some unpaired electrons and become strongly magnetic in an external magnetic field.
- Magnets have a north and a south pole; field lines point from the north to the south pole.

- Current-carrying wires create magnetic fields that are concentric circles surrounding the wire.
- External magnetic fields exert forces on charges moving in any direction except parallel or antiparallel to the field.
- Point charges may undergo uniform circular motion in a uniform magnetic field wherein the centripetal force is the magnetic force acting on the point charge.
- The direction of the magnetic force on a moving charge or current-carrying wire is determined using the right-hand rule.
- The **Lorentz force** is the sum of the electrostatic and magnetic forces acting on a body.

ANSWERS TO CONCEPT CHECKS

5.1

1. The electrons will experience the greater acceleration because they are subject to the same force as the protons but have a significantly smaller mass.
2. Conductors: blood, copper, iron, sulfuric acid; insulators: hair, glass, distilled water
3. The net charge will be –1 C; neutrons do not contribute charge.

5.2

1. The electric field would be 0 because the two charges are the same. In this case, the fields exerted by each charge at the midpoint will cancel out and there will be no electric field.
2. For a pair of charges, a negative electrostatic force points from one charge to the other (attractive), while a positive electrostatic force points from one charge away from the other (repulsive).
3. 
4. Electrostatic force is directly related to each charge and related to the distance by an inverse square relationship. Electric field is unrelated to test charge but is still related to distance by an inverse square relationship. Note that it is the source charge that creates the electric field—not the test charge—so we cannot use the equation $E = \frac{F_e}{q}$ to determine a relationship.

5.3

1. A decrease in potential energy indicates that the system has become more stable. Keep in mind that negative numbers with larger absolute values are more negative, and represent a decrease in value from negative numbers with smaller absolute values (that is, $-4 > -7$ even though $|-4| < |-7|$).
2. Electrical potential energy is Coulomb's law multiplied by distance, whereas gravitational potential energy is the universal law of gravitation multiplied by distance.

3. If both particles have the same charge, the electrical potential energy decreases as distance increases. If the two particles have opposite charges, then the electrical potential energy increases as distance increases.

5.4

1. Electrical potential is the ratio of a charge's electrical potential energy to the magnitude of the charge itself. Voltage, or potential difference, is a measure of the change in electrical potential between two points, which provides an indication of the tendency toward movement in one direction or the other.
2. A charge will move in such a way to minimize its potential energy. Placing a charge at a point of zero electrical potential does not indicate that there is zero potential difference, so the charge may or may not move—and if it moves, it may move toward or away from the source charge depending on the sign of the source charge and test charge.
3. True. Electrical potential energy is measured in joules (J), while electrical potential and potential difference (voltage) are measured in volts (V).

5.5

1. Equipotential lines are the sets of points within space at which the potential difference between any two points is zero. This is best visualized as concentric spheres surrounding a source charge. An electric dipole is the separation of charge within a molecule such that there is a permanent or temporary region of equal and opposite charges at a particular distance.
2. There is no voltage between two points on an equipotential line, so there will be no acceleration along the line. However, there is a potential difference between different sets of equipotential lines, which can cause particles to move and accelerate.
3. The perpendicular bisector of an electric dipole is an equipotential plane that is perpendicular to the axis of the dipole. As such, the equation $V = \frac{kqd}{r^2}\cos\theta$ is necessarily equal to 0 because cos 90° = 0.
4. A dipole will rotate within an external electric field such that its dipole moment aligns with the field.

5.6

1. To create an electric field, one needs a charge. To create a magnetic field, one needs a charge that must also be moving. To create a magnetic force, one needs an external electric field acting on a charge moving any direction except parallel or antiparallel to the external field.
2. We need not determine the actual values of the magnetic fields in these two cases and can compare the two equations instead. The magnetic field created by the current-carrying wire is given by $B = \frac{\mu_0 I}{2\pi r}$; the magnetic field created by the

loop of wire is given by $B = \frac{\mu_0 I}{2r}$. μ_0, I, and r are the same in both equations. Therefore, the magnetic field at the center of the loop must be larger because the denominator in that equation does *not* include π.

3.

v	B	Particle	F
Up the page	Left	Electron	Into the page
Into the page	Out of the page	Proton	None (sin 180° = 0)
Right	Into the page	Proton	Up the page
Out of the page	Left	Electron	Up the page
Down the page	Right	Neutron	None ($q = 0$)

EQUATIONS TO REMEMBER

(5.1) **Coulomb's law:** $F_e = \frac{kq_1q_2}{r^2}$

(5.2) **Electric field:** $E = \frac{F_e}{q} = \frac{kQ}{r^2}$

(5.3) **Electrical potential energy:** $U = \frac{kQq}{r}$

(5.4) **Electrical potential (from electrical potential energy):** $V = \frac{U}{q}$

(5.5) **Electrical potential (from source charge):** $V = \frac{kQ}{r}$

(5.6) **Voltage:** $\Delta V = V_b - V_a = \frac{W_{ab}}{q}$

(5.7) **Electrical potential near a dipole:** $V = \frac{kqd}{r^2}\cos\theta$

(5.8) **Dipole moment:** $\mathbf{p} = q\mathbf{d}$

(5.9) **Electric field on the perpendicular bisector of a dipole:** $E = \frac{1}{4\pi\varepsilon_0} \times \frac{p}{r^3}$

(5.10) **Torque on a dipole in an electric field:** $\tau = pE \sin\theta$

(5.11) **Magnetic field from a straight wire:** $B = \frac{\mu_0 I}{2\pi r}$

(5.12) **Magnetic field from a loop of wire:** $B = \frac{\mu_0 I}{2r}$

(5.13) **Magnetic force on a moving point charge:** $F_B = qvB \sin\theta$

(5.14) **Magnetic force on a current-carrying wire:** $F_B = ILB \sin\theta$

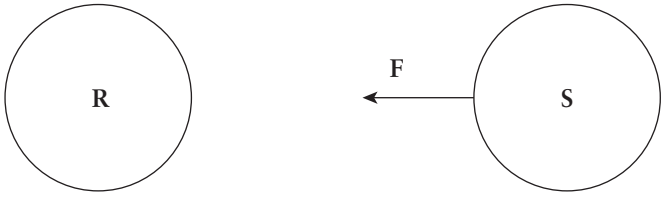
Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

Questions 1–3 refer to the figure below, in which F represents the electrostatic force exerted on charged particle S by charged particle R.



1. In the figure, the magnitude of the electric force on R due to S is:

A. $\frac{F}{2}$.
B. F.
C. $2F$.
D. $4F$.

2. If the distance between the centers of the spheres is halved, the magnitude of the force on S due to R will be:

A. $\frac{F}{2}$.
B. $\frac{F}{4}$.
C. $2F$.
D. $4F$.

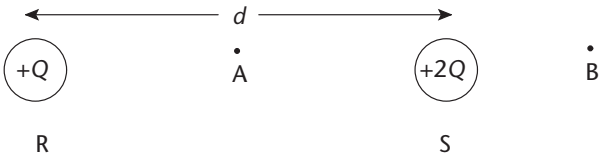
3. Assume the direction of **F** is the same direction as the electric field between R and S. If an electron were placed midway between R and S, the resultant electric force on the electron would be:

A. toward R.
B. toward S.
C. upward in the plane of the page.
D. downward in the plane of the page.

4. If the electric field at a distance r away from charge Q is 36 $\frac{\text{N}}{\text{C}}$, what is the ratio of the electric fields at r, $2r$, and $3r$?

A. 9:3:1
B. 36:9:4
C. 36:18:9
D. 36:18:12

5. A positive charge of $+Q$ is fixed at point R a distance d away from another positive charge of $+2Q$ fixed at point S. Point A is located midway between the charges, and point B is a distance $\frac{d}{2}$ from $+2Q$, as shown below. In which direction will a positive charge move if placed at point A and point B, respectively?

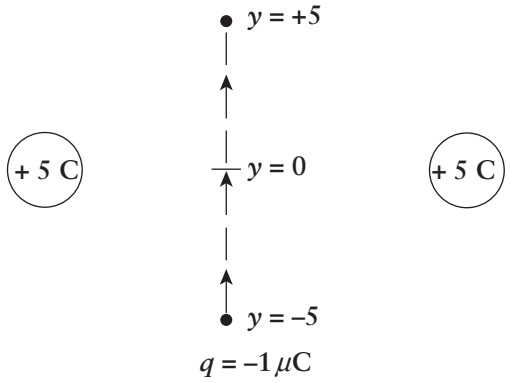


A. Toward the $+Q$ charge for both
B. Toward the $+2Q$ charge for both
C. Toward the $+Q$ charge at point A, and toward the right at point B
D. Toward the $+2Q$ charge at point A, and toward the right at point B

6. Two parallel conducting plates are separated by a distance d. One plate carries a charge $+Q$ and the other carries a charge $-Q$. The voltage between the plates is 12 V. If a +2 μC charge is released from rest at the positive plate, how much kinetic energy does it have when it reaches the negative plate?

A. 2.4×10^{-6} J
B. 4.8×10^{-6} J
C. 2.4×10^{-5} J
D. 4.8×10^{-5} J

7. The negative charge in the figure below (-1 μC) moves from $y = -5$ to $y = +5$ and is made to follow the dashed line. What is the work required to move the negative charge along this dashed line?



A. –10 J
B. –5 J
C. 0 J
D. 10 J

8. If the magnetic field a distance r away from a current-carrying wire is 10 T, what will be the net magnetic field at r if another wire is placed a distance $2r$ from the original wire (with r in the middle) and has a current twice as strong flowing in the opposite direction?

A. 0 T
B. 15 T
C. 20 T
D. 30 T

9. Given an electric dipole, the electrical potential is zero:

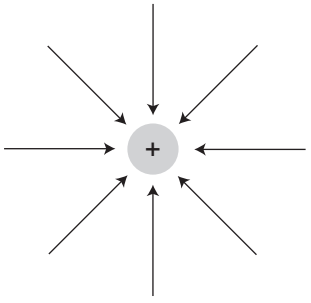
A. only at the midpoint of the dipole axis.
B. anywhere on the perpendicular bisector of the dipole axis and at infinity.
C. anywhere on the dipole axis.
D. only for points at infinity.

10. An electron is accelerated over a distance d by an electrical potential V. The electrical potential applied to this electron is then increased by a factor of 4 and the electron is accelerated over the same distance d. The speed of the electron at the end of the second trial will be larger than at the end of the first trial by a factor of:

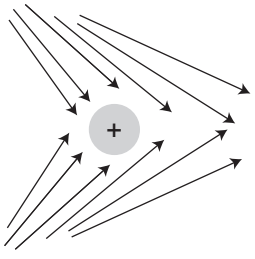
A. 16.
B. 8.
C. 4.
D. 2.

11. Which of the following accurately depicts the field lines created by a proton that is moving toward the right on this page?

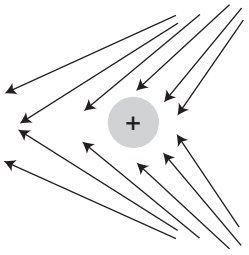
A.



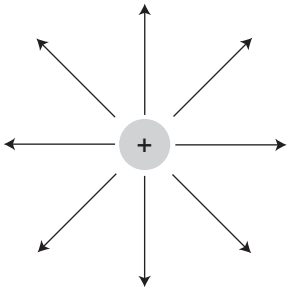
B.



C.



D.



12. A certain 9 V battery is used as a power source to move a 2 C charge. How much work is done by the battery?

A. 4.5 J
B. 9 J
C. 18 J
D. 36 J

13. A proton and an alpha particle (a helium nucleus) repel each other with a force of **F** while they are 20 nm apart. If each particle combines with three electrons, what is the magnitude of the new force between them?

A. $9F$
B. $3F$
C. F
D. $\frac{F}{9}$

14. A moving negative charge placed in an external magnetic field circulates counterclockwise in the plane of the paper. In which direction is the magnetic field pointing?

A. Into the page
B. Out of the page
C. Toward the center of the circle
D. Tangent to the circle

15. A dipole is placed in an electric field and is allowed to come to equilibrium. How would the dipole react if the direction of the electric field is suddenly reversed?

A. It rotates to align with the new field.
B. It accelerates linearly along the field lines.
C. It experiences no rotational or linear movement.
D. It both rotates to align with the new field and accelerates linearly along the field lines.

Explanations to Discrete Practice Questions

1. B

According to Newton's third law, if R exerts a force on S, then S exerts a force with equal magnitude but opposite direction back on R. Therefore, the magnitude of the force on R due to S is F.

2. D

The force is inversely proportional to r^2. Cutting the distance in half will therefore multiply the force by 2^2, making it four times its original value:

$$F_{old} \propto \frac{1}{r^2}$$
$$F_{new} \propto \frac{1}{\left(\frac{r}{2}\right)^2} = \frac{4}{r^2} = 4 \times F_{old}$$

3. B

An electric field's direction at a given point is defined as the direction of the force that would be exerted on a positive test charge in that position. Because electrons are negatively charged particles, they will therefore feel a force in the opposite direction of the electric field's vector. In this case, because the force points to the left (toward R), an electron will feel a force pointing to the right (toward S) if **E** is in the same direction as **F**.

4. B

The first step in answering this question is to remember that the magnitude of the electric field is inversely proportional to the square of the distance:

$$E = \frac{kQ}{r^2} \rightarrow E \propto \frac{1}{r^2}$$

Therefore, if the electric field at radius r, E_r, is 36 $\frac{N}{C}$, then the electric field at radius $2r$ will be

$$E_{2r} \propto \frac{1}{(2r)^2} = \frac{1}{4r^2} = \frac{E_r}{4}$$
$$= \frac{\left(36 \frac{N}{C}\right)}{4} = 9 \frac{N}{C}$$

Similarly, the electric field at radius $3r$ is equal to

$$E_{3r} \propto \frac{1}{(3r)^2} = \frac{1}{9r^2} = \frac{E_r}{9}$$
$$= \frac{\left(36 \frac{N}{C}\right)}{9} = 4 \frac{N}{C}$$

Therefore, the ratio of E_r:E_{2r}:E_{3r} is 36:9:4.

5. C

A positive charge placed at A will experience two forces: a force to the left due to $+2Q$ and a force to the right due to $+Q$. Because point A is the same distance from $+Q$ and $+2Q$, the force due to $+2Q$ will be larger than that due to $+Q$, and there will be a net force to the left (toward $+Q$). At point B, the forces from both $+Q$ and $+2Q$ will point to the right, so there will be a net force to the right.

6. C

Recall that the change in potential energy, ΔU, and the change in potential, ΔV, are related by $W = \Delta U = q\Delta V$. Therefore, $\Delta U = (2 \times 10^{-6}\ C) \times (-12\ V) = -2.4 \times 10^{-5}$ J. The positive charge is moving from the positive to the negative plate, and is therefore decreasing in potential energy; this is reflected by the fact that the voltage is –12 V rather than +12 V.

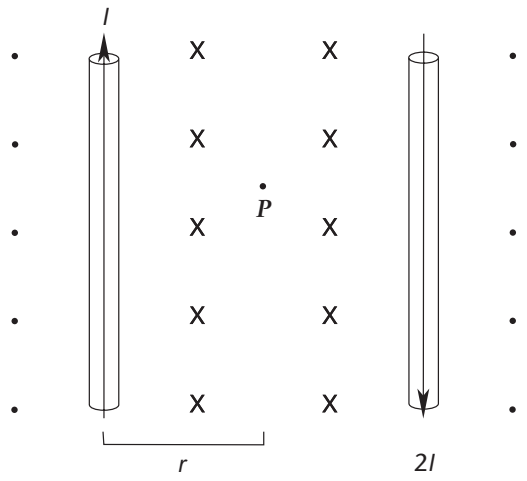
The potential energy that is lost is converted into kinetic energy, so the charge must gain 2.4×10^{-5} J of kinetic energy.

7. C

There will be work done in moving the negative charge from its initial position to $y = 0$. However, in moving the negative charge from $y = 0$ to the final position, the same amount of work is done but with the opposite sign. This is because the force changes direction as the electron crosses $y = 0$. Therefore, the two quantities of work cancel each other out. This argument depends crucially on the symmetry of the initial and final positions.

8. D

The safest way to answer this question is to quickly draw a diagram:



Notice right away that between the two wires, the direction of the magnetic field is the same: into the page. Therefore, because the vector direction is the same, we can just focus on the magnitudes of the two magnetic fields. We know that $B_1 = 10$ T at a distance r. Consider the relationships in the equation $B = \frac{\mu_0 I}{2\pi r}$. Magnetic field and current are directly proportional, whereas magnetic field and distance are inversely proportional. Therefore, doubling the current will result in double the magnetic field of the first wire, or 20 T. The overall magnitude of the magnetic field is 10 T + 20 T = 30 T into the page.

9. B

Potential is a scalar quantity. The total potential is the sum of the potentials of the positive and negative charges:

$$V_T = V_+ + V_- = \frac{+kq}{r_+} + \left(\frac{-kq}{r_-}\right)$$

where r_+ and r_- represent the distances from the positive and negative charge, respectively. The sum of these terms will be zero at any point where $r_+ = r_-$. This will be at any point along the perpendicular bisector of the dipole axis, as well as at infinity.

10. D

The electrical potential (V) is equal to the amount of work done (W) divided by the test charge (q). This means that the potential is directly proportional to the amount of work done, which is equal to the amount of energy gained by the particle; therefore, the overall amount of energy increases by a factor of 4. Because energy is directly proportional to the square of the speed (according to $\frac{1}{2}mv^2$), the speed must increase by a factor of 2.

11. D

You should know that the field lines for a positively charged particle will always point away from the particle in a radial pattern, regardless of the direction in which the particle is moving. This is because field lines point in the direction a positive test charge would move in that field (that is, the direction that a force would be exerted on a positive test charge in that field).

12. C

Voltage (ΔV) is equal to the quotient of the amount of work done (W) divided by the charge of the particle on which the work is done (q), according to the equation $V = \frac{\Delta U}{q} = \frac{W}{q}$. Because the voltage equals 9 V and the charge equals 2 C, the work done must equal 9 V × 2 C = 18 J.

13. C

The magnitude of the electrostatic force is given by the equation $F_e = \frac{kq_1q_2}{r^2}$. Because the distance does not change during the interaction in the question, the value of r is irrelevant to the answer. Currently, q_1 and q_2 are equal to $+1e$ and $+2e$, respectively;the addition of three electrons (each of which carries a charge of $-e$) will change the charges to $-2e$ and $-1e$. Therefore, the product q_1q_2 before the interaction is equal to the product q_1q_2 after the interaction ($+2e^2$). Because k and r also remain constant in this system, the magnitude of the force does not change.

14. B

This problem is an application of the right-hand rule. The velocity vector **v** is always tangent to the circle. The magnetic force must always point radially toward the center of the circle. Consider when the negative charge is at the "12 o'clock" position in its circle and apply the right-hand rule. Your thumb points to the left, tangent to the circle at this point. The back of your hand, which represents the force on a negative charge, points down the page, radially toward the center of the circle. Your fingers must point out of the page to get your hand into this position. Therefore, the direction of the magnetic field must be out of the page.

15. C

Torque is a function of both force applied and the angle at which it is applied. A dipole placed in an electric field will experience a torque until it comes to rest oriented within the field, at which point the angle between the plane of the dipole and the electric field is 0°. Once this point is reached, inverting the electric field has no impact on the dipole because it will now have an angle of 180°, the sine of which is still 0. Note, however, that this is an unstable setup; any deviation in the dipole from its rest position will immediately result in torque on the dipole and force it to realign with the new field.

Concept Summary 210

Introduction

Batteries, electric circuits, and electrical equipment pervade our everyday world. Think of any piece of equipment, tool, or toy that has a battery or a power cord, and you've identified an object that depends on the movement of electrons and the delivery of electrical potential energy to carry out its function. Turn on a light, watch TV, or toast bread, and you can literally watch electrons at work as they emit light. Electricity is not restricted to the inorganic, material world—even in our bodies, we find electricity serving a key role in a number of physiological functions. Not only do the neurons in our brain and conduction system in our heart rely on electricity, but so does every cell that utilizes mitochondria to carry out oxidative phosphorylation.

This chapter reviews the essentials of circuits. From this broad knowledge base, we will draw on specific topics within circuit theory: conductivity, electromotive force (emf), resistance, power, Kirchhoff's laws, resistors, capacitors, meters, and series and parallel arrangements of circuit components. As you encounter the concepts of this chapter and the equations associated with them, remember this: the MCAT approaches the topic of circuits with a greater emphasis on the concepts than on the math. You will be expected to calculate, say, the equivalent resistance for resistors in series or parallel, but the circuits you encounter on Test Day will, on the whole, be simpler than what you may have seen in your college physics class.

6.1 Current

In the last chapter we examined the behaviors of still charges, but in most cases we are interested in the movement of charge, or current. Because of historical conventions, **current** is considered the flow of positive charge—even though only negative charges are actually moving. Any conductive substance may act as a medium through which current can pass.

CONDUCTIVITY

Conductivity can be divided into two categories: **metallic conductivity**, as seen in solid metals and the molten forms of some salts, or **electrolytic conductivity**, as seen in solutions. **Conductance** is the reciprocal of resistance, a property we will examine in detail later. The SI unit for conductance is the **siemens** (**S**), sometimes given as siemens per meter $\left(\frac{S}{m}\right)$ for conductivity.

Bridge

Remember that the metals are found on the left side of the periodic table. These are the atoms with the lowest ionization energies; thus, it is easiest for these atoms to lose electrons. Due to this weak hold, electrons are free to move around in the metal, conducting electrical charges. Periodic trends are discussed in Chapter 2 of *MCAT General Chemistry Review*.

Metallic Conductivity

Some materials allow free flow of electric charge within them; these materials are called electrical conductors. Metal atoms can easily lose one or more of their outer electrons, which are then free to move around in the larger collection of metal atoms. This makes most metals good electrical and thermal conductors. The **metallic bond** has often been visualized as a sea of electrons flowing over and past a rigid lattice of metal cations. While this model is generally appropriate for the MCAT, metallic bonding is more accurately described as an equal distribution of the charge density of free electrons across all of the neutral atoms within the metallic mass.

Electrolytic Conductivity

While not substantially different from metallic conductivity, it is important to note that electrolytic conductivity depends on the strength of a solution. Distilled deionized water has such a low ion concentration that it may be considered an insulator, while sea water and orange juice are excellent conductors. Conductivity in an electrolyte solution is measured by placing the solution as a resistor in a circuit and measuring changes in voltage across the solution. Because concentration and conductivity are directly related, this method is often used to determine ionic concentrations in solutions, such as blood. One caveat is that conductivity in nonionic solutions is always lower than in ionic solutions. While the concentration of total dissolved solids does relate to conductivity, the contribution of nonionic solids is much, much less important than ion concentration.

CURRENT

Chapter 5 of *MCAT Physics and Math Review* introduced the concept of electrical current: the flow of charge between two points at different electrical potentials connected by a conductor, such as a copper wire. The magnitude of the **current** I is the amount of charge Q passing through the conductor per unit time Δt, and it can be calculated as:

$$I = \frac{Q}{\Delta t}$$

Equation 6.1

The SI unit of current is the **ampère** $\left(1\ \text{A} = 1\ \frac{\text{C}}{\text{s}}\right)$. Charge is transmitted by a flow of electrons in a conductor, and because electrons are negatively charged, they move from a point of lower electrical potential to a point of higher electrical potential (and, in doing so, reduce their electrical potential energy). By convention, however, the direction of current is the direction in which positive charge would flow (from higher potential to lower potential). Thus, the direction of current is opposite to the direction of actual electron flow. The two patterns of current flow are **direct current (DC)**, in which the charge flows in one direction only, and **alternating current (AC)**, in which the flow changes direction periodically. Direct current is produced by household batteries, while the current supplied over long distances to homes and other buildings is alternating current. Our discussion of circuits will assume direct current, which is tested on the MCAT to the exclusion of alternating current.

A **potential difference** (**voltage**) can be produced by an electrical generator, a galvanic (voltaic) cell, a group of cells wired into a battery, or—as seen in classic science fair projects—even a potato. When no charge is moving between the two terminals of a cell that are at different potential values, the voltage is called the **electromotive force** (**emf** or $\boldsymbol{\varepsilon}$). Do not be misled by this term, as emf is not actually a force; it is a potential difference (voltage) and, as such, has units of joules per coulomb $\left(1\ \text{V} = 1\ \frac{\text{J}}{\text{C}}\right)$—not newtons. It may be helpful to think of emf as a "pressure to move" that results in current, in much the same way that a pressure difference between two points in a fluid-filled tube causes the fluid to flow.

Bridge

The standard batteries in flashlights and remote controls are examples of galvanic (voltaic) cells. These house spontaneous oxidation–reduction reactions that generate emf as a result of differences in the reduction potentials of two electrodes. Electrochemistry is discussed in Chapter 12 of *MCAT General Chemistry Review*.

CIRCUIT LAWS

Currents (and circuits in general) are governed by the laws of conservation. Charge and energy must be fully accounted for at all times and can be neither created nor destroyed. An electric circuit is a conducting path that usually has one or more voltage sources (such as a battery) connected to one or more passive circuit elements (such as resistors). **Kirchhoff's laws** are two rules that deal with the conservation of charge and energy within a circuit.

Key Concept

Kirchhoff's junction rule is just like a fork in a river. There are a certain number of water molecules in a river, and at any junction, that number has to go in one of the diverging directions; no water molecules spontaneously appear or disappear. The same holds true for the amount of current at any junction.

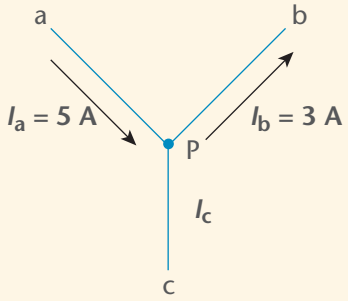
Kirchhoff's Junction Rule

At any point or junction in a circuit, the sum of currents directed into that point equals the sum of currents directed away from that point. This is an expression of conservation of electrical charge and can be expressed as

$$I_{\text{into junction}} = I_{\text{leaving junction}}$$

Equation 6.2

Example: Three wires (a, b, and c) meet at a junction point P, as shown below. A current of 5 A flows into P along wire a, and a current of 3 A flows away from P along wire b. What is the magnitude and direction of the current along wire c?



Solution: The sum of currents entering P must equal the sum of the currents leaving P. Assume for now that I_c flows out of P. If we find that it is negative, then we know the current must be going the other direction (into P).

$$I_a = I_b + I_c$$
$$5\text{ A} = 3\text{ A} + I_c$$
$$I_c = 2\text{ A}$$

Thus, a current of 2 A flows out of P along wire c.

Key Concept

If all of the voltage wasn't "used up" in each loop of the circuit, then the voltage would build after each trip around the circuit, which is impossible.

Kirchhoff's Loop Rule

Around any closed circuit loop, the sum of voltage sources will always be equal to the sum of voltage (potential) drops. This is a consequence of the conservation of energy. All the electrical energy supplied by a source gets fully used up by the other elements within that loop. No excess energy appears, and no energy disappears that cannot be accounted for. Of course, energy can be changed from one form to another, so the kinetic energy of the electrons can be converted to thermal energy, light, or sound by the particular apparatus that is connected into the circuit. Remember that although Kirchhoff's loop rule is a consequence of

the law of conservation of energy, this law is in terms of voltage (joules per coulomb), not just energy (joules). This can be expressed mathematically as

$$V_{source} = V_{drop}$$

Equation 6.3

MCAT Concept Check 6.1:

Before you move on, assess your understanding of the material with these questions.

1. Define the following terms and provide their SI units.
   - Current:

     _____

   - Voltage:

     _____

   - Electromotive force (emf):

     _____

   - Conductivity:

     _____

2. Which likely has a higher conductivity: 1 *M* glucose or 0.25 *M* NaCl? Why?

   _____

   _____

3. True or False: In a circuit, the number of electrons entering a point and leaving that point are the same.

4. True or False: The sum of the voltage sources in a circuit is equal to the sum of the voltage drops in that circuit.

6.2 Resistance ★★★

Resistance is the opposition within any material to the movement and flow of charge. Electrical resistance can be thought of like friction, air resistance, or viscous drag: in all of these cases, motion is being opposed. Materials that offer almost no resistance are called conductors, and those materials that offer very high resistance

are called insulators. Conductive materials that offer amounts of resistance between these two extremes are called **resistors**.

PROPERTIES OF RESISTORS

The resistance of a resistor is dependent upon certain characteristics of the resistor, including resistivity, length, cross-sectional area, and temperature. Three of these are summarized by the equation for resistance:

$$R = \frac{\rho L}{A}$$

Equation 6.4

where ρ is the resistivity, L is the length of the resistor, and A is its cross-sectional area. We will explore the effects of each of these variables and temperature in this section.

Resistivity

Some materials are intrinsically better conductors of electricity than others. For example, copper conducts electricity better than plastic, which is why electrical wires have a copper core surrounded by a layer of plastic rather than the other way around. The number that characterizes the intrinsic resistance to current flow in a material is called the **resistivity** (ρ), for which the SI unit is the **ohm–meter** ($\Omega \cdot m$).

Length

According to the resistance equation, the resistance of a resistor is directly proportional to its length. A longer resistor means that electrons will have to travel a greater distance through a resistant material. This factor scales linearly: if a resistor doubles its length, it will also double its resistance.

Cross-Sectional Area

The equation for resistance also demonstrates an inverse proportionality between resistance and the cross-sectional area of the resistor: if a resistor's cross-sectional area is doubled, its resistance will be cut in half. This is because the increase in cross-sectional area increases the number of pathways through the resistor, called **conduction pathways**. The wider the resistor, the more current that can flow. This is analogous to a river, where the wider the river, the less resistance there is to water flow. Note, however, that electrical current does not follow the continuity equation that applies to incompressible fluids ($A_1v_1 = A_2v_2$); it instead obeys Kirchhoff's laws.

Temperature

Although not evident from the resistance equation, most conductors have greater resistance at higher temperatures. This is due to increased thermal oscillation of the atoms in the conductive material, which produces a greater resistance to electron flow. Because temperature is an intrinsic quality of all

MCAT Expertise

On the MCAT, the most common resistors you will see outside of generic, unlabeled resistors are light bulbs, although all appliances function as resistors. You may also see resistance applied atypically, as in resistance to air flow in the lungs or to blood moving in the circulatory system. The same mathematical relationships will be useful in both circumstances.

MCAT Expertise

It is always good practice to be able to derive the units of a variable from equations you know. If you were to solve for resistivity (ρ) in the resistance equation, you'd end up with $\frac{AR}{L}$. Because A is in square meters, R is in ohms, and L is in meters, it simplifies to meters times ohms, which are the units for resistivity.

matter, we can think of the resistivity as a function of temperature. A few materials do not follow this general rule, including glass, pure silicon, and most semiconductors.

OHM'S LAW AND POWER

Now that we've covered voltage, current, and resistance, we can begin to bring these variables together to solve circuits.

Ohm's Law

Electrical resistance results in an energy loss, which reflects a drop in electrical potential. The voltage drop between any two points in a circuit can be calculated according to Ohm's law:

$$V = IR$$

Equation 6.5

where V is the voltage drop, I is the current, and R is the magnitude of the resistance, measured in **ohms** (**Ω**). **Ohm's law** is the basic law of electricity because it states that for a given magnitude of resistance, the voltage drop across the resistor will be proportional to the magnitude of the current. Likewise, for a given resistance, the magnitude of the current will be proportional to the magnitude of the emf (voltage) impressed upon the circuit. The equation applies to a single resistor within a circuit, to any part of a circuit, or to an entire circuit (provided one can calculate the equivalent resistance from all of the resistors in the circuit). As current moves through a set of resistors in a circuit, the voltage drops some amount in each resistor; the current (or sum of currents for a divided circuit) is constant. No charge is gained or lost through a resistor; thus, if resistors are connected in series, all of the current must pass through each resistor.

Conductive materials, such as copper wires, act as weak resistors themselves, offering some magnitude of resistance to current and causing a drop in electrical potential (voltage). Even the very sources of emf, such as batteries, have some small but measurable amount of **internal resistance**, r_{int}. As a result of this internal resistance, the voltage supplied to a circuit is reduced from its theoretical emf value by some small amount. The actual voltage supplied by a cell to a circuit can be calculated from

$$V = E_{cell} - ir_{int}$$

Equation 6.6

where V is the voltage provided by the cell, E_{cell} is the emf of the cell, i is the current through the cell, and r_{int} is its internal resistance.

MCAT Expertise

Most batteries on the MCAT will be considered "perfect batteries," and you will not have to account for their internal resistances.

Real World

Superconductors, a special class of materials, are the one major exception to the rules of internal resistance. When these elements and compounds are cooled to very low temperatures (usually well below 100 K, but the exact threshold varies by material), the resistivity of the material (ρ) completely dissipates, dropping to zero. Because these materials break a generally applicable law of physics, superconductors have many interesting and unusual applications.

If the cell is not actually driving any current (such as when a switch is in the open position), then the internal resistance is zero, and the voltage of the cell is equal to its emf. For cases when the current is not zero and the internal resistance is not negligible, then voltage will be less than emf.

When a cell is discharging, it supplies current, and the current flows from the positive, higher potential end of the cell around the circuit to the negative, lower potential end. Certain types of cells (called **secondary batteries**) can be recharged. When these batteries are being recharged, an external voltage is applied in such a way to drive current toward the positive end of the secondary battery. In electrochemical terms, the cell acts as a galvanic (voltaic) cell when it discharges and as an electrolytic cell when it recharges.

Measuring Power

In Chapter 2 of *MCAT Physics and Math Review*, we briefly mentioned that power is the rate at which energy is transferred or transformed. Power is measured as the ratio of work (energy expenditure) to time and can be expressed as follows:

$$P = \frac{W}{t} = \frac{\Delta E}{t}$$

Equation 6.7

In electric circuits, energy is supplied by the cell that houses a spontaneous oxidation–reduction reaction, which when allowed to proceed (by the closing of a switch, for example), generates a flow of electrons. These electrons, which have electrical potential energy, convert that energy into kinetic energy as they move around the circuit, driven by the emf of the cell. As mentioned above, emf is not a force, but is better thought of as a pressure to move, exerted by the cell on the electrons. Current delivers energy to the various resistors, which convert this energy to some other form, depending on the particular configuration of the resistor. One particularly recognizable example of resistors at work is the coils inside a toaster. The coils turn red-hot when the toaster is powered on and dissipate thermal energy, which is a direct consequence of the resistance that the coils pose to the current running through them.

MCAT Expertise

These equations for calculating the power of a resistor or collection of resistors are extremely helpful for the MCAT. Commit them to memory—and, more importantly, understand them—and your efforts will be rewarded as points on Test Day.

The rate at which energy is dissipated by a resistor is the power of the resistor and can be calculated from

$$P = IV = I^2R = \frac{V^2}{R}$$

Equation 6.8

where I is the current through the resistor, V is the voltage drop across the resistor, and R is the resistance of the resistor. Note that these different versions of the power equation can be interconverted by substitution using Ohm's law ($V = IR$).

RESISTORS IN SERIES AND PARALLEL

Resistors can be connected into a circuit in one of two ways: either in **series**, in which all current must pass sequentially through each resistor connected in a linear arrangement, or in **parallel**, in which the current will divide to pass through resistors separately.

Resistors in Series

For resistors connected in series, the current has no choice but to travel through each resistor in order to return to the cell, as shown in Figure 6.1.

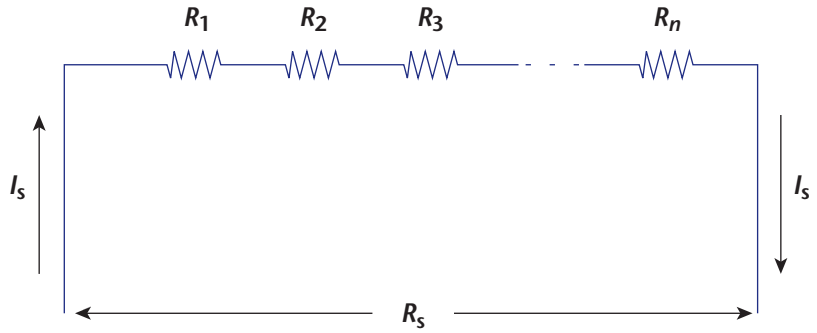


Figure 6.1. Resistors in Series
R_s increases as more resistors are added.

As the electrons flow through each resistor, energy is dissipated, and there is a voltage drop associated with each resistor. The voltage drops are additive; that is, for a series of resistors, R_1, R_2, R_3, … R_n, the total voltage drop will be

$$V_s = V_1 + V_2 + V_3 + \cdots + V_n$$

Equation 6.9

Because $V = IR$, we can also see that the resistances of resistors in series are also additive, such that

$$R_s = R_1 + R_2 + R_3 + \cdots + R_n$$

Equation 6.10

The set of resistors wired in series can be treated as a single resistor with a resistance equal to the sum of the individual resistances, termed the **equivalent** or **resultant resistance**. Note that R_s will always increase as more resistors are added.

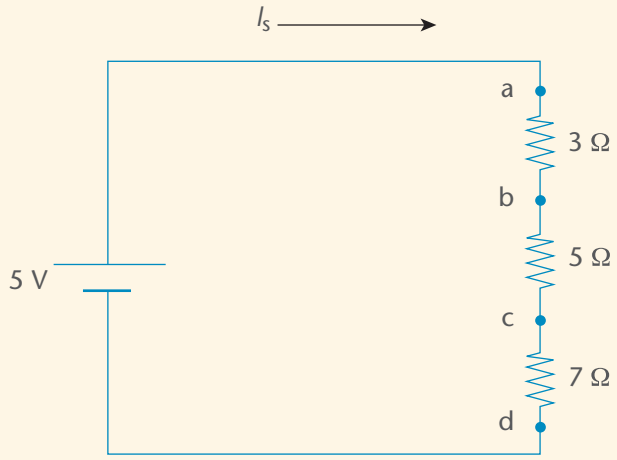
Real World

Because power equals voltage times current, power companies can manipulate these two values while keeping power constant. One option is to increase current, which results in a decrease in voltage. The other option would be to increase voltage, thus decreasing the current. Power lines are high-voltage lines, which allows them to carry a smaller current—thus decreasing the amount of energy lost from the system.

Key Concept

When there is only one path for the current to take, the current will be the same at every point in the line, including through every resistor. Once you know the current of the whole circuit, you can use $V = IR$ to solve for the voltage drop across each resistor (assuming you know the resistances of the resistors).

Example: A circuit is wired with one cell supplying 5 V in series with three resistors of 3 Ω, 5 Ω, and 7 Ω, also wired in series as shown below. What is the resulting voltage across and current through each resistor of this circuit, as well as the entire circuit?



Solution: The total resistance of the resistors is

$$R_s = R_1 + R_2 + R_3 = 3\ \Omega + 5\ \Omega + 7\ \Omega = 15\ \Omega$$

Now use Ohm's law to get the current through the entire circuit:

$$I_s = \frac{V_s}{R_s} = \frac{5\ \text{V}}{15\ \Omega} = 0.33\ \text{A}$$

Because everything is in series, this is also the current through each circuit element. Now, use Ohm's law for each of the resistors in turn. From a to b, the voltage drop across R_1 is

$$IR_1 = (0.33\ \text{A})(3\ \Omega) = 1.0\ \text{V}$$

From b to c, the voltage drop across R_2 is

$$IR_2 = (0.33\ \text{A})(5\ \Omega) = 1.67\ \text{V}$$

From c to d, the voltage drop across R_3 is

$$IR_3 = (0.33\ \text{A})(7\ \Omega) = 2.33\ \text{V}$$

Resistors in Parallel

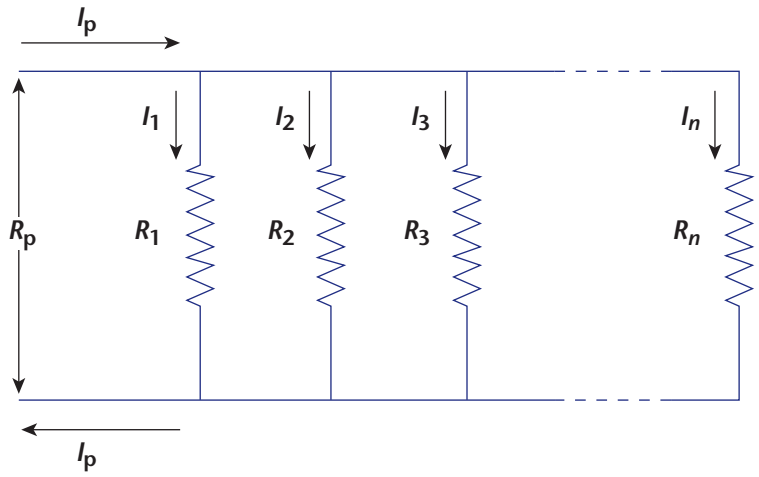


Figure 6.2. Resistors in Parallel
R_p decreases as more resistors are added.

When resistors are connected in parallel, they are wired with a common high-potential terminal and a common low-potential terminal, as shown in Figure 6.2. This configuration allows charge to follow different parallel paths between the high-potential terminal and the low-potential terminal. In this arrangement, electrons have a "choice" regarding which path they will take: some will choose one pathway, while others will choose a different pathway. No matter which path is taken, however, the voltage drop experienced by each division of current is the same because all pathways originate from a common point and end at a common point within the circuit. This is analogous to a river that splits into multiple streams before plunging over different waterfalls, which then come back together to reform the river at a lower height. If all the water starts at some common height and ends at a lower common height, then it doesn't matter how many "steps" the water fell over to get to the bottom of the falls: the change in height is the same for each stream. In circuits with parallel arrangements of resistors, this is expressed mathematically as:

$$V_p = V_1 = V_2 = V_3 = \cdots = V_n$$

Equation 6.11

While the voltage is the same for all parallel pathways, the resistance of each pathway may differ. In this case, electrons prefer the path of least resistance; in other words, the current will be largest through the pathways with the lowest resistance. In fact, there is an inverse relationship between the portion of the current that travels through a particular pathway and the resistance offered by that pathway.

Key Concept

Remember Kirchhoff's loop rule: if every resistor is in parallel, then the voltage drop across each pathway alone must be equal to the voltage of the source.

The resistance equation previously discussed shows us that there is an inverse relationship between the cross-sectional area of a resistor and the resistance of that resistor. Like opening up rush-hour lanes to reduce traffic congestion or performing cardiac bypass to perfuse hypoxic heart tissue, the configuration of resistors in parallel allows for a greater total number of conduction paths, and the effect of connecting resistors in parallel is a reduction in the equivalent resistance. In effect, we could replace all resistors in parallel with a single resistor that has a resistance that is less than the resistance of the smallest resistor in the circuit. The equivalent resistance of resistors in parallel is calculated by

$$\frac{1}{R_p} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R_n}$$

Equation 6.12

Note that R_p will always decrease as more resistors are added.

Because the voltage drop across any one circuit branch must be same as the voltage drops across each of the other parallel branches, we can see that the magnitude of the current in each branch will be inversely proportional to the resistance offered by each branch. This comes directly from Ohm's law. Thus, if a circuit divides into two branches and one branch has twice the resistance of the other, the one with twice the resistance will have half the magnitude of current compared to the other. Remember that the sum of the currents going into each division, according to Kirchhoff's junction rule, must equal the total current going into the point at which the current divides.

Example: Consider two equal resistors wired in parallel. What is the equivalent resistance of the setup?

Solution: The equation for summing resistors in parallel is

$$\frac{1}{R_p} = \frac{1}{R_1} + \frac{1}{R_2}$$

Next, find the common denominator of the right side:

$$\frac{1}{R_p} = \frac{R_2}{R_1R_2} + \frac{R_1}{R_1R_2} = \frac{R_1 + R_2}{R_1R_2}$$

Then, take the inverse:

$$R_p = \frac{R_1R_2}{R_1 + R_2}$$

This is a special case where $R_1 = R_2$. Substituting in, we get:

$$R_p = \frac{R^2}{2R} = \frac{R}{2}$$

In the example above, we can see that the total resistance is halved by wiring two identical resistors in parallel. More generally, when n identical resistors are wired in parallel, the total resistance is given by $\frac{R}{n}$. Note that the voltage across each of the parallel resistors is equal and that, for equal resistances, the current flowing through each of the resistors is also equal (that is, a current of $\frac{I_{\text{total}}}{n}$ runs through each).

Example: Consider two resistors wired in parallel with $R_1 = 5\,\Omega$ and $R_2 = 10\,\Omega$. If the voltage across them is 10 V, what is the current through each of the two resistors?

Solution: First, the current flowing through the whole circuit must be found. To do this, the equivalent resistance must be calculated:

$$\frac{1}{R_p} = \frac{1}{R_1} + \frac{1}{R_2} = \frac{1}{10\,\Omega} + \frac{1}{5\,\Omega} = \frac{3}{10\,\Omega}$$

$$R_p = \frac{10}{3}\,\Omega$$

Using Ohm's law to calculate the current flowing through the circuit gives

$$I_p = \frac{V_p}{R_p} = \frac{10\text{ V}}{\left(\frac{10}{3}\,\Omega\right)} = 3\text{ A}$$

Three amps flow through the combination of R_1 and R_2. Because the resistors are in parallel, $V_p = V_1 = V_2 = 10$ V. Apply Ohm's law to each resistor individually:

$$I_1 = \frac{V_p}{R_1} = \frac{10\text{ V}}{5\,\Omega} = 2\text{ A}$$

$$I_2 = \frac{V_p}{R_2} = \frac{10\text{ V}}{10\,\Omega} = 1\text{ A}$$

As a check, note that $I_p = 3\text{ A} = I_1 + I_2$. More current flows through the smaller resistor. In particular, note that R_1, with half the resistance of R_2, has twice the current. Once I_p was found to be 3 A, the problem could have been solved by noting the ratio of the resistances of the two branches.

MCAT Expertise

When approaching circuit problems, the first things you need to find are the total (circuit) values: the total voltage (almost always given as the voltage of the battery), the total (equivalent) resistance, and the total current. To find the total current, first find the total resistance of the circuit.

MCAT Concept Check 6.2:

Before you move on, assess your understanding of the material with these questions.

1. How does adding or removing a resistor change the total resistance of a circuit with resistors in series? In parallel?
   - Series:

     _____
   - Parallel:

     _____

2. What four physical quantities determine the resistance of a resistor?
   - _____
   - _____
   - _____
   - _____

3. How does power relate to current, voltage, and resistance?

_____

_____

4. True or False: The internal resistance of a battery will lower the amount of current it can provide.

6.3 Capacitance and Capacitors ★★★

Aside from batteries and resistors, the other major circuit element tested on the MCAT is the capacitor. **Capacitors** are characterized by their ability to hold charge at a particular voltage. There are excellent real-world examples of capacitors. Perhaps the most important capacitor you'll encounter in the clinics is the defibrillator. While a defibrillator is charging, a high-pitched electronic tone sounds as electrons build up on the capacitor. When the defibrillator is fully charged, that charge can be released in one surge of power (after the operator yells *Clear!*). The clouds and the ground during a lightning storm also act as a capacitor, with the charge building up between them eventually **discharging** as a bolt of lightning. The MCAT focuses on a particular type of capacitor called a parallel plate capacitor, and all of our discussion will center on capacitors of this type.

PROPERTIES OF CAPACITORS

When two electrically neutral metal plates are connected to a voltage source, positive charge builds up on the plate connected to the positive (higher potential) terminal, and negative charge builds up on the plate connected to the negative (lower potential) terminal. The two-plate system is a capacitor because it can store a particular amount of charge at a particular voltage. The **capacitance** of a capacitor is defined as the ratio of the magnitude of the charge stored on one plate to the potential difference (voltage) across the capacitor. Therefore, if a voltage V is applied across the plates of a capacitor and a charge Q collects on it (with $+Q$ on the positive plate and $-Q$ on the negative plate), then the capacitance is given by

$$C = \frac{Q}{V}$$

Equation 6.13

The SI unit for capacitance is the **farad** $\left(1\,\text{F} = 1\,\frac{\text{C}}{\text{V}}\right)$. Because one coulomb is such a large quantity of charge, one farad is a very large capacitance. Capacitances are usually given in microfarads (1 μF = 1 × 10^{-6} F) or picofarads (1 pF = 1 × 10^{-12} F). Be careful not to confuse the farad with the Faraday constant from electrochemistry, F, which is the amount of charge in one mole of electrons $\left(96{,}485\,\frac{\text{C}}{\text{mol } e^-}\right)$.

The capacitance of a parallel plate capacitor is dependent upon the geometry of the two conduction surfaces. For the simple case of the parallel plate capacitor, the capacitance is given by

$$C = \varepsilon_0\left(\frac{A}{d}\right)$$

Equation 6.14

where ε_0 is the permittivity of free space $\left(8.85 \times 10^{-12}\,\frac{\text{F}}{\text{m}}\right)$, A is the area of overlap of the two plates, and d is the separation of the two plates. The separation of charges sets up a **uniform electric field** between the plates with parallel field vectors, the magnitude of which can be calculated as

$$E = \frac{V}{d}$$

Equation 6.15

The direction of the electric field at any point between the plates is from the positive plate toward the negative plate. If we imagine placing a positively charged particle between the oppositely charged plates, we would expect the particle to accelerate in that same direction. This should not be surprising, as electric field lines always point in the direction a force would be exerted on a positive charge.

Regardless of the particular geometry of a capacitor (parallel plate or otherwise), the function of a capacitor is to store an amount of energy in the form of charge separation at a particular voltage. This is akin to the function of a dam, the purpose of which is to store gravitational potential energy by holding back a mass of water at a given height. The potential energy stored in a capacitor is

$$U = \frac{1}{2}CV^2$$

Equation 6.16

Key Concept

If you look back to the equations discussed in Chapter 5 of *MCAT Physics and Math Review*, you can see that the equation for E here can be derived from the other fundamental electrostatics equations. If $V = \frac{kQ}{r}$ and $E = \frac{kQ}{r^2}$, then $V = E \times r$. r in this setup is the distance between the plates, d, so we can rewrite this as $V = Ed$.

DIELECTRIC MATERIALS

The term **dielectric material** is just another way of saying insulation. When a dielectric material, such as air, glass, plastic, ceramic, or certain metal oxides, is introduced between the plates of a capacitor, it increases the capacitance by a factor called the **dielectric constant** (κ). The dielectric constant of a material is a measure of its insulating ability, and a vacuum has a dielectric constant of 1, by definition. For reference, the dielectric constant of air is just slightly above 1, glass is 4.7, and rubber is 7. These numbers need not be memorized; any relevant dielectric constants will be given on Test Day.

Key Concept

A dielectric material can never decrease the capacitance; thus κ can never be less than 1.

The capacitance due to a dielectric material is

$$C' = \kappa C$$

Eqation 6.17

where C' is the new capacitance with the dielectric present and C is the original capacitance.

Dielectrics in Isolated Capacitors

When a dielectric material is placed in an isolated, charged capacitor—that is, a charged capacitor disconnected from any circuit—the voltage across the capacitor decreases. This is the result of the dielectric material shielding the opposite charges from each other. By lowering the voltage across a charged capacitor, the dielectric has increased the capacitance of the capacitor by a factor of the dielectric constant. Thus, when a dielectric material is introduced into an isolated capacitor, the increase in capacitance arises from a decrease in voltage.

Dielectrics in Circuit Capacitors

When a dielectric material is placed in a charged capacitor within a circuit—that is, still connected to a voltage source—the charge on the capacitor increases. The voltage must remain constant because it must be equal to that of the voltage source. By increasing the amount of charge stored on the capacitor, the dielectric has increased the capacitance of the capacitor by a factor of the dielectric constant. Thus, when a dielectric material is introduced into a circuit capacitor, the increase in capacitance arises from an increase in stored charge.

The stored energy in a capacitor is only useful if it is allowed to discharge. The charge can be released from the plates either by discharging across the plates or through some conductive material with which the plates are in contact. For example, capacitors can discharge into wires, causing a current to pass through the wires in much the same way that batteries cause current to move through a circuit. The paddles of the defibrillator machine, once charged, are placed on either side of a patient's heart that has gone into a life-threatening arrhythmia

(such as *ventricular fibrillation*). The reason the doctor yells *Clear!* before discharging the paddles is because the current needs to travel through the patient's heart—not through any other people who might be touching the patient and creating a parallel pathway. On a much larger scale, lightning occurs when a very, very large amount of charge exceeds the capacitance of the Earth's surface and the underside of the cloud (the two serving, approximately, as a parallel plate capacitor). The large rapid discharge across the plates of a capacitor is termed a failure of the capacitor, while creating a current through the attached wires is the normal function of a capacitor.

Example: The voltage across the terminals of an isolated 3 μF capacitor is 4 V. If a piece of ceramic having dielectric constant $\kappa = 2$ is placed between the plates, find the new charge, capacitance, and voltage of the capacitor.

Solution: The introduction of a dielectric by itself has no effect on the charge stored on the isolated capacitor. There is no new charge, so the charge is the same as before. The charge stored is therefore given by

$$Q' = Q = CV = (3\ \mu\text{F})(4\ \text{V}) = 12\ \mu\text{C}$$

By introducing a dielectric with a dielectric constant of 2, the capacitance of the capacitor is multiplied by 2 ($C' = \kappa C$). Hence, the new capacitance is 6 μF.

Now, the new voltage across the capacitor can be determined:

$$V' = \frac{Q'}{C'} = \frac{12\ \mu\text{C}}{6\ \mu\text{F}} = 2\,\text{V}$$

Example: A 3 μF capacitor is connected to a 4 V battery. If a piece of ceramic having dielectric constant $\kappa = 2$ is placed between the plates, find the new charge, capacitance, and voltage of the capacitor.

Solution: This question is very similar to the previous one, but the voltage is held constant here by a battery. Thus, the new voltage is still 4 V.

By introducing a dielectric with a dielectric constant of 2, the capacitance of the capacitor is multiplied by 2 ($C' = \kappa C$). Hence, the new capacitance is 6 μF.

Now, the new charge on the capacitor can be determined:

$$Q' = C'V' = (6\ \mu\text{F})(4\ \text{V}) = 24\ \mu C$$

CAPACITORS IN SERIES AND PARALLEL

Just like resistors, capacitors can be arranged within a circuit either in parallel or in series. They can also be arranged with resistors, although this is beyond the scope of the MCAT in most cases.

Capacitors in Series

When capacitors are connected in series, the total capacitance decreases in similar fashion to the decreases in resistance seen in parallel resistors, as shown in Figure 6.3.

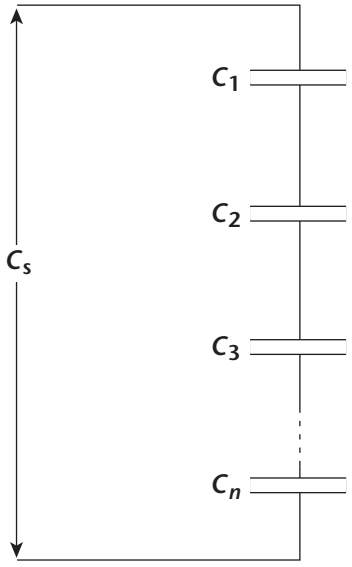

Figure 6.3. Capacitors in Series
C_s decreases as more capacitors are added.

This is because the capacitors must share the voltage drop in the loop and therefore cannot store as much charge. Functionally, a group of capacitors in series acts like one equivalent capacitor with a much larger distance between its plates (in fact, with a distance equal to those of each of the series capacitors added together). This increase in distance, as seen earlier, means a smaller capacitance.

Rather than memorizing the following equations independently, understand the conceptual basis for the mathematics of resistors in series and in parallel, and then simply reverse that mathematical approach for capacitors. The equation for calculating the equivalent capacitance for capacitors in series is

$$\frac{1}{C_s} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots + \frac{1}{C_n}$$

Equation 6.18

which shows that C_s decreases as more capacitors are added. Note that for capacitors in series, the total voltage is the sum of the individual voltages, just like resistors in series.

Capacitors in Parallel

Capacitors wired in parallel, shown in Figure 6.4, produce a resultant capacitance that is equal to the sum of the individual capacitances.

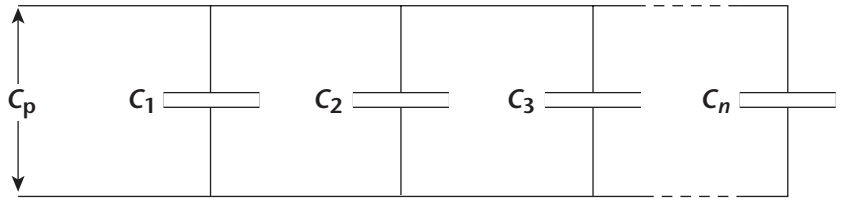

Figure 6.4. Capacitors in Parallel
C_p increases as more capacitors are added.

Therefore, C_p increases as more capacitors are added:

$$C_p = C_1 + C_2 + C_3 + \cdots + C_n$$

Equation 6.19

Just as we saw with resistors in parallel, the voltage across each parallel capacitor is the same and is equal to the voltage across the source.

MCAT Concept Check 6.3:
Before you move on, assess your understanding of the material with these questions.

1. Assuming the plates are attached by a conducting material, how does a capacitor behave after the voltage source has been removed from a circuit?

_____

_____

2. How does a dielectric material impact capacitance? Voltage? Charge?
   - Capacitance:

     _____
   - Voltage:

     _____
   - Charge:

     _____

3. How does adding or removing a capacitor change the total capacitance of a circuit with capacitors in series? In parallel?
   - Series:

     _____

   - Parallel:

     _____

4. What physical qualities contribute to the capacitance of a capacitor?

_____

_____

6.4 Meters ★

While we've been focused on calculations of hypothetical circuits so far, it's important for us to spend some time considering real ones. While we will not analyze any complex circuits here, it is important to be familiar with **meters**, the devices that are used to measure circuit quantities in the real world.

AMMETERS

Ammeters are used to measure the current at some point within a circuit. Using an ammeter requires the circuit to be on, or the current will be 0 A. Ammeters are inserted in series where the current is being measured and use the magnetic properties of a current-carrying wire to cause a visible needle movement or a calibrated display of the current. If there is a particularly high current, this will overwhelm the ammeter, and a special low resistance shunt is used in parallel with the ammeter to allow a reading. Ideally, an ammeter will not change circuit mathematics when it is inserted into the circuit. To do so, it must have an extremely low resistance. Ideal ammeters have zero resistance and no voltage drop across themselves.

VOLTMETERS

A **voltmeter**, like an ammeter, requires a circuit to be active. Voltmeters also use magnetic properties of current-carrying wires. However, voltmeters are used to measure the voltage drop across two points in a circuit. They are wired in parallel to these two points. Because the goal with any meter is to minimize its impact on the rest of the circuit, and voltmeters are wired in parallel, an ideal voltmeter has infinite resistance.

OHMMETERS

Unlike voltmeters and ammeters, an **ohmmeter** does not require a circuit to be active (in fact, some ohmmeters will give false readings or can be damaged by an active circuit). Ohmmeters will often have their own battery of known voltage and then function as ammeters through another point in the circuit. Because only one circuit element is being analyzed, Ohm's law can be used to calculate resistance by knowing the ohmmeter's voltage and the current created through another point in the circuit.

MCAT Concept Check 6.4:

Before you move on, assess your understanding of the material with these questions.

1. What do each of the following types of meters measure? Where are they placed in circuits? What are their ideal resistances?

Meter Type	Measures...	Placement	Ideal Resistance
Ammeter			
Voltmeter			
Ohmmeter			

2. True or False: A voltmeter and an ammeter should not be placed in the same circuit.

Conclusion

This chapter covered a lot of material. We began with a review of current, taking special note of the conventional definition of current as the movement of positive charge (when, in fact, negatively-charged electrons are actually moving). We considered the basic laws of electricity and circuits: Kirchhoff's laws, which are expressions of conservation of charge and energy, and Ohm's law, which relates voltage, current, and resistance. We defined resistance and analyzed the relationships between resistance and resistivity (directly proportional), resistance and length (directly proportional), and resistance and cross-sectional area (inversely proportional). We also defined capacitance as the ability to store charge at some voltage, thereby storing energy. Throughout, we stressed the importance of the both the conceptual and mathematical treatment of resistors and capacitors in series and in parallel as a major testing topic on the MCAT. Finally, we covered the different meters that can be used to measure circuit quantities.

Electricity is often a challenging concept for MCAT students. Unlike kinematics, thermodynamics, and fluids, which are often more tangible, electricity is often best understood through schematics and models. Take time to review these last two chapters, as they will assuredly pay off as points on Test Day. In the next chapter, we turn our attention to a completely different topic that is no more tangible—but is far more audible: sound.

CONCEPT SUMMARY

Current

- **Current** is the movement of charge that occurs between two points that have different electrical potentials.
  - By convention, current is defined as the movement of positive charge from the high-potential end of a voltage source to the low-potential end.
  - In reality, it is negatively-charged particles (electrons) that move in a circuit, from low potential to high potential.
- Current flows only in **conductive materials**.
  - **Metallic conduction** relies on uniform movement of free electrons in metallic bonds.
  - **Electrolytic conduction** relies on the ion concentration of a solution.
  - **Insulators** are materials that do not conduct a current.
- **Kirchhoff's laws** express conservation of charge and energy.
  - **Kirchhoff's junction rule** states that the sum of currents directed into a point within a circuit equals the sum of the currents directed away from that point.
  - **Kirchhoff's loop rule** states that in a closed loop, the sum of voltage sources is always equal to the sum of voltage drops.

Resistance

- **Resistance** is opposition to the movement of electrons through a material.
- **Resistors** are conductive materials with a moderate amount of resistance that slow down electrons without stopping them.
- Resistance is calculated using the resistivity, length, and cross-sectional area of the material in question.
- **Ohm's law** states that for a given resistance, the magnitude of the current through a resistor is proportional to the voltage drop across the resistor.
- Resistors in circuits can be combined to calculate the equivalent resistance of a full or partial circuit.
  - Resistors in **series** are additive and sum together to create the total resistance of a circuit.
  - Resistors in **parallel** cause a decrease in equivalent resistance of a circuit.
- Across each resistor in a circuit, a certain amount of power is dissipated, which is dependent on the current through the resistor and the voltage drop across the resistor.

Capacitance and Capacitors

- **Capacitors** have the ability to store and discharge electrical potential energy.
- **Capacitance** in parallel plate capacitors is determined by the area of the plates and the distance between the plates.
- Capacitors in series cause a decrease in the equivalent capacitance of a circuit.
- Capacitors in parallel sum together to create a larger equivalent capacitance.
- **Dielectric materials** are insulators placed between the plates of a capacitor that increase capacitance by a factor equal to the material's **dielectric constant**, κ.

Meters

- **Ammeters** are inserted in series in a circuit to measure current; they have negligible resistance.
- **Voltmeters** are inserted in parallel in a circuit to measure a voltage drop; they have very large resistances.
- **Ohmmeters** are inserted around a resistive element to measure resistance; they are self-powered and have negligible resistance.

ANSWERS TO CONCEPT CHECKS

6.1

1. Current is the movement of positive charge through a conductive material over time and is given in ampères $\left(\frac{\text{C}}{\text{s}}\right)$. Voltage is a potential difference between two points and is given in volts $\left(\frac{\text{J}}{\text{C}}\right)$. Electromotive force (emf) refers to the potential difference of the voltage source for a circuit, usually a battery, and is given in volts. Conductivity is the reciprocal of resistance and is a measure of permissiveness to current flow; it is measured in siemens (S).
2. The sodium chloride solution likely has a higher conductivity because it is a salt and will increase the ion content of water. Glucose does not dissociate, and therefore it has a near-zero impact on conductivity.
3. True. This is a restatement of Kirchhoff's junction rule.
4. False. While the voltage sources and voltage drops are equal in any closed loop, this is not necessarily true for the entire circuit. For example, a 9 V battery that powers 10 light bulbs in parallel has a 9 V voltage source and a 9 V drop across each light bulb—a total of 90 V of drop across all of the light bulbs combined.

6.2

1. Adding a resistor in series increases the total resistance of a circuit; removing one in series decreases the total resistance in the circuit. These relationships are reversed in parallel: adding a resistor decreases resistance while removing one increases it.
2. Resistivity, length, cross-sectional area, and temperature all contribute to the resistance of a resistor.
3. Power is related to current, voltage, and resistance through the equations $P = IV = I^2R = \frac{V^2}{R}$.
4. True. The internal resistance will lower the available voltage for the circuit. Lowering the available voltage will also lower current for any given resistance.

6.3

1. The capacitor discharges, providing a current in the opposite direction of the initial current.
2. A dielectric material will always increase capacitance. If the capacitor is isolated, its voltage will decrease when a dielectric material is introduced; if it is in a circuit, its voltage is constant because it is dictated by the voltage source. If a capacitor is isolated, the stored charge will remain constant because there is no additional source of charge; if it is in a circuit, the stored charge will increase.

3. Adding a capacitor in series decreases the total capacitance of a circuit; removing one in series increases the total capacitance in the circuit. These relationships are reversed in parallel: adding a capacitor increases capacitance while removing one decreases it.
4. Surface area, distance, and dielectric constant all contribute to the capacitance of a capacitor.

6.4

1.

Meter type	Measures...	Placement	Ideal Resistance
Ammeter	Current	In series with point of interest	0
Voltmeter	Potential difference (voltage)	Parallel with circuit element of interest	∞
Ohmmeter	Resistance	Two points in series with circuit element of interest	0

2. False. Voltmeters and ammeters are designed to have minimum impact on a circuit, thus they can be used together.

EQUATIONS TO REMEMBER

(6.1) **Current:** $I = \frac{Q}{\Delta t}$

(6.2) **Kirchhoff's junction rule:** $I_{\text{into junction}} = I_{\text{leaving junction}}$

(6.3) **Kirchhoff's loop rule:** $V_{\text{source}} = V_{\text{drop}}$

(6.4) **Definition of resistance:** $R = \frac{\rho L}{A}$

(6.5) **Ohm's law:** $V = IR$

(6.6) **Voltage and cell emf:** $V = E_{\text{cell}} - ir_{\text{int}}$

(6.7) **Definition of power:** $P = \frac{W}{t} = \frac{\Delta E}{t}$

(6.8) **Electric power:** $P = IV = I^2R = \frac{V^2}{R}$

(6.9) **Voltage drop across circuit elements (series):** $V_s = V_1 + V_2 + V_3 + \cdots + V_n$

(6.10) **Equivalent resistance (series):** $R_s = R_1 + R_2 + R_3 + \cdots + R_n$

(6.11) **Voltage drop across circuit elements (parallel):** $V_p = V_1 = V_2 = V_3 = \ldots = \mathrm{V}_n$

(6.12) **Equivalent resistance (parallel):** $\frac{1}{R_p} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R_n}$

(6.13) **Definition of capacitance:** $C = \frac{Q}{V}$

(6.14) **Capacitance based on parallel plate geometry:** $C = \varepsilon_0\left(\frac{A}{d}\right)$

(6.15) **Electric field in a capacitor:** $E = \frac{V}{d}$

(6.16) **Potential energy of a capacitor:** $U = \frac{1}{2}CV^2$

(6.17) **Capacitance with a dielectric material:** $C' = \kappa C$

(6.18) **Equivalent capacitance (series):** $\frac{1}{C_s} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots + \frac{1}{C_n}$

(6.19) **Equivalent capacitance (parallel):** $C_p = C_1 + C_2 + C_3 + \cdots + C_n$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. If a defibrillator passes 15 A of current through a patient's body for 0.1 seconds, how much charge goes through the patient's skin?

A. 0.15 C
B. 1.5 C
C. 15 C
D. 150 C

2. A charge of 2 μC flows from the positive terminal of a 6 V battery, through a 100 Ω resistor, and back through the battery to the positive terminal. What is the total potential difference experienced by the charge?

A. 0 V
B. 0.002 V
C. 0.2 V
D. 6 V

3. The resistance of two conductors of equal cross-sectional area and equal lengths are compared, and are found to be in the ratio 1:2. The resistivities of the materials from which they are constructed must therefore be in what ratio?

A. 1:1
B. 1:2
C. 2:1
D. 4:1

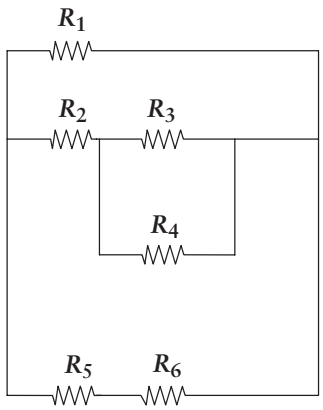
4. A voltaic cell provides a current of 0.5 A when in a circuit with a 3 Ω resistor. If the internal resistance of the cell is 0.1 Ω, what is the voltage across the terminals of the battery when there is no current flowing?

A. 0.05 V
B. 1.5 V
C. 1.505 V
D. 1.55 V

5. A transformer is a device that takes an input voltage and produces an output voltage that can be either larger or smaller than the input voltage, depending on the transformer design. Although the voltage is changed by the transformer, energy is not, so the input power equals the output power. A particular transformer produces an output voltage that is 300 percent of the input voltage. What is the ratio of the output current to the input current?

A. 1:3
B. 3:1
C. 1:300
D. 300:1

6. Given that $R_1 = 20\ \Omega$, $R_2 = 4\ \Omega$, $R_3 = R_4 = 32\ \Omega$, $R_5 = 15\ \Omega$, and $R_6 = 5\ \Omega$, what is the total resistance in the setup shown below?

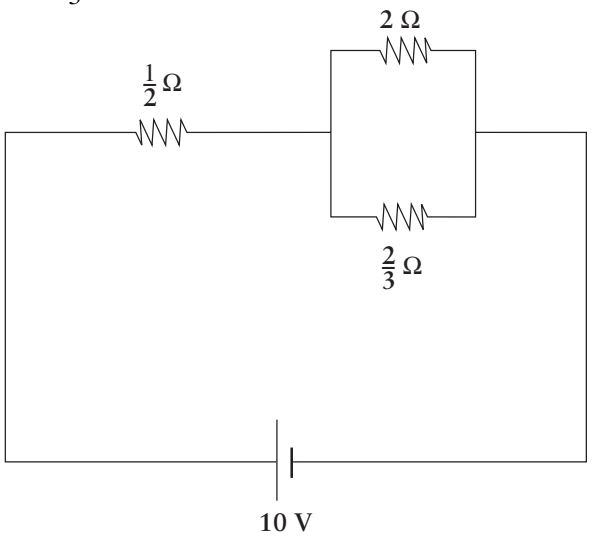


A. 0.15 Ω
B. 6.67 Ω
C. 16.7 Ω
D. 60 Ω

7. How many moles of electrons pass through a circuit containing a 100 V battery and a 2 Ω resistor over a period of 10 seconds? (Note: $F = 9.65 \times 10^4 \frac{C}{\text{mol } e^-}$.)

A. 5.18×10^{-3} moles
B. 500 moles
C. 5.18×10^{3} moles
D. 5.2×10^{6} moles

8. In the circuit below, what is the voltage drop across the $\frac{2}{3}\ \Omega$ resistor?



A. $\frac{1}{2}$ V
B. $\frac{2}{3}$ V
C. 5 V
D. 7.5 V

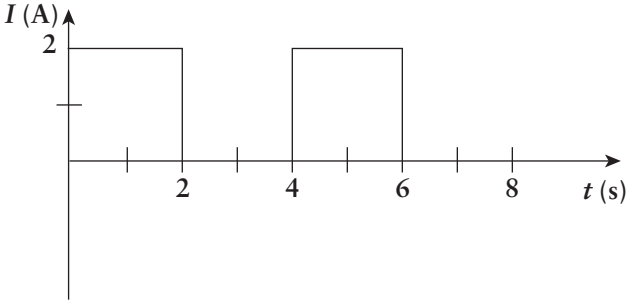
9. If the area of a capacitor's plates is doubled while the distance between them is halved, how will the final capacitance (C_f) compare to the original capacitance (C_i)?

A. $C_f = C_i$
B. $C_f = \frac{1}{2}C_i$
C. $C_f = 2C_i$
D. $C_f = 4C_i$

10. The energy stored in a fully charged capacitor is given by $U = \frac{1}{2}CV^2$. In a typical cardiac defibrillator, a capacitor charged to 7500 V has a stored energy of 400 J. Based on this information, what is the charge on the capacitor in the cardiac defibrillator?

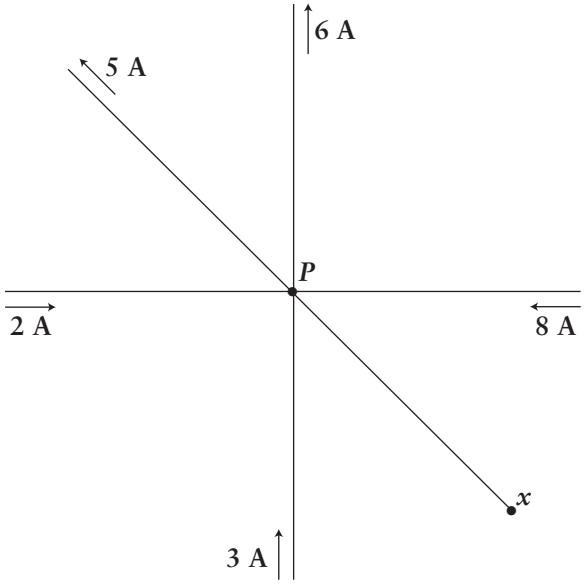
A. 1.1×10^{-5} C
B. 5×10^{-2} C
C. 1.1×10^{-1} C
D. 3.1×10^{6} C

11. A 10 Ω resistor carries a current that varies as a function of time as shown. How much energy has been dissipated by the resistor after 5 s?



A. 40 J
B. 50 J
C. 120 J
D. 160 J

12. In the figure below, six currents meet at point *P*. What is the magnitude and direction of the current between points *P* and *x*?

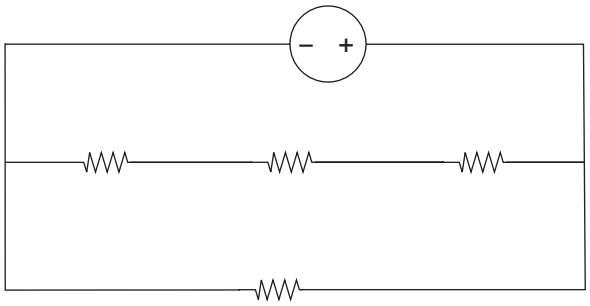


A. 2 A, toward *x*
B. 2 A, toward *P*
C. 10 A, toward *x*
D. 10 A, toward *P*

13. Which of the following will most likely increase the electric field between the plates of a parallel plate capacitor?

A. Adding a resistor that is connected to the capacitor in series
B. Adding a resistor that is connected to the capacitor in parallel
C. Increasing the distance between the plates
D. Adding an extra battery to the system

14. Each of the resistors shown carries an individual resistance of 4 Ω. Assuming negligible resistance in the wire, what is the overall resistance of the circuit?



A. 16 Ω
B. 8 Ω
C. 4 Ω
D. 3 Ω

15. Which of the following best characterizes ideal voltmeters and ammeters?

A. Ideal voltmeters and ammeters have infinite resistance.
B. Ideal voltmeters and ammeters have no resistance.
C. Ideal voltmeters have infinite resistance, and ideal ammeters have no resistance.
D. Ideal voltmeters have no resistance, and ideal ammeters have infinite resistance.

Explanations to Discrete Practice Questions

1. B

Electrical current is defined as charge flow, or in mathematical terms, charge transferred per time: $I = \frac{Q}{\Delta t}$. A 15 A current that acts for 0.1 s will transfer 15 A × 0.1 s = 1.5 C of charge.

2. A

Kirchhoff's loop rule states that the total potential difference around any closed loop of a circuit is 0 V. Another way of saying this is that the voltage gained in the battery (6 V) will be used up through the resistors. Because this charge both started and ended at the positive terminal, its total potential difference is therefore 0 V. 6 V, **choice (D)**, is the voltage gained in the battery as well as the voltage drop in the resistors—creating a net sum of 0 V.

3. B

The resistance of a resistor is given by the formula $R = \frac{\rho L}{A}$ Thus, there is a direct proportionality between resistance and resistivity. Because the other variables are equal between the two resistors, we can determine that if $R_1 : R_2$ is a 1:2 ratio, then $\rho_1 : \rho_2$ is also a 1:2 ratio.

4. D

This question tests our understanding of batteries in a circuit. The voltage across the terminals of the battery when there is no current flowing is referred to as the electromotive force (emf or ε of the battery). However, when a current is flowing through the circuit, the voltage across the terminals of the battery is decreased by an amount equal to the current multiplied by the internal resistance of the battery. Mathematically, this is given by the equation

$$V = \varepsilon - ir_{\text{int}}$$

To determine the emf of the battery, first calculate the voltage across the battery when the current is flowing. For this, we can use Ohm's law:

$$\begin{aligned} V &= IR \\ &= (0.5\text{ A})(3\ \Omega) = 1.5\text{ V} \end{aligned}$$

Because we know the internal resistance of the battery, the current, and the voltage, we can calculate the emf:

$$\begin{aligned} \varepsilon &= V + ir_{\text{int}} \\ &= 1.5\text{ V} + (0.5\text{ A})(0.1\ \Omega) \\ &= 1.5 + 0.05 = 1.55\text{ V} \end{aligned}$$

The answer makes sense in the context of a real battery because its internal resistance is supposed to be very small so that the voltage provided to the circuit is as close as possible to the emf of the cell when there is no current running.

5. A

We are told that transformers conserve energy so that the output power equals the input power. Thus $P_{\text{out}} = P_{\text{in}}$, or $I_{\text{out}}V_{\text{out}} = I_{\text{in}}V_{\text{in}}$. There is therefore an inverse proportionality between current and voltage. If the output voltage is 300% of the input voltage (3 times its amount), then the output current must be $\frac{1}{3}$ of the input voltage. This can be represented as a 1:3 ratio.

6. B

The fastest way to tackle these kinds of questions is to simplify the circuit bit by bit. For example, notice that R_3 and R_4 are in parallel with each other and are in series with R_2; similarly, R_5 and R_6 are in series. If we determine the total resistance in each branch, we will be left with three branches in parallel. To start, find the total resistance in the middle branch:

$$\frac{1}{R_{3+4}} = \frac{1}{R_3} + \frac{1}{R_4} = \frac{1}{32\ \Omega} + \frac{1}{32\ \Omega} \rightarrow R_{3+4} = 16\ \Omega$$
$$R_{2+3+4} = R_2 + R_{3+4} = 4\ \Omega + 16\ \Omega = 20\ \Omega$$

Next, take a look at the total resistance in the bottom branch:

$$R_{5+6} = R_5 + R_6 = 15\ \Omega + 5\ \Omega = 20\ \Omega$$

The circuit can now be viewed as three resistors in parallel, each providing a resistance of 20 Ω. The total resistance in the circuit is thus

$$\frac{1}{R_{tot}} = \frac{1}{R_1} + \frac{1}{R_{2+3+4}} + \frac{1}{R_{5+6}} =$$
$$\frac{1}{20\ \Omega} + \frac{1}{20\ \Omega} + \frac{1}{20\ \Omega} \rightarrow \frac{20}{3}\ \Omega = 6.67\ \Omega$$

7. A

To determine the moles of charge that pass through the circuit over a period of 10 s, we will have to calculate the amount of charge running through the circuit. Charge is simply current times time, and the current can be calculated using Ohm's law:

$$V = IR \quad \text{and} \quad I = \frac{Q}{\Delta t} \rightarrow Q = \frac{V\Delta t}{R}$$
$$Q = \frac{(100\ \text{V})(10\ \text{s})}{2\ \Omega} = 500\ \text{C}$$

Then, calculate the number of moles of charge that this represents by using the Faraday constant and approximating F as $10^5\ \frac{\text{C}}{\text{mol}\ e^-}$:

$$500\ \text{C}\left[\frac{\text{mol}\ e^-}{10^5\ \text{C}}\right] = 5 \times 10^{-3}\ \text{mol}\ e^-$$

This is closest to **choice (A)**.

8. C

To determine the voltage drop across the $\frac{2}{3}\ \Omega$ resistor, start by calculating the total resistance in the circuit. For the resistors in parallel, the equivalent resistance is

$$\frac{1}{R_p} = \frac{1}{2\ \Omega} + \frac{3}{2\ \Omega} \rightarrow R_p = \frac{1}{2}\ \Omega$$

The total resistance in the circuit is the sum of the remaining resistor and the equivalent resistance of the other two:

$$R_s = \frac{1}{2}\ \Omega + \frac{1}{2}\ \Omega = 1\ \Omega$$

Now that we know the equivalent resistance, we can calculate the total current using Ohm's law:

$$I = \frac{V}{R} = \frac{10\ \text{V}}{1\ \Omega} = 10\ \text{A}$$

Finally, we can determine the voltage drop across the parallel resistors. The voltage drop across the $\frac{1}{2}\ \Omega$ resistor must be $(10\ \text{A})\left(\frac{1}{2}\ \Omega\right) = 5\ \text{V}$. Therefore, there must be a 5 V drop across both the $\frac{2}{3}\ \Omega$ resistor and 2 Ω resistor, according to Kirchhoff's loop rule. Each of these resistors forms a complete loop in combination with the $\frac{1}{2}\ \Omega$ resistor and 10 V voltage source, and the net potential difference around any closed loop must be 0 V.

9. D

This question should bring to mind the equation $C = \varepsilon_0\left(\frac{A}{d}\right)$, where ε_0 is the permittivity of free space, A is the area of the plates, and d is the distance between the plates. From this equation, we can infer that doubling the area will double the capacitance, and halving the distance will also double the capacitance. Therefore, the new capacitance is four times larger than the initial capacitance.

10. C

Because the question is asking us to calculate the charge on the capacitor, use the formula $Q = CV$. We are given $V = 7500$ V and can calculate C from the formula for energy, $U = \frac{1}{2}CV^2$:

$$U = \frac{1}{2}CV^2 = \frac{1}{2}\left(\frac{Q}{V}\right)V^2 = \frac{QV}{2}$$
$$Q = \frac{2U}{V} = \frac{2(400\ \text{J})}{7500\ \text{V}} \approx \frac{800}{8000} = 0.1\ \text{C}$$

Thus, the charge is close to 0.1 C, which is closest to **choice (C)**.

11. C

Power is energy dissipated per unit time; therefore, the energy dissipated is $E = P\Delta t$. In the five-second interval during which the resistor is active, it has a 2 A current for three of those seconds. The power dissipated by a resistor R carrying a current I is $P = I^2R$. Therefore, the energy dissipated is

$$E = I^2R\Delta t = (2\ \text{A})^2(10\ \Omega)(3\ \text{s}) = 4 \times 10 \times 3 = 120\ \text{J}$$

12. A

Kirchhoff's junction rule states that the sum of all currents directed into a point is always equal to the sum of all currents directed out of the point. The currents directed into point *P* are 8 A, 2 A, and 3 A, so the sum is 13 A. The currents directed out of point *P* are 5 A and 6 A, so the total is 11 A. Because the two numbers must always be equal, an additional current of 2 A must be directed away from point *P* toward point *x*.

13. D

The electric field between two plates of a parallel plate capacitor is related to the potential difference between the plates of the capacitor and the distance between the plates, as shown in the formula $E = \frac{V}{d}$. The addition of another battery will increase the total voltage applied to the circuit, which, consequently, will increase the electric field. The addition of a resistor in series will increase the resistance and decrease the voltage applied to the capacitor, eliminating **choice (A)**. Adding a resistor in parallel will not change the voltage drop across the capacitor and should not change the electric field, eliminating **choice (B)**. Increasing the distance between the plates, **choice (C)**, would decrease the electric field, not increase it.

14. D

The resistance of the three resistors wired in series is equal to the sum of the individual resistances (12 Ω). This means that the circuit functionally contains a 12 Ω resistor and a 4 Ω resistor in parallel. To determine the overall resistance of this system, use the formula

$$\frac{1}{R_p} = \frac{1}{R_1} + \frac{1}{R_2} = \frac{1}{12\ \Omega} + \frac{1}{4\ \Omega} = \frac{1+3}{12\ \Omega} \rightarrow R_p = 3\ \Omega$$

15. C

While this is primarily a recall question, it should also be intuitive. Voltmeters are attempting to determine a change in potential from one point to another. To do this, they should not provide an alternate route for charge flow and should therefore have infinite resistance. Ammeters attempt to determine the flow of charge at a single point and should not contribute to the resistance of a series circuit; therefore, they should have no resistance.

Concept Summary 246

Introduction

As a species, our interactions with sound are amazingly complex. The human ear developed as a means of detecting longitudinal waves carried in the air—this likely served an evolutionary purpose. A rustle in the leaves could indicate not only a potential meal, but also a potential predator. Our brains are highly attuned to analyze the sounds around us, as discussed in Chapter 2 of *MCAT Behavioral Sciences Review*. This includes not only the normal auditory pathway from the pinna through the tympanic membrane, ossicles, cochlea, and vestibulocochlear nerve to the temporal lobe, but also secondary structures such as the superior olive, which helps localize sound, and the inferior colliculus, which is involved in the startle reflex.

Language is also inextricably linked to sound. Through changes in pitch and timbre, we can imply or evoke dozens of complex feelings. Through music, our relationship with sound becomes even more profound. As E.T.A. Hoffman, a musicologist and pedagogue, wrote in his vivid description of Beethoven's opening motif for *Symphony No. 5 in C minor*, op. 67:

Radiant beams shoot through this region's deep night, and we become aware of gigantic shadows which, rocking back and forth, close in on us and destroy everything within us except the pain of endless longing—a longing in which every pleasure that rose up in jubilant tones sinks and succumbs, and only through this pain, which, while consuming but not destroying love, hope, and joy, tries to burst our breasts with full-voiced harmonies of all the passions, we live on and are captivated beholders of the spirits.

Indeed, sound can create entire worlds that we can explore. This chapter, however, aims only to lay the foundation for understanding wave phenomena. The general

properties of waves will be introduced, including a discussion of wavelength, frequency, wave speed, amplitude, and resonance. We will also review the interactions of waves meeting at a point in space through constructive and destructive interference and examine the mathematics of standing waves—the means by which musical instruments produce their characteristic sounds. The subject of sound is reviewed as a specific example of the longitudinal waveform with a focus on wave phenomena like the Doppler effect. Finally, we provide a brief discussion of the use of ultrasound and shock waves in medicine.

7.1 General Wave Characteristics ★★

It is important to use a common language when describing waves. We'll establish the terminology associated with wave phenomena, and then spend the rest of this chapter looking at the application of wave principles to sound. In the next chapter, we'll shift our focus to electromagnetic waves.

TRANSVERSE AND LONGITUDINAL WAVES

The MCAT is primarily concerned with **sinusoidal waves**. In these waves, which may be transverse or longitudinal, the individual particles oscillate back and forth with a displacement that follows a sinusoidal pattern. **Transverse waves** are those in which the direction of particle oscillation is perpendicular to the **propagation** (movement) of the wave. To visualize this, consider "The Wave" in a stadium. While "The Wave" moves around the stadium, individuals in the stands do not run around the stadium themselves. Rather, they move perpendicular to the direction of "The Wave"—by standing up and sitting down. More common examples on the MCAT include electromagnetic waves, such as visible light, microwaves, and x-rays. You could also form a transverse wave by attaching a string to a fixed point, and then moving your hand up and down, as is demonstrated in Figure 7.1a. In any waveform, energy is delivered in the direction of wave travel, so we can say that for a transverse wave, the particles are oscillating perpendicular to the direction of energy transfer.

Key Concept

Transverse waves have particle oscillation perpendicular to the direction of propagation and energy transfer. Longitudinal waves have particle oscillation parallel to the direction of propagation and energy transfer.

Longitudinal waves are ones in which the particles of the wave oscillate parallel to the direction of propagation; that is, the wave particles are oscillating in the direction of energy transfer. Sound waves are the classic example of longitudinal waves, but because we can't see sound, this waveform is a little more difficult to picture. Figure 7.1b helps us visualize what a longitudinal waveform traveling through air would look like. In this case, the longitudinal wave created by the person moving the piston back and forth causes air molecules to oscillate through cycles of **compression** and **rarefaction** (**decompression**) along the direction of motion of the wave. You could also form a longitudinal wave by laying a slinky flat on a table top and tapping it on the end.

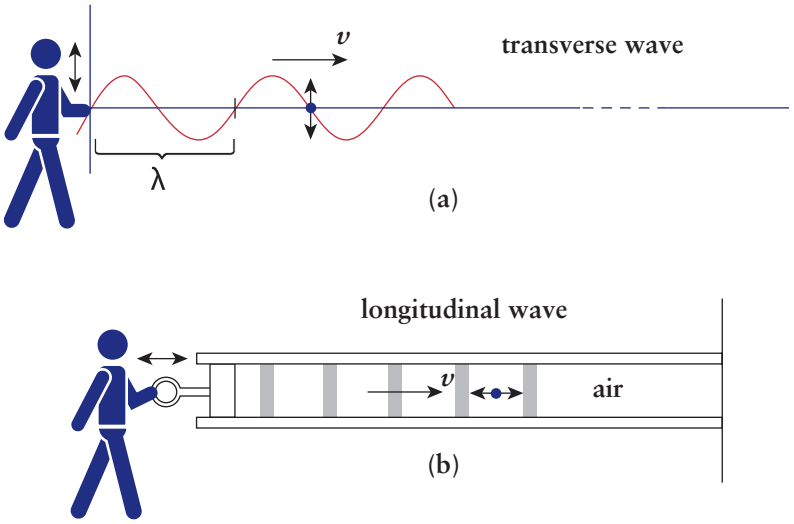

Figure 7.1. Wave Types
(a) Transverse: particles oscillate perpendicular to the direction of propagation; (b) Longitudinal: particles oscillate parallel to the direction of propagation.

DESCRIBING WAVES

Waves can be described mathematically or graphically. To do so, we must first assign meaning to the physical quantities that waves represent. The distance from one maximum (**crest**) of the wave to the next is called the **wavelength** (**λ**). The **frequency** (***f***) is the number of wavelengths passing a fixed point per second, and is measured in **hertz** (**Hz**) or cycles per second (cps). From these two values, one can calculate the **propagation speed** (***v***) of a wave:

$$v = f\lambda$$

Equation 7.1

If frequency defines the number of cycles per second, then its inverse—**period** (***T***)—is the number of seconds per cycle:

$$T = \frac{1}{f}$$

Equation 7.2

Frequency is also related to **angular frequency** (***ω***), which is measured in radians per second, and is often used in consideration of simple harmonic motion in springs and pendula:

$$\omega = 2\pi f = \frac{2\pi}{T}$$

Equation 7.3

MCAT Expertise

Even if simple harmonic motion in springs and strings (pendula) are not on the formal content lists for the MCAT, it is still important to be familiar with the jargon of wave motion because sound and light (electromagnetic radiation) *are* on those content lists!

Waves oscillate about a central point called the **equilibrium position**. The **displacement** (**x**) in a wave describes how far a particular point on the wave is from the equilibrium position, expressed as a vector quantity. The maximum magnitude of displacement in a wave is called its **amplitude** (***A***). Be careful with the terminology: note that the amplitude is defined as the maximum displacement from the equilibrium position to the top of a crest or bottom of a trough, not the total displacement between a crest and a trough (which would be double the amplitude). These quantities are shown in Figure 7.2.

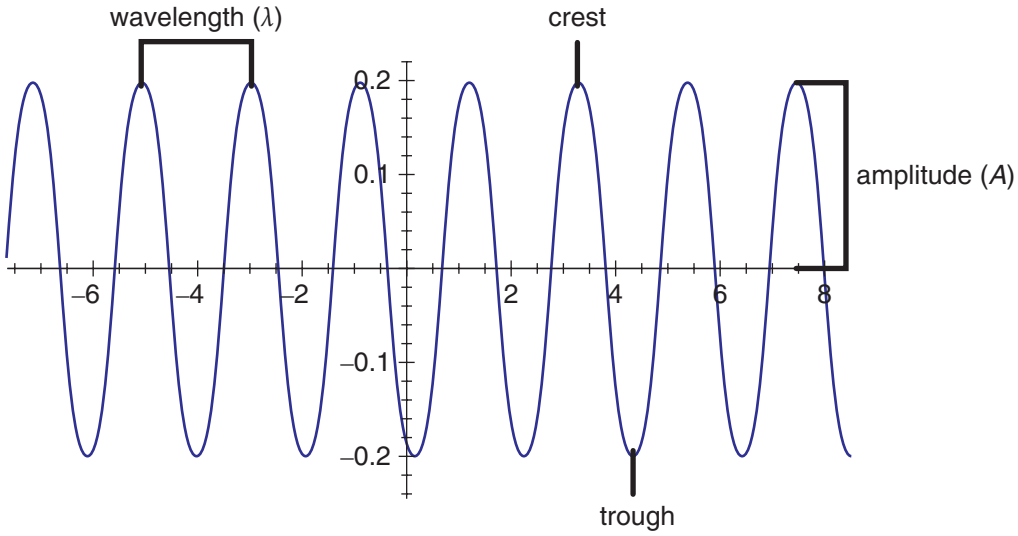

Figure 7.2. Anatomy of a Wave

PHASE

When analyzing waves that are passing through the same space, we can describe how "in step" or "out of step" the waves are by calculating the **phase difference**. If we consider two waves that have the same frequency, wavelength, and amplitude and that pass through the same space at the same time, we can say that they are *in phase* if their respective crests and troughs coincide (line up with each other). When waves are perfectly in phase, we say that the phase difference is zero. However, if the two waves travel through the same space in such a way that the crests of one wave coincide with the troughs of the other, then we would say that they are *out of phase*, and the phase difference would be one-half of a wave. This could be expressed as $\frac{\lambda}{2}$ or, if given as an angle, 180° (one cycle = one wavelength = 360°). Of course, waves can be out of phase with each other by any other fraction of a cycle, as well.

PRINCIPLE OF SUPERPOSITION

The **principle of superposition** states that when waves interact with each other, the displacement of the resultant wave at any point is the sum of the displacements of the two interacting waves. When the waves are perfectly in phase, the displacements

always add together and the amplitude of the resultant is equal to the sum of the amplitudes of the two waves. This is called **constructive interference**. When waves are perfectly out of phase, the displacements always counteract each other and the amplitude of the resultant wave is the difference between the amplitudes of the interacting waves. This is called **destructive interference**.

If waves are not perfectly in phase or out of phase with each other, **partially constructive** or **partially destructive** interference can occur. As shown in Figure 7.3a, two waves that are nearly in phase will mostly add together. While the displacement of the resultant is simply the sum of the displacements of the two waves, the waves do not perfectly add together because they are not quite in phase. Therefore, the amplitude of the resultant wave is not quite the sum of the two waves' amplitudes. In contrast, Figure 7.3b shows two waves that are almost perfectly out of phase. The two waves do not quite cancel, but the resultant wave's amplitude is clearly much smaller than that of either of the other waves.

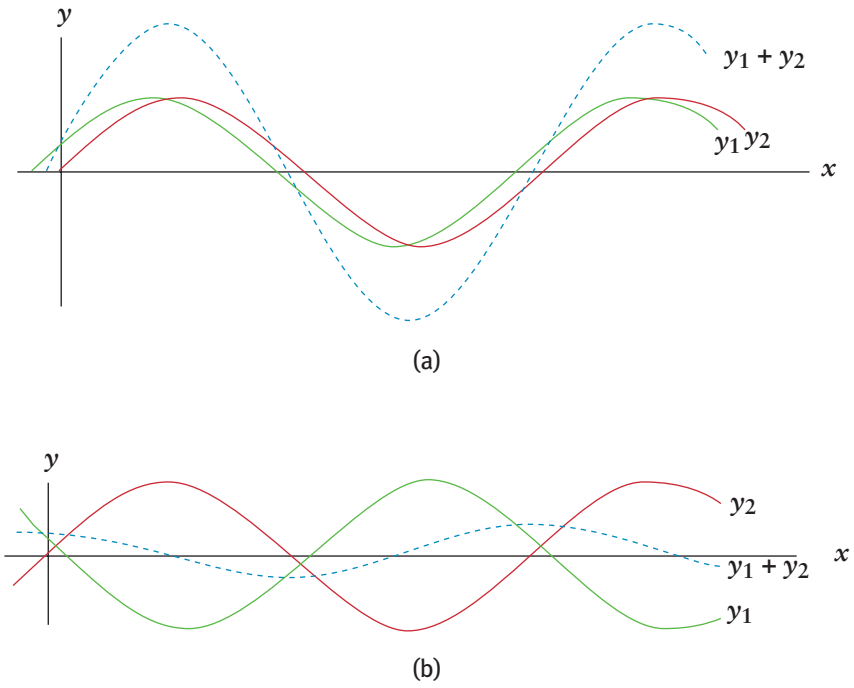

Figure 7.3. Phase Difference
(a) In phase with a difference of almost zero; (b) Out of phase with a difference of almost 180 degrees $\left(\frac{\lambda}{2}\right)$

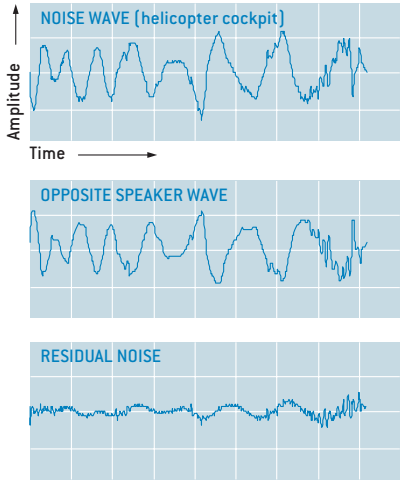
Noise-canceling headphones operate on the principle of superposition. They do not simply muffle sound, but actually capture the environmental noise and, using computer technology, produce a sound wave that is almost perfectly out of phase. The combination of the two waves inside the headset results in destructive interference, thereby canceling—or nearly canceling—the ambient noise.

Key Concept

If two waves are perfectly in phase, the resultant wave has an amplitude equal to the sum of the amplitudes of the two waves. If two equal waves are exactly 180 degrees out of phase, then the resultant wave has zero amplitude.

Real World

In noise-canceling headphones, pressure waves from noise are canceled by destructive interference. The speaker creates a wave that is 180 degrees out of phase and of similar amplitude. Many frequencies are usually present in the noise, so it is difficult to get perfect noise cancellation.



TRAVELING AND STANDING WAVES

If a string fixed at one end is moved up and down, a wave will form and travel, or propagate, toward the fixed end. Because this wave is moving, it is called a **traveling wave**. When the wave reaches the fixed boundary, it is reflected and inverted, as shown in Figure 7.4. If the free end of the string is continuously moved up and down, there will then be two waves: the original wave moving down the string toward the fixed end and the reflected wave moving away from the fixed end. These waves will then interfere with each other.

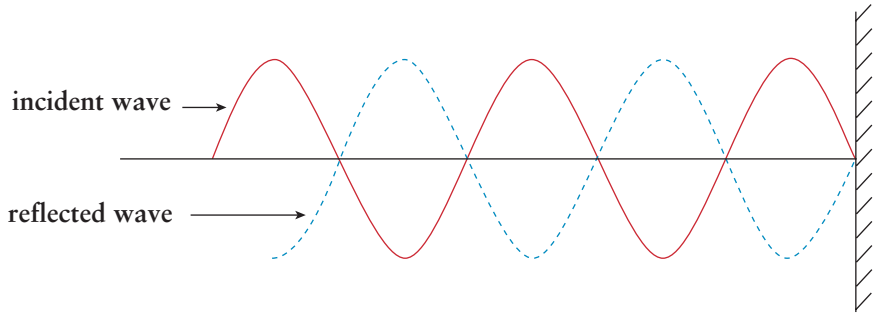


Figure 7.4. Traveling Wave

Now consider the case when both ends of the string are fixed and traveling waves are excited in the string. Certain wave frequencies will cause interference between the traveling wave and its reflected wave such that they form a waveform that appears to be stationary. In this case, the only apparent movement of the string is fluctuation of amplitude at fixed points along the length of the string. These waves are known as **standing waves**. Points in the wave that remain at rest (where amplitude is constantly zero) are known as **nodes**. Points midway between the nodes fluctuate with maximum amplitude and are known as **antinodes**. In addition to strings fixed at both ends, pipes that are open at both ends can support standing waves, and the mathematics relating the standing wave wavelength and the length of the string or the open pipe are similar. Pipes that are open at one end and closed at the other can also support standing waves, but because the closed end contains a node and the open end contains an antinode, the mathematics are different. Standing waves in strings and pipes are discussed in more detail later, within the context of sound, because standing wave formation is integral to the formation of sound in certain contexts.

RESONANCE

Why are clarinets, pianos, and even half-filled wine glasses considered musical instruments, but not pencils, chairs, or paper? This discrepancy has much to do with the **natural** (**resonant**) **frequencies** of these objects. Any solid object, when hit, struck, rubbed, or disturbed in any way will begin to vibrate. Tapping a pencil on a surface will cause it to vibrate, as will hitting a chair or crumpling a piece of paper. Blowing air pressure between a clarinet reed and a mouthpiece, striking a taut piano

string, and creating friction on a wine glass's surface will also cause vibration. If the natural frequency is within the frequency detection range of the human ear, the sound will be audible. The quality of the sound, called **timbre**, is determined by the natural frequency or frequencies of the object. Some objects vibrate at a single frequency, producing a pure tone. Other objects vibrate at multiple frequencies that have no relation to one another. These objects produce sounds that we do not find particularly musical, such as tapping a pencil, hitting a chair, or crumpling paper. These sounds are called **noise**, scientifically. Still other objects vibrate at multiple natural frequencies (a **fundamental pitch** and multiple **overtones**) that are related to each other by whole number ratios, producing a richer, more full tone. The human brain perceives these sounds as being more musical, and all nonpercussion instruments produce such overtones. Of note for the MCAT, the frequencies between 20 Hz and 20,000 Hz are generally audible to healthy young adults, and high-frequency hearing generally declines with age.

The natural frequency of most objects can be changed by changing some aspect of the object itself. For example, a set of eight identical glasses can be filled with different levels of water so that each vibrates at a different natural frequency, producing the eight notes of a diatonic musical scale. Strings have an infinite number of natural frequencies that depend on the length, linear density, and tension of the string.

If a periodically varying force is applied to a system, the system will then be driven at a frequency equal to the frequency of the force. This is known as **forced oscillation**. If the frequency of the applied force is close to that of the natural frequency of the system, then the amplitude of oscillation becomes much larger. This can easily be demonstrated by a child on a swing being pushed by a parent. If the parent pushes the child at a frequency nearly equal to the frequency at which the child swings back toward the parent, the arc of the swinging child will become larger and larger: the amplitude is increasing because the **force frequency** is nearly identical to the swing's natural frequency.

If the frequency of the periodic force is equal to a natural (resonant) frequency of the system, then the system is said to be **resonating**, and the amplitude of the oscillation is at a maximum. If the oscillating system were frictionless, the periodically varying force would continually add energy to the system, and the amplitude would increase indefinitely. However, because no system is completely frictionless, there is always some damping, which results in a finite amplitude of oscillation. In general, **damping** or **attenuation** is a decrease in amplitude of a wave caused by an applied or nonconservative force. Furthermore, many objects cannot withstand the large amplitude of oscillation and will break or crumble. A dramatic demonstration of resonance is the shattering of a wine glass by loudly singing the natural frequency of the glass. This is actually possible with a steady, loud tone—the glass will resonate (oscillate with maximum amplitude) and eventually shatter.

MCAT Concept Check 7.1:

Before you move on, assess your understanding of the material with these questions.

1. Define the following terms:
   - Wave speed:

     _____
   - Frequency:

     _____
   - Angular frequency:

     _____
   - Period:

     _____
   - Equilibrium position:

     _____
   - Amplitude:

     _____
   - Traveling wave:

     _____
   - Standing wave:

     _____

2. If two waves are out of phase at any interval besides 180 degrees, how does the amplitude of the resultant wave compare to the amplitudes of the two interfering waves?

   _____

   _____

   _____

3. True or False: Sound waves are a prime example of transverse waves.

4. How does applying a force at the natural frequency of a system change the system?

   _____

   _____

   _____

7.2 Sound

Sound is a longitudinal wave transmitted by the oscillation of particles in a deformable medium. As such, sound can travel through solids, liquids, and gases, but cannot travel through a vacuum. The speed of sound is given by the equation

$$v = \sqrt{\frac{B}{\rho}}$$

Equation 7.4

where B is the bulk modulus, a measure of the medium's resistance to compression (B increases from gas to liquid to solid), and ρ is the density of the medium. Because the bulk modulus increases disproportionately more than density as one goes from gas to liquid to solid, sound travels fastest through a solid and slowest through a gas. The speed of sound in air at 20°C is approximately 343 $\frac{\text{m}}{\text{s}}$.

Key Concept

The speed of sound is fastest in a solid with low density, and slowest in a very dense gas.

PRODUCTION OF SOUND

Sound is produced by the mechanical disturbance of particles in a material along the sound wave's direction of propagation. Although the particles themselves do not travel along with the wave, they do vibrate or oscillate about an equilibrium position, which causes small regions of compression to alternate with small regions of rarefaction (decompression). These alternating regions of increased and decreased particle density travel through the material, allowing the sound wave to propagate.

Because sound involves vibration of material particles, the source of any sound is ultimately a mechanical vibration of some frequency. They can be produced by the vibration of solid objects or the vibration of fluids, including gases. Solid objects that can vibrate to produce musical sound include strings (on a piano, violin, guitar, and so on), metal (bells), or wood bars (xylophone or marimba). Vibration of air within certain objects, including all woodwinds and brass instruments, pipe organs, and even a soda bottle, can also create musical sound. The pitch (frequency) at which the air column within the instrument vibrates is determined by the length of the air column, which can be changed either by covering holes in the instrument or directly changing its length.

The human voice is no less a musical instrument than any of those listed above. Sound is created by passing air between the vocal cords, which are a pair of thin membranes stretched across the larynx. As the air moves past the cords, they vibrate like the double reed of an oboe or bassoon, causing the air to vibrate at the same frequency. The pitch of the sound is controlled by varying the tension of the cords. Adult male vocal cords are larger and thicker than those of adult females; thus, the male voice is typically lower in pitch.

FREQUENCY AND PITCH

We've discussed frequency as the rate at which a particle or wave completes a cycle. Our perception of the frequency of sound is called the **pitch**. Lower-frequency sounds have lower pitch, and higher-frequency sounds have higher pitch. On the MCAT, sound frequencies are usually within the normal range of human hearing, from 20 Hz to 20,000 Hz. Sound waves with frequencies below 20 Hz are called **infrasonic** waves, and those with frequencies above 20,000 Hz are called **ultrasonic** waves. Both dog whistles, which emit frequencies between 20 and 22 kHz, and medical ultrasound machines, which emit frequencies in excess of 2 GHz, are examples of ultrasonic waves.

Doppler Effect

We've all witnessed the Doppler effect: an ambulance or fire truck with its sirens blaring is quickly approaching from the other lane, and as it passes, one can hear a distinct drop in the pitch of the siren. This phenomenon affecting frequency is called the **Doppler effect**, which describes the difference between the actual frequency of a sound and its perceived frequency when the source of the sound and the sound's detector are moving relative to one another. If the source and detector are moving toward each other, the perceived frequency, f', is greater than the actual frequency, f. If the source and detector are moving away from each other, the perceived frequency is less than the actual frequency. This can be seen from the Doppler effect equation:

$$f' = f\frac{(v \pm v_D)}{(v \mp v_S)}$$

Equation 7.5

where f' is the perceived frequency, f is the actual emitted frequency, v is the speed of sound in the medium, v_D is the speed of the detector, and v_S is the speed of the source. Note the unusual signs in the equation. If memorized in this form, the upper sign should be used when the detector or source is moving *toward* the other object. The lower sign should be used when the detector or source is moving *away* from the other object.

This sign convention is usually the most confusing part of the Doppler effect equation, so let's take a closer look. Imagine the situation presented earlier: you're driving down the street when you hear an ambulance approaching from behind. In this scenario, you are the detector and the ambulance is the sound source. At this time, you would say that you are driving away from the ambulance; even though the ambulance is moving faster and getting closer to you, the direction in which you are driving is still *away* from the ambulance. By this logic, the lower sign (–) should be used in the numerator, which relates to the detector. The driver of the ambulance, on the other hand, would say that he is driving *toward* you. By

Bridge

The Doppler effect applies to all waves, including light. This means that if a source of light is moving toward the detector, the observed frequency will increase. This is called blue shift because blue is at the high-frequency end of the visible spectrum. If the source is moving away from the detector, the observed frequency will decrease, causing red shift. Light and electromagnetic waves are discussed in Chapter 8 of *MCAT Physics and Math Review*.

Mnemonic

Sign convention in the Doppler equation:
- Top sign for "toward"
- Bottom sign for "away"

this logic, the top sign (–) should be used in the denominator, which relates to the source. In this case, the Doppler effect equation would look like this:

$$f' = f\frac{(v - v_D)}{(v - v_S)}$$

Because $v_S > v_D$, we know that $f' > f$.

Now imagine that the ambulance has passed you and continues to speed down the road. At this point, you would say that you are driving *toward* the ambulance (top sign in the numerator, +), even if you are not going as fast as it is. The ambulance driver would say that he is driving away from you (bottom sign in the denominator, +) and the corresponding Doppler effect equation would be:

$$f' = f\frac{(v + v_D)}{(v + v_S)}$$

Here, because $v_S > v_D$, $f' < f$. This change in f' from being greater than f to being less than f is perceived as a drop in pitch.

The Doppler effect can be visualized by considering the sound waves in front of a moving object as being compressed, while the sound waves behind the object are stretched out, as shown in Figure 7.5.

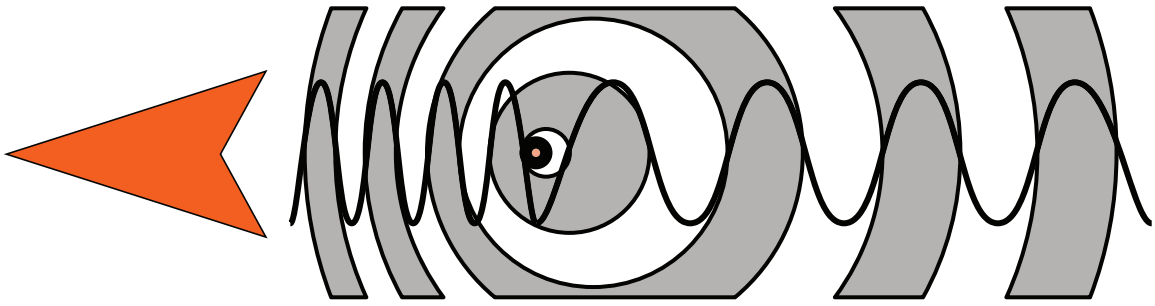

Figure 7.5. The Doppler Effect
Orange arrow indicates the direction of motion. In front of the object, crests of the sound wave (grey) are compressed together, increasing the frequency (pitch). Behind the object, crests of the sound wave are stretched apart, decreasing the frequency.

The Doppler effect can be used by animals through the process of **echolocation**. In echolocation, the animal emitting the sound (usually a dolphin or bat) serves as both the source and the detector of the sound. The sound bounces off of a surface and is reflected back to the animal. How long it takes for the sound to return, and the change in frequency of the sound, can be used to determine the position of objects in the environment and the speed at which they are moving.

Example: A train traveling south at 144 $\frac{\text{km}}{\text{hr}}$ is sounding its whistle while passing by a stationary observer. The whistle emits sound at a frequency of 1450 Hz. What is the frequency heard by the stationary observer when the train is moving toward the observer, and when the train has passed the observer? (Note: The speed of sound in air is approximately 340 $\frac{\text{m}}{\text{s}}$.)

Solution: To do this problem, the speed of the train (v_S) must first be converted to $\frac{\text{m}}{\text{s}}$:

$$v_S = 144\,\frac{\text{km}}{\text{hr}}\left[\frac{1\text{ hr}}{3600\text{ s}}\right]\left[\frac{1000\text{ m}}{1\text{ km}}\right] = 40\,\frac{\text{m}}{\text{s}}$$

When the train is moving toward the stationary observer, the top sign should be used in the denominator. The numerator is simply v because $v_D = 0$. This gives

$$f' = f\frac{v}{v - v_S}$$

$$= (1450\text{ Hz})\left(\frac{340\,\frac{\text{m}}{\text{s}}}{340\,\frac{\text{m}}{\text{s}} - 40\,\frac{\text{m}}{\text{s}}}\right) = 1450\left(\frac{340}{300}\right) = 1643\,\text{Hz}$$

When the train is moving away from the observer, the sign in the denominator changes. The numerator remains unchanged because the observer is still stationary:

$$f' = f\frac{v}{v + v_S}$$

$$= (1450\text{ Hz})\left(\frac{340\,\frac{\text{m}}{\text{s}}}{340\,\frac{\text{m}}{\text{s}} + 40\,\frac{\text{m}}{\text{s}}}\right) = 1450\left(\frac{340}{380}\right) = 1297\text{ Hz}$$

Shock Waves

In a special case of the Doppler effect, an object that is producing sound while traveling at or above the speed of sound allows wave fronts to build upon one another at the front of the object. This creates a much larger amplitude at that point. Because amplitude for sound waves is related to the degree of compression of the medium, this creates a large pressure differential or pressure gradient. This highly condensed wave front is called a **shock wave**, and it can cause physical disturbances as it passes through other objects. The passing of a shock wave creates a very high pressure, followed by a very low pressure, which is responsible for the phenomenon known as a **sonic boom**. Unlike its depiction in movies and television, a sonic boom can be heard any time that an object traveling at or faster than the speed of sound

passes a detector, not just at the point that the speed of sound is exceeded (**Mach 1**). Once an object moves faster than the speed of sound, some of the effects of the shock wave are mitigated because all of the wave fronts will trail behind the object, destructively interfering with each other.

INTENSITY AND LOUDNESS OF SOUND

The **loudness** or **volume** of a sound is the way in which we perceive its intensity. Perception of loudness is subjective, and depends not only on brain function, but also physical factors such as obstruction of the ear canal, stiffening of the ossicles, or damage to cochlear hair cells by exposure to loud noises or with age. Sound intensity, on the other hand, is objectively measurable. **Intensity** is the average rate of energy transfer per area across a surface that is perpendicular to the wave. In other words, intensity is the power transported per unit area. The SI units of intensity are therefore watts per square meter $\left(\frac{\text{W}}{\text{m}^2}\right)$. Intensity is calculated using the equation

$$I = \frac{P}{A}$$

Equation 7.6

where P is the power and A is the area. Rearranging this equation, we could consider that the power delivered across a surface, such as the tympanic membrane (eardrum), is equal to the product of the intensity I and the surface area A, assuming the intensity is uniformly distributed.

The amplitude of a sound wave and its intensity are also related to each other: intensity is proportional to the square of the amplitude. Therefore, doubling the amplitude produces a sound wave that has four times the intensity.

Intensity is also related to the distance from the source of the sound wave. As sound waves emanate outward from their source, it is as though the waves are pushing against the interior wall of an ever-expanding spherical balloon. Because the surface area of a sphere increases as a function of the square of the radius ($A = 4\pi r^2$), sound waves transmit their power over larger and larger areas the farther from the source they travel. Intensity, therefore, is inversely proportional to the square of the distance from the source. For example, sound waves that have traveled 2 meters from their source have spread their energy out over a surface area that is four times larger than that for identical sound waves that have traveled 1 meter from their source.

The softest sound that the average human ear can hear has an intensity equal to about $1 \times 10^{-12} \frac{\text{W}}{\text{m}^2}$. The mechanical disturbance associated with the threshold of hearing is remarkably small—the displacement of air particles is on the order of one billionth of a centimeter. At the other end of the spectrum, the intensity of sound at the threshold of pain is $10 \frac{\text{W}}{\text{m}^2}$ and the intensity that causes instant perforation of

Bridge

We use logarithms with scales that have an extremely large range. The MCAT will mostly deal with base-ten logarithms (common logarithms). As an example, log 1000 = 3 because $10^3 = 1000$. As another example, log 1 = 0 because $10^0 = 1$. Logarithms are discussed in Chapter 10 of *MCAT Physics and Math Review*.

the eardrum is approximately $1 \times 10^4 \frac{\text{W}}{\text{m}^2}$. This is a huge range, which would be unmanageable to express on a linear scale. To make this range easier to work with, we use a logarithmic scale, called the **sound level** (β), measured in **decibels** (**dB**):

$$\beta = 10 \log \frac{I}{I_0}$$

Equation 7.7

where I is the intensity of the sound wave and I_0 is the threshold of hearing $\left(1 \times 10^{-12} \frac{\text{W}}{\text{m}^2}\right)$, which is used as a reference intensity. When the intensity of a sound is changed by some factor, one can calculate the new sound level by using the equation

$$\beta_\text{f} = \beta_\text{i} + 10 \log \frac{I_\text{f}}{I_\text{i}}$$

Equation 7.8

where $\frac{I_\text{f}}{I_\text{i}}$ is the ratio of the final intensity to the initial intensity.

The sound levels and relative intensities of several sound sources and thresholds are shown in Table 7.1.

Sound Source	Sound Level (dB)	Intensity $\left(\frac{\text{W}}{\text{m}^2}\right)$
(Threshold of Hearing)	0	1×10^{-12}
Rustling Leaves	10	1×10^{-11}
Whisper	20	1×10^{-10}
Quiet Room at Night	30	1×10^{-9}
Quiet Library	40	1×10^{-8}
Moderate Rainfall	50	1×10^{-7}
Conversational Speech at 1 m	60	1×10^{-6}
Vacuum Cleaner at 1 m	70	1×10^{-5}
Door Slamming	80	1×10^{-4}
Lawn Mower at 1 m	90	1×10^{-3}
Jackhammer at 1 m	100	1×10^{-2}
Loud Rock Concert	110	1×10^{-1}
Thunder	120	1×10^{0}
(Threshold of Pain)	130	1×10^{1}
Rifle at 1 m	140	1×10^{2}
Jet Engine at 30 m	150	1×10^{3}
(Eardrum Perforation)	160	1×10^{4}

Table 7.1. Sound Level and Intensity of Sound Sources and Important Thresholds

Example: A detector with a surface area of 1 square meter is placed 1 meter from a blender. It measures the average power of the blender's sound as being 10^{-3} W. Find the intensity and sound level of the blender, and the ratio of the intensities of the blender and a jet engine. (Note: Assume $\beta_{\text{jet}} = 150$ dB.)

Solution: Intensity is defined as the power per area:

$$I = \frac{P}{A} = \frac{10^{-3}\,\text{W}}{1\,\text{m}^2} = 10^{-3}\,\frac{\text{W}}{\text{m}^2}$$

The sound level can then be calculated from the intensity:

$$\beta = 10 \log \frac{I}{I_0} = 10 \log \left(\frac{10^{-3}\,\frac{\text{W}}{\text{m}^2}}{10^{-12}\,\frac{\text{W}}{\text{m}^2}} \right) = 10 \log 10^9 = 90\ \text{dB}$$

Finally, the ratio of two sound intensities can be found from the difference of their sound levels:

$$\beta_{\text{jet}} = \beta_{\text{blender}} + 10 \log \frac{I_{\text{jet}}}{I_{\text{blender}}}$$

$$150\ \text{dB} = 90\ \text{dB} + 10 \log \frac{I_{\text{jet}}}{I_{\text{blender}}}$$

$$6 = \log \frac{I_{\text{jet}}}{I_{\text{blender}}}$$

$$10^6 = \frac{I_{\text{jet}}}{I_{\text{blender}}}$$

Thus, the jet engine's sound is 1,000,000 times more intense than the blender's sound.

Attenuation

Sound is not transmitted undiminished. Even after the decrease in intensity associated with distance, real world measurements of sound will be lower than those expected from calculations. This is a result of **damping**, or **attenuation**. Oscillations are a form of repeated linear motion, so sound is subject to the same nonconservative forces as any other system, including friction, air resistance, and viscous drag.

The presence of a nonconservative force causes the system to decrease in amplitude during each oscillation. Because amplitude, intensity, and sound level (loudness) are related, there is a corresponding gradual loss of sound. Note that damping does not have an effect on the frequency of the wave, so the pitch will

not change. This phenomenon, along with reflection, explains why it is more difficult to hear in a confined or cluttered space than in an empty room: friction from the surfaces of the objects in the room actually decreases the sound waves' amplitudes. Over small distances, attenuation is usually negligible.

STANDING WAVES

Remember that standing waves are produced by the constructive and destructive interference of a traveling wave and its reflected wave. More broadly, we can say that a standing wave will form whenever two waves of the same frequency traveling in opposite directions interfere with one another as they travel through the same medium. Standing waves appear to be standing still—that is, not propagating—because the interference of the wave and its reflected wave produce a resultant that fluctuates only in amplitude. As the waves move in opposite directions, they interfere to produce a new wave pattern characterized by alternating points of maximum displacement (amplitude) and points of no displacement. The points in a standing wave with no fluctuation in displacement are called **nodes**. The points with maximum fluctuation are called **antinodes**.

Not every frequency of traveling wave will result in standing wave formation. The length of the medium dictates the wavelengths (and, by extension, the frequencies) of traveling waves that can establish standing waves. Objects that support standing waves have boundaries at both ends. **Closed boundaries** are those that do not allow oscillation and that correspond to nodes. The closed end of a pipe and the secured ends of a string are both considered closed boundaries. **Open boundaries** are those that allow maximal oscillation and correspond to **antinodes**. The open end of a pipe and the free end of a flag are both open boundaries.

Strings

Consider a string, such as a guitar or violin string, or a piano wire, fixed rigidly at both ends. Because the string is secured at both ends and is therefore immobile at these points, they are considered nodes. If a standing wave is set up such that there is only one antinode between the two nodes at the ends, the length of the string corresponds to one-half the wavelength of this standing wave, as shown in Figure 7.6a. This is because on a sine wave, the distance from one node to the next node is one-half of a wavelength. If a standing wave is set up such that there are two antinodes between the ends, there must be a third node located between the antinodes, as shown in Figure 7.6b. In this case, the length of the string corresponds to the wavelength of this standing wave. Again, the distance on a sine wave from a node to the second consecutive node is exactly one wavelength. This pattern suggests that the length L of a string must be equal to some multiple of half-wavelengths ($L = \frac{\lambda}{2}, \frac{2\lambda}{2}, \frac{3\lambda}{2}$, and so on).

MCAT Expertise

Like nonconservative forces, attenuation is generally negligible on Test Day. If it is important for answering a question, the MCAT will make it clear that you should consider the effects of damping (attenuation) on an oscillating system.

Mnemonic

Nodes are places of **No D**isplacement

The equation that relates the wavelength λ of a standing wave and the length L of a string that supports it is:

$$\lambda = \frac{2L}{n}$$

Equation 7.9

where n is a positive nonzero integer ($n = 1, 2, 3$, and so on) called the **harmonic**. The harmonic corresponds to the number of half-wavelengths supported by the string. From the relationship that $f = \frac{v}{\lambda}$ where v is the wave speed, the possible frequencies are:

$$f = \frac{nv}{2L}$$

Equation 7.10

The lowest frequency (longest wavelength) of a standing wave that can be supported in a given length of string is known as the **fundamental frequency** (first harmonic). The frequency of the standing wave given by $n = 2$ is known as the first overtone or second harmonic. This standing wave has one-half the wavelength and twice the frequency of the first harmonic. The frequency of the standing wave given by $n = 3$ is known as the second overtone or third harmonic, as shown in Figure 7.6c. All the possible frequencies that the string can support form its **harmonic series**.

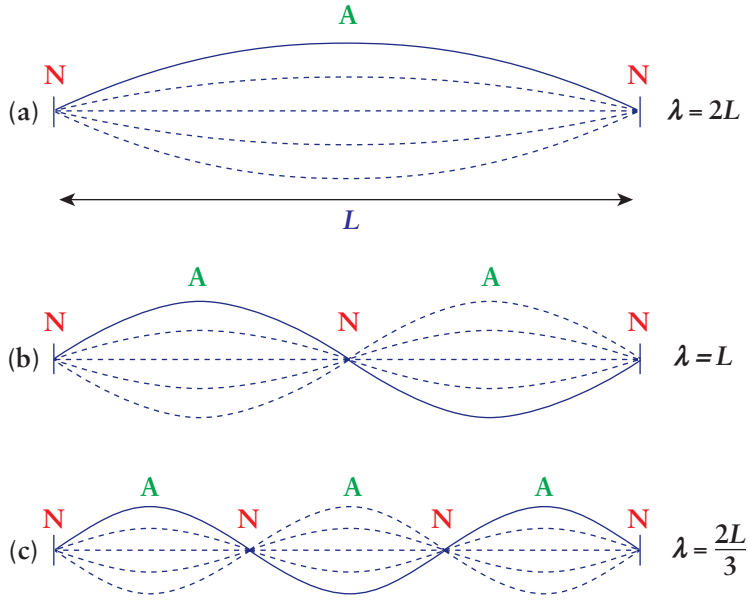

Figure 7.6. First, Second, and Third Harmonics of a String
The harmonic is given by the number of half-wavelengths supported by the string. N = node; A = antinode.

MCAT Expertise

As a shortcut, for strings attached at both ends, the number of antinodes present will tell you which harmonic it is.

Open Pipes

Pipes can support standing waves and produce sound as well. Many musical instruments are straight or curved tubes within which air will oscillate at particular frequencies to set up standing waves. The end of a pipe can be open or closed. If the end of the pipe is open, it will support an antinode. If it is closed, it will support a node. One end of the pipe must be open at least slightly to allow for the entry of air, but sometimes these openings are small and covered by the musician's mouth—in these cases, they function as a closed end. Pipes that are open at both ends are called **open pipes**, while those that are closed at one end (and open at the other) are called **closed pipes**. The flute functions as an open pipe instrument, while the clarinet and brass instruments are closed pipe instruments. If you are a musician, this may be counterintuitive. The distal end of a flute is open, but the proximal end is closed; however, the mouthpiece of a flute is close enough to this closed end for it to function as an open end. Similarly, while air must pass through the mouthpiece of a reed or brass instrument, the opening is sufficiently small to function as a closed end.

An open pipe, being open at both ends, has antinodes at both ends. If a standing wave is set up such that there is only one node between the two antinodes at the ends, the length of the pipe corresponds to one-half the wavelength of this standing wave, as shown in Figure 7.7a. This is analogous a string except that the ends are both antinodes instead of nodes. The analogy continues throughout: the second harmonic (first overtone) has a wavelength equal to the length of the pipe, as shown in Figure 7.7b. The third harmonic (second overtone) has a wavelength equal to two-thirds the length of the pipe, as shown in Figure 7.7c. Again, an open pipe can contain any multiple of half-wavelengths; the number of half-wavelengths corresponds to the harmonic of the wave. The relationship between the wavelength λ of a standing wave and the length L of an open pipe that supports it is $\lambda = \frac{2L}{n}$, and the possible frequencies of the harmonic series are $f = \frac{nv}{2L}$, just like a string.

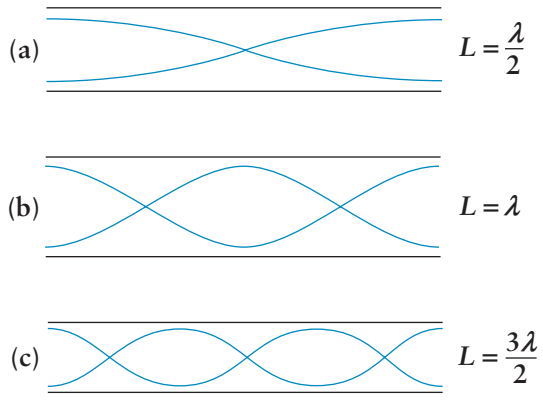

Figure 7.7. First, Second, and Third Harmonics of an Open Pipe
The harmonic is given by the number of half-wavelengths supported by the pipe.

MCAT Expertise

As a shortcut, for open pipes, the number of nodes present will tell you which harmonic it is.

It is worthwhile to note that Figure 7.7 is really a symbolic representation of the first three harmonics in an open pipe. We use the term symbolic because the conventional way of diagramming standing waves is to represent sound waves as transverse, rather than longitudinal, waves (which are much harder to draw).

Closed Pipes

In the case of a closed pipe, the closed end will correspond to a node, and the open end will correspond to an antinode. The first harmonic in a closed pipe consists of only the node at the closed end and the antinode at the open end, as shown in Figure 7.8a. In a sinusoidal wave, the distance from a node to the following antinode is one-quarter of a wavelength. Indeed, unlike strings or open pipes, the harmonic in a closed pipe is equal to the number of quarter-wavelengths supported by the pipe. Because the closed end must always have a node and the open end must always have an antinode, there can only be odd harmonics. This is because an even number of quarter-wavelengths would be an integer number of half-wavelengths—which would necessarily have either two nodes or two antinodes at the ends. The first harmonic has a wavelength that is four times the length of the closed pipe. The third harmonic (first overtone) has a wavelength that is four-thirds the length of the closed pipe, as shown in Figure 7.8b. The fifth harmonic (second overtone) has a wavelength that is four-fifths the length of the closed pipe, as shown in Figure 7.8c. The equation that relates the wavelength λ of a standing wave and the length L of a closed pipe that supports it is:

$$\lambda = \frac{4L}{n}$$

Equation 7.11

where n can only be an odd integers (n = 1, 3, 5, and so on). The frequency of the standing wave in a closed pipe is:

$$f = \frac{nv}{4L}$$

Equation 7.12

where v is the wave speed.

MCAT Expertise

Unlike strings and open pipes, one cannot simply count the number of nodes or antinodes to determine the harmonic of the wave in closed pipes. Therefore, when presented with a closed pipe, make sure to actually count the number of quarter-wavelengths contained in the pipe to determine the harmonic.

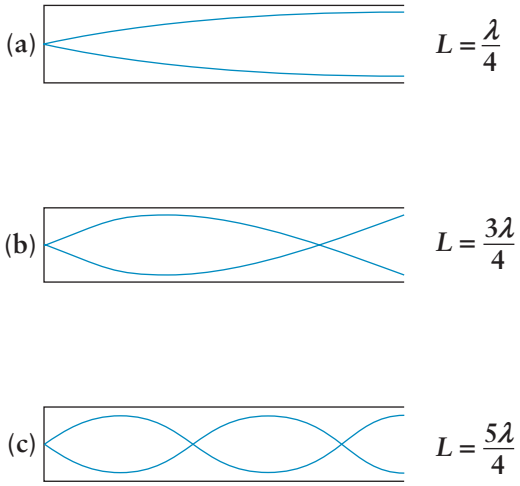

Figure 7.8. First, Third, and Fifth Harmonics of a Closed Pipe
The harmonic is given by the number of quarter-wavelengths supported by the pipe.

ULTRASOUND

Until this point we've focused on sound in the audible range; however, in medicine we can also use sound waves to visualize organs, anatomy, and pathology. This imaging modality can be used for prenatal screening, or to diagnose gallstones and breast or thyroid masses, or for needle guidance in a biopsy. **Ultrasound** uses high frequency sound waves outside the range of human hearing to compare the relative densities of tissues in the body. An ultrasound machine consists of a transmitter that generates a pressure gradient, which also functions as a receiver that processes the reflected sound, as seen in Figure 7.9. Because the speed of the wave and travel time is known, the machine can generate a graphical representation of borders and edges within the body by calculating the traversed distance. Note that ultrasound ultimately relies on reflection; thus, an interface between two objects is necessary to visualize anything. Reflection will be discussed further in the next chapter.

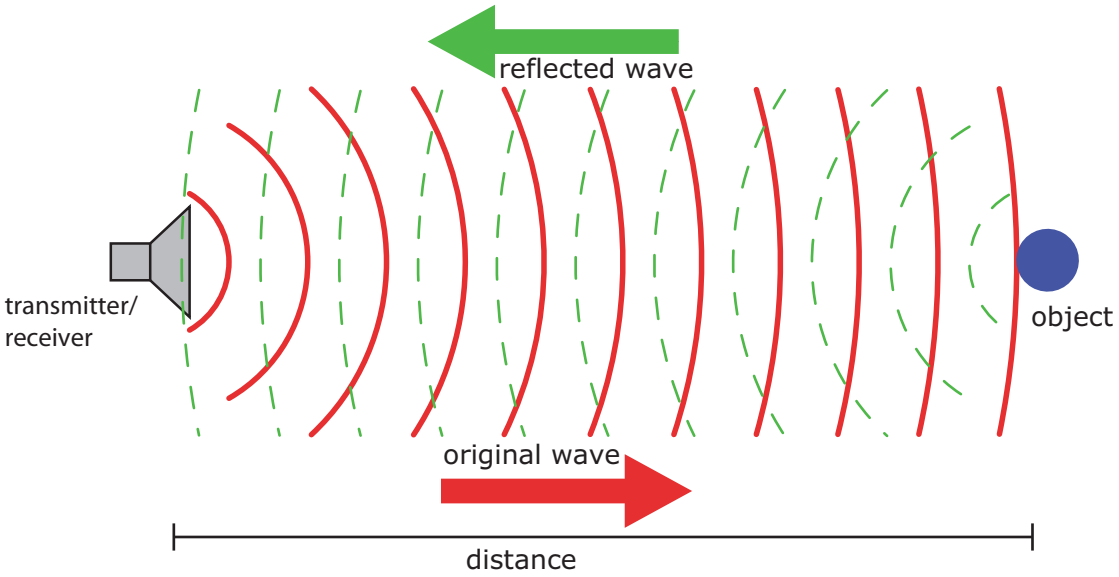

Figure 7.9. Ultrasound
The transmitter generates a wave, which reflects off of an object and returns to the transmitter (which also functions as a receiver).

Most ultrasound transmitters and receivers are packaged in a single unit. The transmitter and receiver do not function simultaneously, however, because one of the objectives of the system is to reduce interference. In addition to the standard ultrasound, most modern ultrasound machines also have a Doppler mode. **Doppler ultrasound** is used to determine the flow of blood within the body by detecting the frequency shift that is associated with movement toward or away from the receiver.

Ultrasound can also be used therapeutically. Ultrasound waves create friction and heat when they act on tissues, which can increase blood flow to a site of injury in deep tissues and promote faster healing. Focused ultrasound also has a range of applications. Focusing a sound wave using a parabolic mirror causes constructive interference at the focal point of the mirror. This creates a very high-energy wave exactly at that point, which can be used to noninvasively break up a kidney stone (*lithotripsy*) or ablate (destroy) small tumors. Ultrasound can also be used for dental cleaning and destruction of cataracts (*phacoemulsification*). In each case, the ultrasound waves are applied for a sufficient time period to achieve the desired effect.

MCAT Concept Check 7.2:

Before you move on, assess your understanding of the material with these questions.

1. How is sound produced and transmitted?

_____

_____

_____

2. To which properties of a sound wave do amplitude and frequency correspond?
   - Amplitude:

     _____
   - Frequency:

     _____

3. If two objects are traveling toward each other, how does the apparent frequency differ from the original frequency? What if two objects are traveling away from each other? What if one object is following the other?
   - Toward each other:

     _____
   - Away from each other:

     _____
   - One object follows the other:

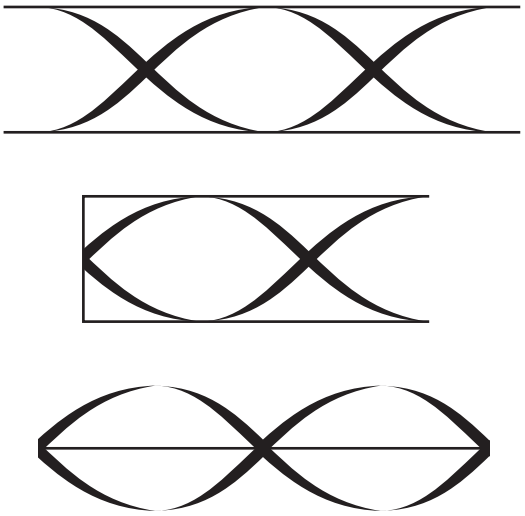
     _____

4. What phenomena can be detected or treated using ultrasound?

_____

_____

5. For each of the following diagrams, label the type of pipe or string it represents, a node and antinode, and the relevant equation relating λ and L:



Conclusion

In this chapter, we reviewed the general characteristics of waves, including the phenomena of interference and resonance, and analyzed the characteristics and behaviors of sound as an example of a longitudinal waveform. Sound is the mechanical disturbance of particles creating oscillating regions of compression and rarefaction parallel to the direction of wave movement. The intensity of a sound wave is perceived as the sound level (loudness) of the sound and is measured in decibels. The decibel scale is a logarithmic scale used to describe the ratio of a sound's intensity to a reference intensity (the threshold of human hearing). We also reviewed the Doppler effect and a special case with shock waves. We then reviewed the mathematics governing the formation of standing waves, which are important in the formation of musical sounds in strings, open pipes, and closed pipes. Finally, we discussed a medical application of sound that incorporates many of these topics: ultrasound.

Continue to review these MCAT topics—it's easy to think about sound if you listen to music when you study! Whether you turn on Top 40, smooth jazz, or rococo fugues, the principles of sound production and propagation are key to your enjoyment of these harmonious sounds. Sound, of course, is not the only waveform tested on the MCAT. Light waves (and electromagnetic radiation in general) are heavily-tested topics on Test Day—we'll review them in the next chapter.

CONCEPT SUMMARY

General Wave Characteristics

- **Transverse waves** have oscillations of wave particles perpendicular to the direction of wave **propagation** (examples: "The Wave", electromagnetic waves).
- **Longitudinal waves** have oscillations of wave particles parallel to the direction of wave propagation (example: sound waves).
- **Displacement** (**x**) in a wave refers to how far a point is from the **equilibrium position**, expressed as a vector quantity.
- The **amplitude** (***A***) of a wave is the magnitude of its maximal displacement.
- The maximum point of a wave (point of most positive displacement) is called a **crest**.
- The minimum point of a wave (point of most negative displacement) is called a **trough**.
- The **wavelength** ($\boldsymbol{\lambda}$) of a wave is the distance between two crests or two troughs.
- The **frequency** (***f***) of a wave is the number of cycles it makes per second. It is expressed in **hertz** (**Hz**).
- The **angular frequency** ($\boldsymbol{\omega}$) is another way of expressing frequency and is expressed in radians per second.
- The **period** (***T***) of a wave is the number of seconds it takes to complete a cycle. It is the inverse of frequency.
- **Interference** describes the ways in which waves interact in space to form a **resultant wave**.
  - **Constructive interference** occurs when waves are exactly **in phase** with each other. The amplitude of the resultant wave is equal to the sum of the amplitudes of the two interfering waves.
  - **Destructive interference** occurs when waves are exactly **out of phase** with each other. The amplitude of the resultant wave is equal to the difference in amplitude between the two interfering waves.
  - **Partially constructive** and **partially destructive interference** occur when two waves are not quite perfectly in or out of phase with each other. The displacement of the resultant wave is equal to the sum of the displacements of the two interfering waves.
- **Traveling waves** have continuously shifting points of maximum and minimum displacement.
- **Standing waves** are produced by the constructive and destructive interference of two waves of the same frequency traveling in opposite directions in the same space.

- **Antinodes** are points of maximum oscillation.
- **Nodes** are points where there is no oscillation.

- **Resonance** is the increase in amplitude that occurs when a periodic force is applied at the **natural** (**resonant**) **frequency** of an object.
- **Damping** is a decrease in amplitude caused by an applied or nonconservative force.

Sound

- **Sound** is produced by mechanical disturbance of a material that creates an oscillation of the molecules in the material.
- Sound propagates through all forms of matter (but not a vacuum).
  - Sound propagates fastest through solids, followed by liquids, and slowest through gases.
  - Within a medium, as density increases, the speed of sound decreases.
- The **pitch** of a sound is related to its frequency.
- The **Doppler effect** is a shift in the perceived frequency of a sound compared to the actual frequency of the emitted sound when the source of the sound and its detector are moving relative to one another.
  - The apparent frequency will be higher than the emitted frequency when the source and detector are moving toward each other.
  - The apparent frequency will be lower than the emitted frequency when the source and detector are moving away from each other.
  - The apparent frequency can be higher, lower, or equal to the emitted frequency when the two objects are moving in the same direction, depending on their relative speeds.
  - When the source is moving at or above the speed of sound, **shock waves** (**sonic booms**) can form.
- Loudness or volume of sound (**sound level**) is related to its **intensity**.
  - Intensity is related to a wave's amplitude.
  - Intensity decreases over distance and some energy is lost to **attenuation** (damping) from frictional forces.
- Strings and **open pipes** (open at both ends) support standing waves, and the length of the string or pipe is equal to some multiple of half-wavelengths.
- **Closed pipes** (closed at one end) also support standing waves, and the length of the pipe is equal to some odd multiple of quarter-wavelengths.
- Sound is used medically in **ultrasound** machines for both imaging (diagnostic) and treatment (therapeutic) purposes.

ANSWERS TO CONCEPT CHECKS

7.1

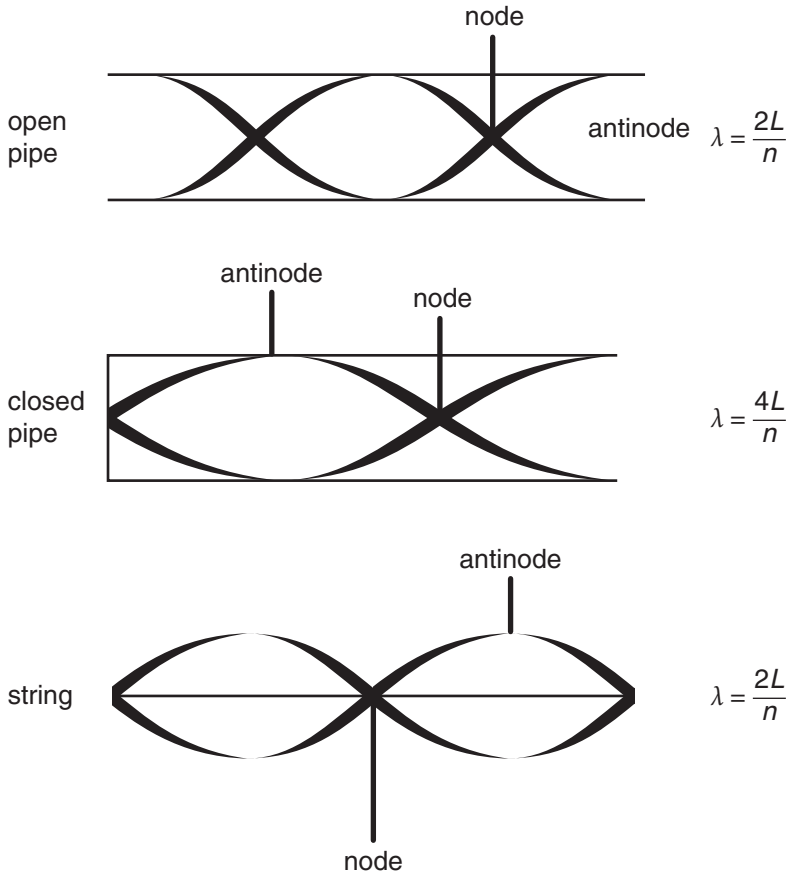
1. Wave speed is the rate at which a wave transmits the energy or matter it is carrying. Wave speed is the product of frequency and wavelength. Frequency is a measure of how often a waveform passes a given point in space. It is measured in Hz. Angular frequency is the same as frequency, but is measured in radians per second. Period is the time necessary to complete a wave cycle. The equilibrium position is the point with zero displacement in an oscillating system. Amplitude is the maximal displacement of a wave from the equilibrium position. Traveling waves have nodes and antinodes that move with wave propagation. Standing waves have defined nodes and antinodes that do not move with wave propagation.
2. If two waves are perfectly in phase, the amplitude of the resulting wave is equal to the sum of the amplitudes of the interfering waves. If two waves are perfectly out of phase, the amplitude of the resulting wave is the difference of the amplitudes of the interfering waves. Therefore, if the two waves are anywhere between these two extremes, the amplitude of the resulting wave will be somewhere between the sum and difference of the amplitudes of the interfering waves.
3. False. Sound waves are the most common example of longitudinal waves on the MCAT.
4. The object will resonate because the force frequency equals the natural (resonant) frequency. The amplitude of the oscillation will increase.

7.2

1. Sound is produced by mechanical vibrations. These are usually generated by solid objects like bells or vocal cords, but occasionally can be generated by fluids. Sound is propagated as longitudinal waves in matter, so it cannot propagate in a vacuum.
2. The amplitude of a wave is related to its sound level (volume). The frequency of a wave is related to its pitch.
3. When two objects are traveling toward each other, the apparent frequency is higher than the original frequency $\left(f' = f\frac{(v + v_D)}{(v - v_S)}\right)$. When two objects are traveling away from each other, the apparent frequency is lower than the original frequency $\left(f' = f\frac{(v - v_D)}{(v + v_S)}\right)$. When one object follows the other, the apparent frequency could be higher, lower, or equal to the original frequency depending on the relative speeds of the detector and the source $\left(f' = f\frac{(v + v_D)}{(v + v_S)} \text{ or } f' = f\frac{(v - v_D)}{(v - v_S)}\right)$.

4. Ultrasound can be used for prenatal screening or to diagnose gallstones, breast and thyroid masses, and blood clots. It can be used for needle guidance in a biopsy, for dental cleaning, and for treating deep tissue injury, kidney stones, certain small tumors, cataracts, among many other applications.

5.



EQUATIONS TO REMEMBER

(7.1) **Wave speed:** $v = f\lambda$

(7.2) **Period:** $T = \frac{1}{f}$

(7.3) **Angular frequency:** $\omega = 2\pi f = \frac{2\pi}{T}$

(7.4) **Speed of sound:** $v = \sqrt{\frac{B}{\rho}}$

(7.5) **Doppler effect:** $f' = f\frac{(v \pm v_D)}{(v \mp v_S)}$

(7.6) **Intensity:** $I = \frac{P}{A}$

(7.7) **Sound level:** $\beta = 10 \log \frac{I}{I_0}$

(7.8) **Change in sound level:** $\beta_f = \beta_i + 10 \log \frac{I_f}{I_i}$

(7.9) **Wavelength of a standing wave (strings and open pipes):** $\lambda = \frac{2L}{n}$

(7.10) **Frequency of a standing wave (strings and open pipes):** $f = \frac{nv}{2L}$

(7.11) **Wavelength of a standing wave (closed pipes):** $\lambda = \frac{4L}{n}$

(7.12) **Frequency of a standing wave (closed pipes):** $f = \frac{nv}{4L}$

Discrete Practice Questions

Consult your online resources for Full-Length Exams and Passage-Based Questions (for certain chapters).

1. An opera singer has two precisely identical glasses. The singer produces as pure a tone as possible and shatters the first glass at a frequency of 808 Hz. She then sings a frequency of 838 Hz in the presence of the second glass. The second glass will likely:

A. shatter after a longer amount of time because the applied frequency is higher.
B. shatter after a shorter amount of time because the applied frequency is higher.
C. not shatter because the applied frequency is not equal to the natural frequency of the glass.
D. not shatter because higher-frequency sounds are associated with more attenuation.

2. A child is practicing the first overtone on his flute. If his brother covers one end of the flute for a brief second, how will the sound change, assuming that the new pitch represents the first overtone in the new setup?

A. The pitch of the sound will go up.
B. The pitch of the sound will go down.
C. The pitch of the sound will not change.
D. The change in the pitch depends on the starting pitch.

3. Which of the following is necessarily true regarding frequency, angular frequency, and period of a given wave?

A. The magnitude of the angular frequency is larger than the magnitude of the period.
B. The product of the frequency and period is equal to the angular frequency.
C. The magnitude of the angular frequency is larger than the magnitude of the frequency.
D. The product of the angular frequency and period is 1.

4. Ultrasound machines calculate distance based upon:

A. intensity of the reflected sound.
B. travel time of the reflected sound.
C. angle of incidence of the sound.
D. the detected frequency of the sound.

5. The period for a certain wave is 34 ms. If there is a Doppler shift that doubles the perceived frequency, which of the following must be true?

I. The detector is moving toward the source at a velocity equal to the speed of sound.
II. The source is moving toward the detector at a velocity equal to half the speed of sound.
III. The perceived period is 17 ms.
IV. The perceived period is 68 ms.

A. III only
B. I and IV only
C. II and III only
D. I, II, and IV only

6. If the speed of a wave is 3 $\frac{m}{s}$ and its wavelength is 10 cm, what is its period?

A. 0.01 s
B. 0.03 s
C. 0.1 s
D. 0.3 s

7. What is the angular frequency of the third harmonic in a pipe of length 0.6 m with one closed end? (Note: The speed of the sound is approximately 340 $\frac{m}{s}$.)

A. 213 radians per second
B. 425π radians per second
C. 425 radians per second
D. 850π radians per second

8. A certain sound level is increased by 20 dB. By what factor does its intensity increase?

A. 2
B. 20
C. 100
D. log 2

9. In some forms of otosclerosis, the stapedial foot plate, which transmits vibrations from the bones of the middle ear to the fluid within the cochlea, can become fixed in position. This limits the displacement of the stapedial foot plate during vibration. Based on this mechanism, which of the following symptoms would most likely be seen in an individual with otosclerosis?

A. An increase in the perceived volume of sounds
B. A decrease in the perceived volume of sounds
C. An increase in the perceived pitch of sounds
D. A decrease in the perceived pitch of sounds

10. If two waves with the same frequency are 180° out of phase, what is the amplitude of the resultant wave if the amplitudes of the original waves are 5 cm and 3 cm?

A. 2 cm
B. 3 cm
C. 5 cm
D. 8 cm

11. A student is measuring sound frequencies from the side of a road while walking east. For which of the following situations could the student determine that the difference between the perceived frequency and the actual emitted frequency is zero?

A. A plane flying directly above him from east to west
B. A police car passing the student with its siren on
C. A person playing piano in a house on the street
D. A dog barking in a car that moves east

12. In which of the following media does sound travel the fastest?

A. Vacuum
B. Air
C. Water
D. Glass

13. Shock waves have the greatest impact when the source is traveling:

A. just below the speed of sound.
B. exactly at the speed of sound.
C. just above the speed of sound.
D. well above the speed of sound.

14. As an officer approaches a student who is studying with his radio playing loudly beside him, he experiences the Doppler effect. Which of the following statements remains true while the officer moves closer to the student?

I. The apparent frequency of the music is increased.
II. The same apparent frequency would be produced if the officer were stationary and the student approached him at the same speed.
III. The apparent velocity of the wave is decreased.

A. I only
B. II only
C. I and III only
D. I, II, and III

15. Ignoring attenuation, how does the intensity of a sound change as the distance from the source doubles?

A. It is four times as intense.
B. It is twice as intense.
C. It is half as intense.
D. It is one-quarter as intense.

Explanations to Discrete Practice Questions

1. C

If these two glasses are perfectly identical, then the fact that the first glass shattered at 808 Hz tells us that this is very close (if not identical) to the natural (resonant) frequency of the glass. If she produces a frequency that is not equal (or very close) to the natural frequency, then the applied frequency will not cause the glass to resonate, and there will not be the increase in wave amplitude associated with resonating objects. Attenuation will increase with increased frequency because there is more motion over which nonconservative forces can damp the sound wave; however, even if sound level was matched to that which shattered the first glass when accounting for attenuation, the glass would still not shatter for the reasons described above, eliminating **choice (D)**.

2. B

This question is testing our understanding of pipes open at one or both ends. To begin, remember that high-frequency sounds have a high pitch and low-frequency sounds have a low pitch. The pipe in this example begins as one that is open on both ends, and then one end is closed off. Our task, therefore, is to determine how the frequency of the second harmonic differs between a pipe that is open at both ends from one of equal length that is open at only one end. For a pipe of length L open at both ends, the wavelength for the second harmonic (first overtone) is equal to L:

$$\lambda = \frac{2L}{n} = \frac{2L}{2} = L$$

In contrast, for a pipe open at one end and closed at the other, the wavelength is equal to $\frac{4L}{3}$:

$$\lambda = \frac{4L}{n} = \frac{4L}{3}$$

Keep in mind that the first overtone for a closed pipe corresponds to the third harmonic, not the second. Thus, when the brother covers one end of the flute, the wavelength increases. Given that the wavelength and the frequency of a sound are inversely proportional, an increase in wavelength corresponds to a decrease in frequency. Therefore, when the brother covers one end of the flute, the sound produced by the instrument will be slightly lower in pitch than the original sound.

3. C

The angular frequency is related to the frequency through the equation $\omega = 2\pi f$. Therefore, the magnitude of the angular frequency will always be larger than the magnitude of the frequency. The magnitude of the angular frequency may or may not be larger than the magnitude of period; these variables are inversely proportional, eliminating **choice (A)**. The product of the frequency and the period is always 1 because these two are inverses of each other, eliminating **choice (B)**. Finally, the product of the angular frequency and period will always be 2π because $\omega = 2\pi f = \frac{2\pi}{T}$, eliminating **choice (D)**.

4. B

While intensity, **choice (A),** could be used to measure distance, time of travel is an easier indication and most commonly used by ultrasound machines. Apparent frequency, **choice (D)**, is only used in Doppler ultrasound, and not to calculate distance. Angle of incidence, **choice (C)**, can be used to position various structures on the screen of an ultrasound, but is not used to calculate distance.

5. A

Period is inversely related to frequency. Because the perceived frequency is doubled, the perceived period must be

halved, from 34 ms to 17 ms. While either condition I or II would cause a doubling of the perceived frequency, neither condition must necessarily be true because the opposite could be true instead.

6. B

This question is testing our understanding of traveling waves. We know that frequency and wavelength are related through the equation $v = f\lambda$. Frequency and period are inverses of each other, so this equation could be rearranged to solve for period:

$$v = \left(\frac{1}{T}\right)\lambda \rightarrow T = \frac{\lambda}{v} = \frac{(0.1\text{ m})}{\left(3\frac{\text{m}}{\text{s}}\right)} = 0.03\text{ s}$$

7. D

The angular frequency is related to the frequency of a wave through the formula $\omega = 2\pi f$. Thus, our initial task is to calculate the frequency of the wave. Knowing its speed, we determine the frequency by first calculating its wavelength ($v = f\lambda$). For the third harmonic of a standing wave in a pipe with one closed end, the wavelength is

$$\lambda = \frac{4L}{n} = \frac{4(0.6\text{ m})}{3} = 0.8\text{ m}$$

The frequency of the wave is therefore

$$f = \frac{v}{\lambda} = \frac{340\frac{\text{m}}{\text{s}}}{0.8\text{ m}} = 425\text{ Hz}$$

Finally, obtain the angular frequency simply by multiplying the frequency of the wave by 2π:

$$\omega = 2\pi f = 850\pi \text{ radians per second}$$

8. C

Let I_i be the intensity before the increase and I_f be the intensity after the increase. Using the equation that relates sound level to intensity, obtain the ratio of I_i to I_f:

$$\beta_f = \beta_i + 10\log\frac{I_f}{I_i} \rightarrow \beta_f - \beta_i = 10\log\frac{I_f}{I_i}$$

$$20\text{ dB} = 10\log\frac{I_f}{I_i}$$

$$2 = \log\frac{I_f}{I_i}$$

$$100 = \frac{I_f}{I_i}$$

9. B

Saying that the stapedial footplate has limited displacement during vibration is another way of stating that the amplitude of the vibration has been decreased. Because amplitude is related to intensity, and intensity is related to sound level, the perceived sound level (volume) will be decreased as well. Pitch, described in **choices (C)** and **(D)**, is related to the frequency of a sound, not its amplitude.

10. A

When two waves are out of phase by 180°, the resultant amplitude is the difference between the two waves' amplitudes. In this case, the resulting wave will have an amplitude of 5 cm – 3 cm = 2 cm.

11. D

This question is testing us on our understanding of the Doppler effect. A difference of zero between the perceived and the emitted frequencies implies that the source of the sound is not moving relative to the student. If the car in **choice (D)** is moving at the same speed as the student, then the relative motion between them could be 0. In all of the other cases, the student and the sound source are necessarily moving relative to each other.

12. D

Sound is a mechanical disturbance propagated through a deformable medium; it is transmitted by the oscillation of particles parallel to the direction of the sound wave's propagation. As such, sound needs matter to travel through, eliminating **choice (A)**. The speed of propagation is fastest in solid materials, followed by liquids, and slowest in gases.

13. B

Shock waves are the buildup of wave fronts as the distance between those wave fronts decreases. This occurs maximally when an object is traveling at exactly the same speed as the wave is traveling (the speed of sound). Once an object moves faster than the speed of sound, some of the effects of the shock wave are mitigated because all of the wave fronts will trail behind the object, destructively interfering with each other.

14. A

Here, an observer is moving closer to a stationary source. The applicable version of the Doppler effect equation is $f' = f\frac{(v + v_D)}{v}$ where v is the speed of the sound. Because the numerator is greater than the denominator, f' will be greater than f; therefore, statement I is true. The scenario described in statement II will produce a similar, but not identical, frequency for the officer: the frequency formula would be $f' = f\frac{v}{v - v_S}$. The apparent frequency will increase, but the increase will not be exactly the same as if the officer had been moving. Statement III is false because we already know the frequency increases for the officer—a decrease in velocity would be associated with a decrease in frequency.

15. D

Intensity is equal to power divided by area. In this case, area refers to the surface area of concentric spheres emanating out from the source of the sound. This surface area is given by $4\pi r^2$, so as distance (r) doubles, the intensity will decrease by a factor of four.

Introduction

The next time you're browsing your local convenience store, take a look at the security mirrors—the ones that bulge out from the wall, usually above eye level. Looking into one of these mirrors, notice not just that the image you see of the world is distorted but *how* it is distorted: the image is still right-side up, but everything is much smaller than you'd expect, and the curve of the mirror introduces some slopes that are not present in reality. Additionally, you see a much wider field of vision than you would if the mirror were a simple plane mirror. This is why security mirrors are useful: they are a convenient, low-tech solution that allows the cashier to survey the entire store in one glance. All these features result from the fact that the security mirror is a convex, diverging optical system. Parallel light rays that hit the mirror are reflected in multiple directions, which allows observers to see a large field of vision, even if the image is somewhat distorted and the objects in the image are closer than they appear. Indeed, the passenger-side mirror of a car that bears that same message is also a convex mirror, allowing the driver to see a wider view of the cars behind him or her.

This chapter will first complete a topic from Chapter 7 of *MCAT Physics and Math Review* by analyzing the transverse waveform of visible light and other electromagnetic (EM) waves. We will then consider in detail the rules of optics, which describe the behavior of electromagnetic waves as they bounce off of and travel through various shapes and compositions of matter. The optical systems covered are those tested on the MCAT: concave and convex mirrors, which produce images by reflection, and concave and convex lenses, which produce images by refraction. To finish, we will discuss the phenomena of thin-slit experiments (diffraction) and light polarization.

8.1 Electromagnetic Spectrum ★★★★

The full **electromagnetic spectrum** includes **radio waves** on one end (long wavelength, low frequency, low energy) and **gamma rays** on the other (short wavelength, high frequency, high energy). Between the two extremes, we find, in order from lowest energy to highest energy, **microwaves**, **infrared**, visible light, **ultraviolet**, and **x-rays**. This chapter will focus primarily on the range of wavelengths corresponding to the visible spectrum of light (400 nm to 700 nm).

ELECTROMAGNETIC WAVES

A changing magnetic field can cause a change in an electric field, and a changing electric field can cause a change in a magnetic field. Because of the reciprocating nature of these two fields, we can see how electromagnetic waves occur in nature. Each oscillating field causes oscillations in the other field completely independent of matter, so electromagnetic waves can even travel through a vacuum.

Electromagnetic waves are transverse waves because the oscillating electric and magnetic field vectors are perpendicular to the direction of propagation. The electric field and the magnetic field are also perpendicular to each other. This is illustrated in Figure 8.1.

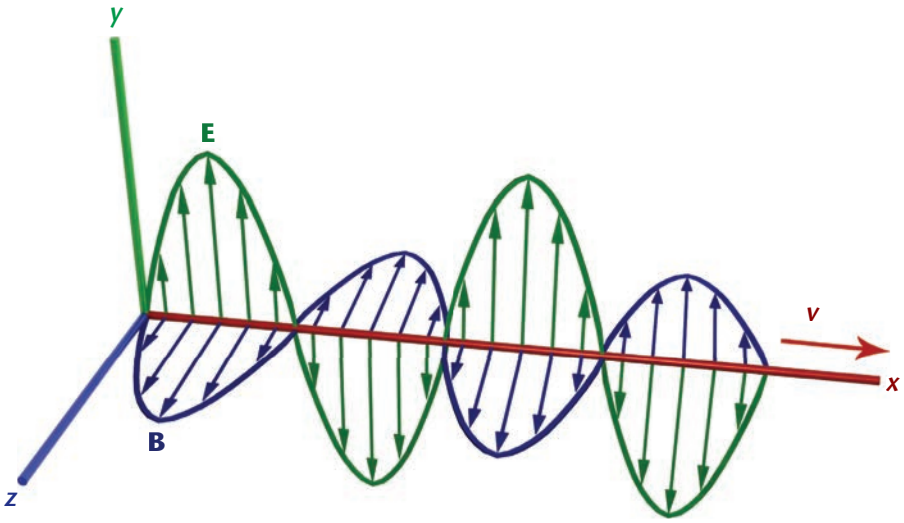

Figure 8.1. Electromagnetic Wave
The electric field (**E**) oscillates up and down the page; the magnetic field (**B**) oscillates into and out of the page.

The **electromagnetic spectrum** describes the full range of frequencies and wavelengths of electromagnetic waves. Wavelengths are often given in the following units: mm (10^{-3} m), μm (10^{-6} m), nm (10^{-9} m), and Å (ångström, 10^{-10} m). The full spectrum is broken up into many regions, which in descending order of wavelength

are radio (10^9–1 m), microwave (1 m–1 mm), infrared (1 mm–700 nm), visible light (700–400 nm), ultraviolet (400–50 nm), x-ray (50–10^{-2} nm), and γ-rays (less than 10^{-2} nm). The electromagnetic spectrum is depicted in Figure 8.2.

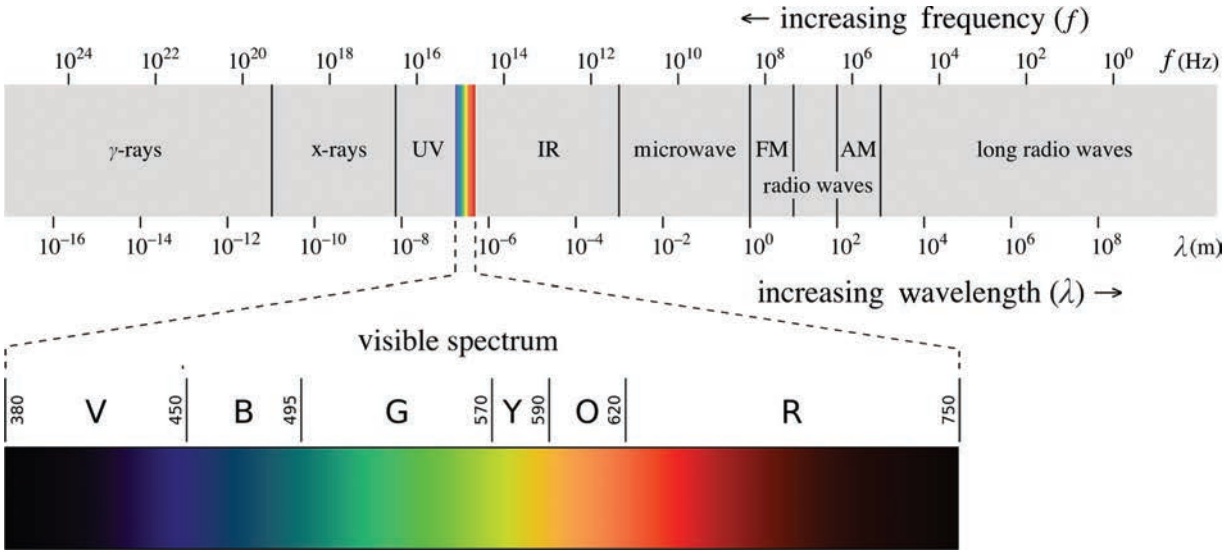

Figure 8.2. The Electromagnetic Spectrum

Electromagnetic waves vary in frequency and wavelength, but in a vacuum, all electromagnetic waves travel at the same speed, called the **speed of light**. This constant is represented by c and is approximately $3.00 \times 10^8 \frac{\text{m}}{\text{s}}$. To a first approximation—and for the purposes of all MCAT-related equations—electromagnetic waves also travel in air with this speed. In reference to electromagnetic waves, the familiar equation $v = f\lambda$ becomes

$$c = f\lambda$$

Equation 8.1

where c is the speed of light in a vacuum and, to a first approximation, also in air, f is the frequency, and λ is the wavelength.

Mnemonic

To recall the order of the colors in the visible spectrum, remember the grade-school "rainbow" of **ROY G. BV** (**r**ed, **o**range, **y**ellow, **g**reen, **b**lue, **v**iolet).

COLOR AND THE VISIBLE SPECTRUM

The only part of the spectrum that is perceived as light by the human eye is the **visible region**. Within this region, different wavelengths are perceived as different colors, with violet at one end of the visible spectrum (400 nm) and red at the other (700 nm).

Light that contains all the colors in equal intensity is perceived as white. The color of an object that does not emit its own light is dependent on the color of light that it reflects. Thus, an object that appears red is one that absorbs all colors of light except red. This implies that a red object under green illumination will appear black

MCAT Expertise

Wavelengths in the visible range are common on the MCAT. Remembering the boundaries of the visible spectrum (about 400–700 nm) will save you time and energy on Test Day.

because it absorbs the green light and has no light to reflect. The term **blackbody** refers to an ideal absorber of all wavelengths of light, which would appear completely black if it were at a lower temperature than its surroundings.

MCAT Concept Check 8.1:

Before you move on, assess your understanding of the material with these questions.

1. Order the types of electromagnetic radiation from highest energy to lowest energy. What other property of light follows the same trend?

_____ > _____ > _____ > _____ > _____ > _____ > _____

- Also follows the same trend: _____

2. True or False: Light waves are longitudinal because the direction of propagation is perpendicular to the direction of oscillation.

3. What are the boundaries of the visible spectrum? How does the range of the visible spectrum compare to the range of the full electromagnetic spectrum?

_____

_____

8.2 Geometrical Optics

When light travels through a homogeneous medium, it travels in a straight line. This is known as **rectilinear propagation**. The behavior of light at the boundary of a medium or interface between two media is described by the theory of geometrical optics. Geometrical optics explains reflection and refraction, as well as the applications of mirrors and lenses.

REFLECTION

Reflection is the rebounding of incident light waves at the boundary of a medium. Light waves that are reflected are not absorbed into the second medium; rather, they bounce off of the boundary and travel back through the first medium. Figure 8.3 illustrates reflection on a plane mirror.

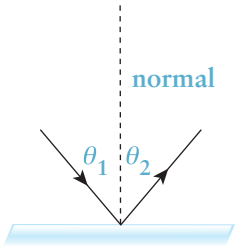

Figure 8.3. Reflection
According to the law of reflection, $\theta_1 = \theta_2$.

The law of reflection is

$$\theta_1 = \theta_2$$

Equation 8.2

where θ_1 is the incident angle and θ_2 is the reflected angle, both measured from the normal. The **normal** is a line drawn perpendicular to the boundary of a medium; all angles in optics are measured from the normal, not the surface of the medium.

Plane Mirrors

In general, images created by a mirror can be either **real** or **virtual**. An image is said to be real if the light actually converges at the position of the image. An image is virtual if the light only *appears* to be coming from the position of the image but does not actually converge there. One of the distinguishing features of real images is the ability of the image to be projected onto a screen.

Parallel incident light rays remain parallel after reflection from a plane mirror; that is, **plane mirrors**—being flat reflective surfaces—cause neither convergence nor divergence of reflected light rays. Because the light does not converge at all, plane mirrors always create virtual images. In a plane mirror, the image appears to be the same distance behind the mirror as the object is in front of it, as shown in Figure 8.4. In other words, plane mirrors create the appearance of light rays originating behind the mirrored surface. Because the reflected light remains in front of the mirror but the image appears behind the mirror, the image is virtual. Plane mirrors include most of the common mirrors found in our homes. To assist in our discussion of spherical mirrors, plane mirrors can be conceptualized as spherical mirrors with an infinite radius of curvature.

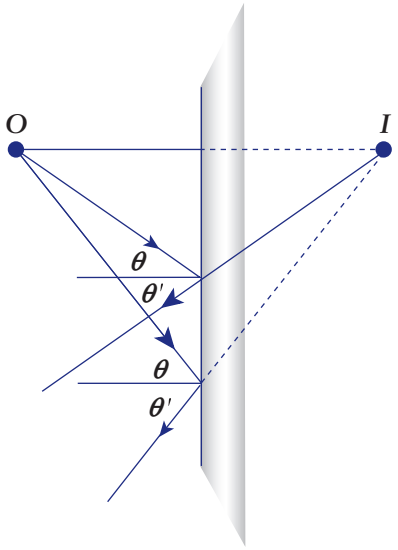

Figure 8.4. Reflection in a Plane Mirror
O is the object and *I* is the (virtual) image; all incident angles (θ) are equal to their respective reflected angles (θ').

Real World

The passenger-side mirrors in cars are an example of convex mirrors (everything appears smaller and further away); the small circular mirrors used for applying makeup are an example of concave mirrors (everything appears bigger and closer).

Mnemonic

Con**cave** is like looking into a **cave**.

Key Concept

Concave mirrors are converging mirrors. Convex mirrors are diverging mirrors. The reverse is true for lenses.

Spherical Mirrors

Spherical mirrors come in two varieties: concave and convex. The word spherical implies that the mirror can be considered a spherical cap or dome taken from a much larger spherically-shaped mirror. Spherical mirrors have an associated center of curvature (C) and a radius of curvature (r). The **center of curvature** is a point on the optical axis located at a distance equal to the **radius of curvature** from the vertex of the mirror; in other words, the center of curvature would be the center of the spherically-shaped mirror if it were a complete sphere.

If we were to look from the inside of a sphere to its surface, we would see a **concave** surface. On the other hand, if we were to look from outside the sphere, we would see a **convex** surface. For a concave surface, the center of curvature and the radius of curvature are located in front of the mirror. For a convex surface, the center of curvature and the radius of curvature are behind the mirror. Concave mirrors are called **converging mirrors** and convex mirrors are called **diverging mirrors** because they cause parallel incident light rays to converge and diverge after they reflect, respectively.

There are several important lengths associated with mirrors, as shown in Figure 8.5. The **focal length** (f) is the distance between the **focal point** (F) and the mirror. Note that for all spherical mirrors, $f = \frac{r}{2}$ where the radius of curvature (r) is the distance between C and the mirror. The distance between the object and the mirror is o; the distance between the image and the mirror is i.

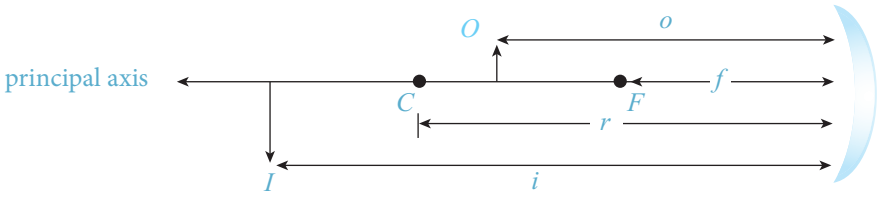

Figure 8.5. Key Variables in Geometrical Optics
The mirror pictured is a concave mirror; light rays are not shown.

There is a simple relationship between these four distances:

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} = \frac{2}{r}$$

Equation 8.3

While it is not important which units of distance are used in this equation, it is important that all values used have the *same* units as each other.

On the MCAT, you will most often use this equation to calculate the **image distance** for all types of mirrors and lenses. If the image has a positive distance ($i > 0$), it is a real image, which implies that the image is in front of the mirror. If the image has a negative distance ($i < 0$), it is virtual and thus located behind the mirror. Plane mirrors can be thought of as spherical mirrors with infinitely large focal distances. As such, for a plane mirror, $r = f = \infty$, and the equation becomes $\frac{1}{o} + \frac{1}{i} = 0$ or $i = -o$. This can be interpreted as saying the virtual image is at a distance behind the mirror equal to the distance the object is in front of the mirror.

The **magnification** (***m***) is a dimensionless value that is the ratio of the image distance to the object distance:

$$m = -\frac{i}{o}$$

Equation 8.4

By extension, the magnification also gives the ratio of the size of the image to the size of the object. Following the sign convention given later in Table 8.1, the orientation of the image (upright or inverted) can be determined: a negative magnification signifies an **inverted** image, while a positive value signifies an **upright** image. If $|m| < 1$, the image is smaller than the object (reduced); if $|m| > 1$, the image is larger than the object (enlarged); and if $|m| = 1$, the image is the same size as the object.

Figure 8.6 shows ray diagrams for a concave spherical mirror with the object at three different points. A **ray diagram** is useful for getting an approximation of where an image is. On Test Day, ray diagrams can be helpful for a quick

determination of the type of image that will be produced by an object some distance from the mirror (real *vs.* virtual, inverted *vs.* upright, and magnified *vs.* reduced). Ray diagrams should be used with caution, however: under the pressure of Test Day, it can be easy to draw them incorrectly. Therefore, it is important to practice drawing ray diagrams to avoid careless errors on Test Day, and it is also important to be familiar with how to solve optics questions mathematically.

When drawing a ray diagram, there three important rays to draw. For a concave mirror, a ray that strikes the mirror parallel to the **axis** (the normal passing through the center of the mirror) is reflected back through the focal point (green lines in Figure 8.6 and 8.7). A ray that passes through the focal point before reaching the mirror is reflected back parallel to the axis (red lines). A ray that strikes the mirror at the point of intersection with the axis is reflected back with the same angle measured from the normal (blue lines). In Figure 8.6a, the object is placed beyond F, and the image produced is real, inverted and magnified. In Figure 8.6b, the object is placed at F, and no image is formed because the reflected light rays are parallel to each other. In terms of the mirror equation, we say that the image distance $i = \infty$ here. For the scenario in Figure 8.6c, the object is placed between F and the mirror, and the image produced is virtual, upright, and magnified.

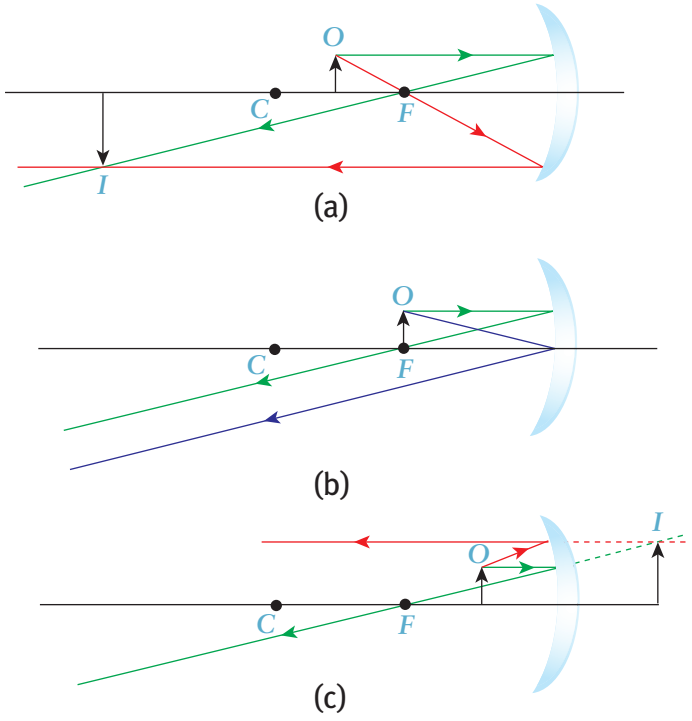

Figure 8.6. Ray Diagrams for Concave (Converging) Mirrors
(a) Object is placed beyond *F*; (b) Object is placed at *F*; (c) Object is placed between *F* and the mirror.

Key Concept

Any time an object is at the focal point of a converging mirror, the reflected rays will be parallel, and thus, the image will be at infinity.

A single diverging mirror forms only a virtual, upright, and reduced image, regardless of the position of the object. The further away the object, the smaller the image will be. To quickly remember these rules, recall the convenience store security mirrors mentioned at the beginning of the chapter. The ray diagram of a diverging mirror is shown in Figure 8.7.

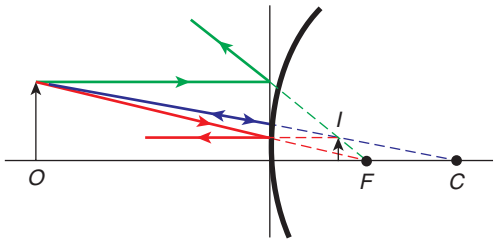

Figure 8.7. Ray Diagrams for Convex (Diverging) Mirrors

Sign Conventions for Mirrors

Table 8.1 provides the sign convention for single mirrors. Note that on the MCAT, for almost all problems involving mirrors, the object will be placed in front of the mirror. Thus, the object distance o is almost always positive.

Symbol	Positive	Negative
o	Object is in front of mirror	Object is behind mirror (extremely rare)
i	Image is in front of mirror (real)	Image is behind mirror (virtual)
r	Mirror is concave (converging)	Mirror is convex (diverging)
f	Mirror is concave (converging)	Mirror is convex (diverging)
m	Image is upright (erect)	Image is inverted

Table 8.1. Sign Convention for a Single Mirror

Example: An object is placed 7 cm in front of a concave mirror that has a 10 cm radius of curvature. Determine the image distance, the magnification, whether the image is real or virtual, and whether it is inverted or upright.

Solution: Use the optics equation:

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} = \frac{2}{r}$$

$$\frac{1}{i} = \frac{2}{r} - \frac{1}{o}$$

$$\frac{1}{i} = \frac{2}{10\text{ cm}} - \frac{1}{7\text{ cm}} = \frac{14-10}{70} = \frac{4}{70}$$

$$i = \frac{70}{4} = +17.5\text{ cm}$$

Key Concept

To find where the image is (for a mirror), draw the following rays and find a point where any two intersect. This point of intersection marks the tip of the image. If the rays you draw do not appear to intersect, extend them to the other side of the mirror, creating a virtual image.

- Ray parallel to axis → reflects back through focal point
- Ray through focal point → reflects back parallel to axis
- Ray to center of mirror → reflects back at same angle relative to normal

Key Concept

The focal length of converging mirrors (and converging lenses) will always be positive. The focal length of diverging mirrors (and diverging lenses) will always be negative.

Mnemonic

Image types with a single lens or mirror (assuming o is positive): **IR** (infrared) and **UV** (ultraviolet) light

- **I**nverted images are always **r**eal
- **U**pright images are always **v**irtual

A positive value for i signifies that the image is in front of the mirror and is therefore real. For a single lens or mirror with $o > 0$, a real image will always be inverted.

The magnification m is

$$m = -\frac{i}{o} = -\frac{17.5\text{ cm}}{7\text{ cm}} = -2.5$$

The negative sign on the magnification confirms that the image is inverted, and the fact that $|m| > 1$ indicates that the image is enlarged.

REFRACTION

Refraction is the bending of light as it passes from one medium to another and changes speed. The speed of light through any medium is always less than its speed through a vacuum. Remember that the speed of light in a vacuum, c, is equal to $3.00 \times 10^8 \frac{\text{m}}{\text{s}}$. The speed of light in air is just slightly lower that this value; on the MCAT, it is appropriate to use $3.00 \times 10^8 \frac{\text{m}}{\text{s}}$ for the speed of light in air.

Real World

When a pencil (or any straight object) is dipped into a glass of water at an angle, it looks impossibly bent where it intersects the surface of the water because the light reflecting off of the portion of the pencil under water is refracted.

Snell's Law

When light is in any medium besides a vacuum, its speed is less than c. For a given medium,

$$n = \frac{\text{c}}{v}$$

Equation 8.5

where c is the speed of light in a vacuum, v is the speed of light in the medium, and n is a dimensionless quantity called the **index of refraction** of the medium. The index of refraction of a vacuum is 1, by definition; for all other materials, the index of refraction will be greater than 1. For air, n is essentially equal to 1 because the speed of light in air is extremely close to c. The indices of refraction for a number of common media are shown in Table 8.2. These values are provided only for reference; they need not be memorized.

Medium	Index of refraction (n)
Vacuum	1 (by definition)
Air	1.0003
Ice	1.31
Water	1.33
Acetone	1.36
Ethanol	1.36
Cornea (human)	1.37–1.40
Lens (human)	1.39–1.41
Glass (various types)	1.48–1.93
Diamond	2.42

Table 8.2. Indices of Refraction of Common Media

Refracted rays of light obey **Snell's law** as they pass from one medium to another:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2$$

Equation 8.6

where n_1 and θ_1 refer to the medium from which the light is coming and n_2 and θ_2 refer to the medium into which the light is entering. Note that θ is once again measured with respect to the normal, as shown in Figure 8.8.

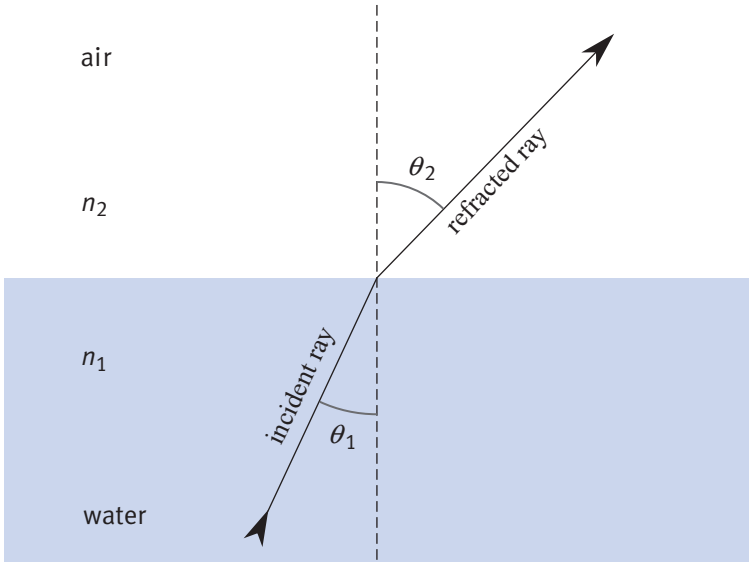

Figure 8.8. Snell's Law

From Snell's law, we can see that when light enters a medium with a higher index of refraction ($n_2 > n_1$), it bends toward the normal ($\sin \theta_2 < \sin \theta_1$; therefore,

$\theta_2 < \theta_1$), as shown in Figure 8.9. Conversely, if the light travels into a medium where the index of refraction is smaller ($n_2 < n_1$), the light will bend away from the normal (sin $\theta_2 >$ sin θ_1; therefore, $\theta_2 > \theta_1$).

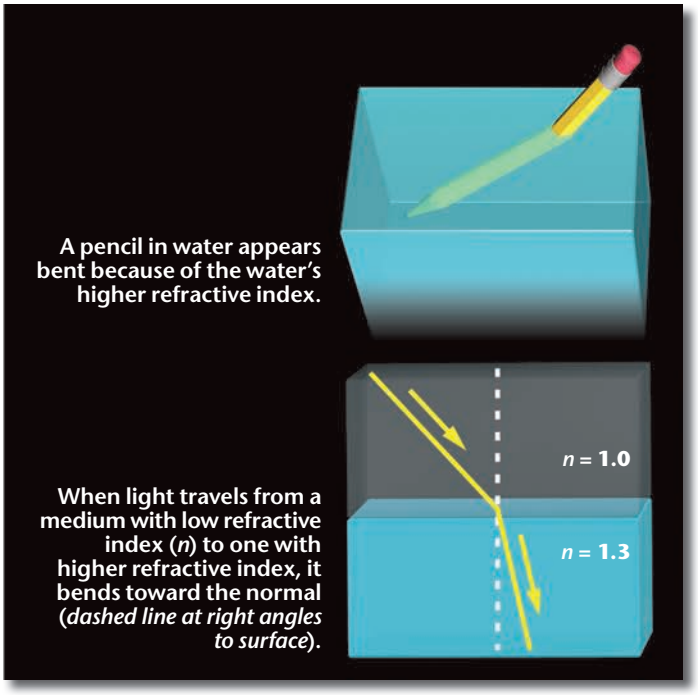

Figure 8.9. Refraction of Light from Air into Water

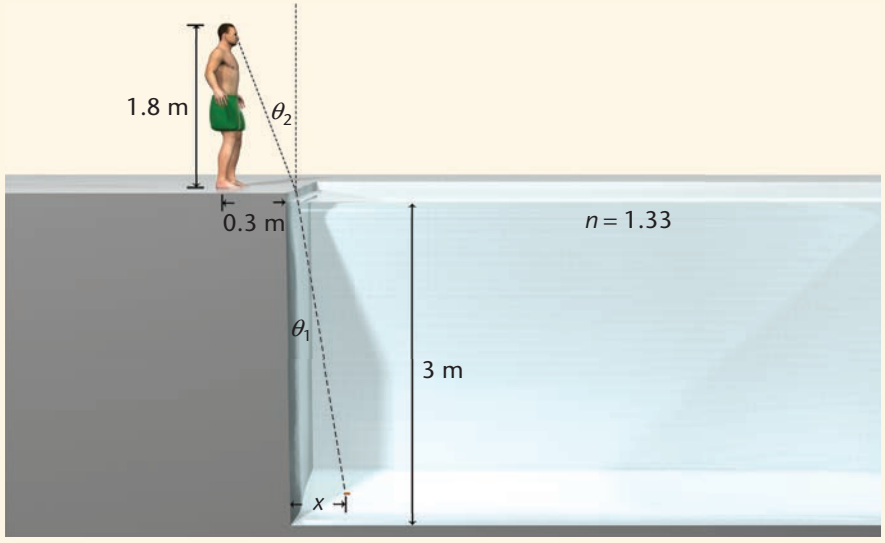
Key Concept

Remember that when light enters a medium with a higher index of refraction, it bends toward the normal. When light enters a medium with a lower index of refraction, it bends away from the normal.

Example: A penny sits at the bottom of a pool of water (n = 1.33) at a depth of 3.0 m. If an observer 1.8 m tall stands 30 cm away from the edge, how close to the side can the penny be and still be visible?

Solution: First, draw a picture of the situation:



Note that the light is coming from the water (n_1 = 1.33) and going into the air ($n_2 \approx 1$), so the light is bent away from the normal ($\theta_2 > \theta_1$). We need to find the angle that the light rays make with the normal to the water's surface:

$$\tan\theta_2 = \frac{0.3\text{ m}}{1.8\text{ m}} = 0.167$$
$$\theta_2 = \tan^{-1}0.167 = 9.5^\circ$$

Using Snell's law, we can solve for θ_1:

$$\sin\theta_1 = \left(\frac{n_2}{n_1}\right)\sin\theta_2 = \left(\frac{1}{1.33}\right)\sin 9.5^\circ = \frac{0.165}{1.33}$$
$$\theta_1 = \sin^{-1}\left(\frac{0.165}{1.33}\right) = 7.1^\circ$$

Now, we can find x using trigonometry:

x = (3 m) × tan θ_1 = 3 tan 7.1° = 3 × 0.124 = 0.37 m = 37 cm

Note that you will not be expected to calculate precise values of trigonometric functions or inverse trigonometric functions on Test Day. This question is provided mainly as an opportunity to see the application of Snell's law.

Total Internal Reflection

When light travels from a medium with a higher index of refraction (such as water) to a medium with a lower index of refraction (such as air), the refracted angle is larger than the incident angle ($\theta_2 > \theta_1$); that is, the refracted light ray bends away from the normal. As the incident angle is increased, the refracted angle also increases, and eventually, a special incident angle called the **critical angle** ($\boldsymbol{\theta_c}$) is reached, for which the refracted angle θ_2 equals 90 degrees. At the critical angle, the refracted light ray passes along the interface between the two media. The critical angle can be derived from Snell's law if $\theta_2 = 90^\circ$, such that

$$\theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right)$$

Equation 8.7

Total internal reflection, a phenomenon in which all the light incident on a boundary is reflected back into the original material, results with any angle of incidence greater than the critical angle, θ_c, as shown in Figure 8.10.

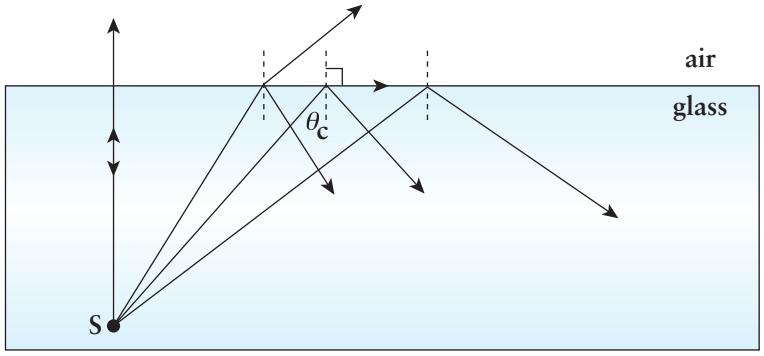


Figure 8.10. Total Internal Reflection
At the incident angle of θ_c, the refracted angle is equal to 90°; at incident angles above 90°, total internal reflection occurs.

Key Concept

Total internal reflection occurs as the light moves from a medium with a higher refractive index to a medium with a lower one.

Example: From the previous example, suppose another penny is 10 times farther away from the edge than the first one. Will a light ray going from this penny to the edge of the pool emerge from the water?

Solution: First, find the critical angle:

$$\theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right) = \sin^{-1}\left(\frac{1}{1.33}\right) = 48.8^\circ$$

The angle made by the second penny's light ray is

$$\theta_1 = \tan^{-1}\left(\frac{\text{opposite}}{\text{adjacent}}\right) = \tan^{-1}\left(\frac{0.37\text{ m} \times 10}{3\text{ m}}\right) = 51^\circ$$

$\theta_1 > \theta_c$; therefore, the light ray will be totally internally reflected and will not emerge.

LENSES

There is an important difference between **lenses** and mirrors, aside from the fact that lenses refract light while mirrors reflect it. When working with lenses, there are two surfaces that affect the light path. For example, a person wearing glasses sees light that travels from an object through the air into the glass lens (first surface). Then the light travels through the glass until it reaches the other side, where again it travels out of the glass and into the air (second surface). The light is refracted twice as it passes from air to lens and from lens back to air.

Thin Spherical Lenses

On the MCAT, lenses generally have negligible thickness. Because light can travel from either side of a lens, a lens has two focal points, with one on each side. The focal length can be measured in either direction from the center. For

thin spherical lenses, the focal lengths are equal, so we speak of just one focal length for the lens as a whole.

Figure 8.11a illustrates that a converging lens is always thicker at the center, while Figure 8.11b illustrates that a diverging lens is always thinner at the center. The basic formulas for finding image distance and magnification for spherical mirrors also apply to lenses. The object distance o, image distance i, focal length f, and magnification m, are related by the equations $\frac{1}{f} = \frac{1}{o} + \frac{1}{i} = \frac{2}{r}$ and $m = -\frac{i}{o}$.

Real World

Converging lenses (reading glasses) are needed by people who are "farsighted". Diverging lenses (standard glasses) are needed by people who are "nearsighted."

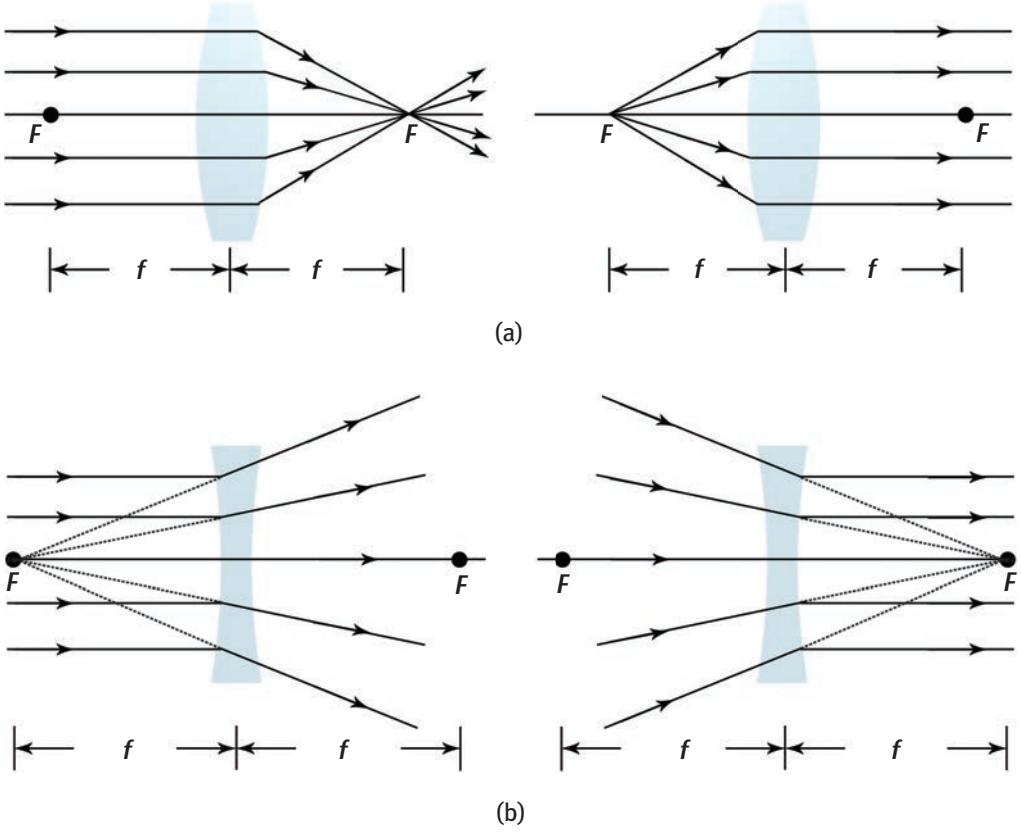

Figure 8.11. Ray Diagrams for Single Lenses
(a) Convex (converging) lenses; (b) Concave (diverging) lenses.

Real Lenses

For lenses where the thickness cannot be neglected, the focal length is related to the curvature of the lens surfaces and the index of refraction of the lens by the **lensmaker's equation**:

$$\frac{1}{f} = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2}\right)$$

Equation 8.8

where n is the index of refraction of the lens material, r_1 is the radius of curvature of the first lens surface and r_2 is the radius of curvature of the second lens surface.

The eye is a complex refractive instrument that uses real lenses. The cornea acts as the primary source of refractive power because the change in refractive index from air is so significant. Then, light is passed through an adaptive lens that can change its focal length before reaching the vitreous humor. It is further diffused through layers of retinal tissue to reach the rods and cones. At this point, the image has been focused and minimized significantly, but is still relatively blurry. Our nervous system processes the remaining errors to provide a crisp view of the world.

Sign Conventions for Lenses

Note that the sign conventions change slightly for lenses. For both lenses and mirrors, positive magnification represents upright images, and negative magnification means inverted images. Also, for both lenses and mirrors, a positive image distance means that the image is real and is located on the real (R) side, whereas a negative image distance means that the image is virtual and located on the virtual (V) side. Table 8.3 summarizes the sign conventions for single lenses.

Key Concept

To find where the image is (for a lens), draw the following rays and find a point where any two intersect. This point of intersection marks the tip of the image. If the rays you draw do not appear to intersect, extend them to the same side of the lens from which the light came, creating a virtual image.

- Ray parallel to axis → refracts through focal point of front face of the lens
- Ray through or toward focal point before reaching lens → refracts parallel to axis
- Ray to center of lens → continues straight through with no refraction

Key Concept

It is important to realize that concave mirrors and convex lenses are both converging and thus have similar properties. Convex mirrors and concave lenses are both diverging and also have similar properties.

Symbol	Positive	Negative
o	Object is on same side of lens as light source	Object is on opposite side of lens from light source (extremely rare)
i	Image is on opposite side of lens from light source (real)	Image is on same side of lens as light source (virtual)
r	Lens is convex (converging)	Lens is concave (diverging)
f	Lens is convex (converging)	Lens is concave (diverging)
m	Image is upright (erect)	Image is inverted

Table 8.3. Sign Convention for a Single Lens
